cannot be invariably baffled, while an article of dress is left, or the necessaries of life provided. It affects minds in the full possession of those powers which render its accomplishment inevitable, and which are best adapted to elude suspicion, to deceive affection, and to counteract the provisions and specific arrangements in an asylum."

CASE OF FEIGNED MADNESS.

The *Annales Médico-Psychologiques* (October 1850, p. 661) records the following case, which formed the subject of a trial in Bavaria.

On the 28th of July 1849, a shepherd, aged 17, was arrested on a charge of having committed a horrible assault upon a girl, seven years old, and of having afterwards assassinated her, by shooting her in the head. The accused, at the moment of his arrest, freely confessed that he had committed the two crimes, saying that he had been instigated to commit them by the devil, that it was the devil who had loaded the gun, who had put it into his hands, had directed it towards the head of his victim, and that he (the prisoner) had done no more than pull the trigger. It appears that this ridiculous defence is not considered extraordinary, by those who are acquainted with the absurd superstitions which still exist among the country people of Bavaria. When the officers proceeded the next day to the residence of the accused, to convey him before the magistrate, an entire change had taken place in his demeanour. Although he was a young man who had always been distinguished by his vivacity and intelligence, he now appeared to have lost all his physical and intellectual faculties. He could hardly stand up, and when by great efforts he succeeded in raising himself on his legs, he tottered, and his knees trembled under him; he could not move a single step without stumbling; his head was continually inclined either forwards or backwards, or fell sometimes on one shoulder, sometimes on the other; he uttered only isolated and incoherent words, and always stammered; he said that his hearing was very bad, and it was impossible to obtain from him any precise answer; lastly, he had entirely lost his memory, and he no longer recognized any one, not even his mother, with whom he had always lived. The magistrate selected two special physicians, MM. Windler and Zinck, to examine into the mental condition of the accused; and these gentlemen, after having carefully observed his conduct, unanimously came to the conclusion that the moral and physical state of this individual was feigned. This opinion was founded upon the following considerations:—that the imbecility, to the degree in which the prisoner seemed to be affected, was always innate; that there never was an example of a person so intelligent and healthy as the accused had been before his arrest, becoming suddenly imbecile and stupid; and that besides, the imbecility of persons who have not evinced it from birth, is at first very slight, and increases gradually and slowly. In consequence of this opinion, the prisoner was observed secretly and continually, and as no change was remarked in him, it was resolved to expose him to violent sensations, to ascertain whether the suspension of the faculties were real or not. To this end, fire-arms were discharged in the middle of the night, close to the outside of the wall against which his bed was placed. The prisoner uttered inarticulate cries, but without moving from his bed. Powerful douche baths were poured upon him suddenly, through holes bored in the ceiling of his cell; he was lodged in a hut, the roof of which was burnt during the night; and he was exposed to other trials, but nothing altered his impassibility. MM. Windler and Zinck, and several other physicians, persisted in their opinion that this young man was feigning imbecility; and he was ordered to be tried before the court of Augsburg. It was necessary to carry him to the court. He looked at first with a stupified air at all parts of the hall; then he relapsed into his ordinary state, placed his arms on the balustrade before the prisoners' bench,

rested his head upon his hands, and went to sleep. It was in vain to shake him; nothing would move him; and it was impossible to interrogate him. The crimes of which he had been accused, were already admitted by himself; and, having been proved before the court by the evidence of numerous witnesses, the presiding judges strongly inclined to the guilt of the accused. The defence represented that, considering the state of the prisoner, there was great probability that, in committing the two crimes for which he was called to account, he had no consciousness of what he was doing, and consequently he could not be considered a responsible person. The judges observed to the jury that, in their deliberations, they ought not to regard the present state of the prisoner, but to endeavour to ascertain if, at the moment of the perpetration of the double crime, he had acted like a sane person. The jury, after deliberating half an hour, brought in a verdict declaring the prisoner guilty, but with weak imputability (foible imputabilité), namely, *that there were very attenuating circumstances.*[1] The prisoner was condemned to three years' imprisonment, and he was taken away from the court in the same state of lethargy as that which he had exhibited during his trial; but he had scarcely returned to his cell, when he began to jump with joy at having escaped capital punishment. He said that, since his arrest, he had never ceased to enjoy good health for a single moment; that he had been throughout in perfect possession of his physical and intellectual faculties; and that he had played his part, in pursuance of advice which had been given him by one of his fellow-prisoners, on the very day when he was consigned to prison. This villain seems to have exhibited, during the long space of fourteen months, a strength of will and of perseverance of the most extraordinary character; and it is the more astonishing, as he was only seventeen years old.

MECHANICAL RESTRAINT IN THE PROVINCIAL ASYLUMS OF FRANCE.

In the autumn of 1850, Dr. Webster visited eight of the provincial asylums of France; and has since published in Dr. Winslow's *Psychological Journal* an interesting account of what he saw and heard. The paper abounds with valuable matter; and the following extract is particularly interesting:—

"The numbers show, that forty-four male lunatics, out of 1464 then resident, were in camisole, some being also otherwise restrained; thereby giving one in restraint to every 33¼ male inmates; or three per hundred. Amongst the females the proportion was larger; seventy-two out of the total 1902 resident patients, being under mechanical coercion; *i.e.*, one female in restraint to every 26¼ inmates; or 3·78 per hundred. In contrast with this report, I place an official statement of the practice at Bethlem Hospital, during the same period. At this establishment, where formerly the strait-waistcoat, with various kinds of personal coercion, were in even greater use, than on the other side of the English channel, *not one insane patient*, amongst an average population of 391 lunatics, was under constraint of any description, during the five weeks ending the 20th of last September: when I first visited that institution, after my return from the continent, and which five weeks embraced the whole time referred to in my narrative".

[We are no advocates for the strait-waistcoat when it can be avoided; but let it be remembered, that it is often a less irritating means of restraint than the personal violence and brawny grasp of "the keeper".]

[1] This verdict would never have been received in an English court of law. If the prisoner was of *weak imputability*, then he was not guilty of the crimes laid to his charge, and he ought to have been sent to a mad-house as a lunatic: if he was in his senses when the acts were committed, then he ought to have been executed. Editors of Lond. Journ. of Med.

DELIRIUM AND INSANITY DURING AND CONSECUTIVE TO ACUTE DISEASES.

In the *Annales Medico-Psychologiques*, October 1850, p. 586, M. Thore has written an article upon this subject.

The author regards pneumonia as one of the most common causes of insanity; and of twelve cases of acute diseases followed by delirium, no less than half were cases of pneumonia. He thinks that it and typhoid fever, are the diseases which predispose most to insanity. He relates two cases, in the first of which a pneumonia of the right lung, terminating by resolution, was followed by maniacal delirium; and, a year afterwards, the same patient was attacked by pneumonia, again terminating in resolution, but again followed by violent delirium with hallucinations: the result, however, being complete recovery, both from the pneumonia and the insanity. In the second case related by the author, the pneumonia and the insanity appeared to alternate with each other; for, on the occurrence of a decided amendment in the symptoms of the first disease, the patient was attacked with violent delirium, attended by hallucinations of sight and hearing, and by loquacity. These symptoms were relieved by baths, and opiates in large doses; but, with the return of reason, the symptoms of pneumonia reappeared. The patient, however, recovered from the pneumonia, and the delirium did not return. The author has also observed, that, in certain cases, the delirium is developed without any alleviation of the pulmonary symptoms; and the two diseases continue simultaneously. The third case is one of tonsillitis, attended by suppuration of the right tonsil; in this case, the pus was evacuated by an incision, and the patient was doing well; but he was attacked suddenly one morning with delirium, attended by hallucinations. He recovered under the use of mild opiates. In the next case, the delirium was developed during recovery from an attack of measles, in a man aged 27, who had never before or since manifested any symptoms of insanity, and who had never been addicted to intemperate habits. In this instance, the maniacal state lasted for twenty-four hours, and then it wholly disappeared. In the last case which is related, the patient was a boy of seventeen, who was attacked by typhoid fever, towards the termination of which several abscesses were formed in various parts of his body, and were opened. When the fever had ceased, symptoms of insanity began to appear, and his words and actions became strange and incoherent; although his bodily health improved, the disorder of the intelligence gained ground, and he was finally consigned to a lunatic asylum, where he died of cholera. The author concludes by remarking, that the form of mental alienation which succeeds acute affections, is very variable; most frequently it is only a fit of maniacal delirium, the duration of which varies, from fifteen or twenty hours to three or four days. It is violent, accompanied by great agitation, and with hallucinations of sight and hearing. It begins at the very moment when convalescence commences. It yields, in general, to a very simple treatment, or rather it is cured spontaneously. "We have often seen," says M. Thore, "individuals, who, in the hospitals where they had been treated for acute diseases, had been attacked with a fit of insanity, arriving at the Bicêtre perfectly cured, and not exhibiting the least disturbance of the intelligence. The cure had taken place during the removal." But although the delirium which occasionally follows such diseases as pneumonia and tonsillitis, is transient, that which follows typhoid fever is more serious and more lasting, as is well exemplified in the last case recorded by M. Thore in his very useful and instructive paper.

THE HOSPITALS OF LONDON. No. VI.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

THE VITAL STATISTICS OF HOSPITALS.

The following is introduced in this place, from the similarity of the general results to those of the London hospitals, as formerly alluded to in this department of the LONDON JOURNAL OF MEDICINE; and as illustrated by Dr. Webster in the present number.

GENERAL HOSPITAL AT VIENNA. The subjoined Statistical Reports of the General Hospital at Vienna for 1848 and 1849, are contained in the *Zeitschrift der K. K. Gesellschaft der Aerzte zu Wien* for November and December 1849, and Sept. and Oct. 1850. If we could obtain room, we should like to reproduce them entire, as excellent models for the compilation of similar returns from the London hospitals. In the mean time, we have combined some of the statistics regarding the mortality in the institution at Vienna.

Table exhibiting the Rate of Mortality in the Wards of the General Hospital in Vienna, during the years 1848 *and* 1849.

	1849	385	235	619	0	2	2	0·00	0·85	0·32
Both years.....		839	520	1359	2	3	5	0·23	0·57	0·36

The preceding table points out distinctly the remarkable influence which certain classes of affections exert, in augmenting or diminishing the rate of mortality. Thus, in the surgical wards, exclusive of those devoted to syphilis and ophthalmic affections, the average mortality for the two years was 9·69 per cent.; but, if to the surgical cases we add the syphilitic and ophthalmic, the rate of mortality becomes diminished to 5·56 per cent.

The statistics of the obstetric, children's, and lunatic departments at Vienna are separately given in other parts of the Report; but we shall at present confine our notice to those classes which are specified in the table.

The Reports of the Vienna Hospital are, moreover, valuable for the tabular view which they give of the relative mortality from each disease. We have reproduced the Vienna statistics, thinking that it would be interesting to those engaged in medical statistics, and might also serve as a model for similar documents in some of our institutions. With this view, we have combined the results for the two years in a single table, omitting the short commentaries which are appended to each anatomical group of diseases.

Statistical Table of the Cases admitted into the General Hospital at Vienna, in 1848 *and* 1849, *arranged anatomically.*

The nosological classification adopted in the foregoing tables, is not unexceptionable,—bronchitis, for instance, being evidently included under the terms "catarrh" and "pneumonia". The system which is carried out, however, is highly laudable ; and the reports reflect great credit on the zeal and ability of Dr. Carl Haller, on whom has devolved the labour of drawing them up. We hope, before a very distant period, to see reports, of at least equal excellence, emanate from the London hospitals.

ROYAL LONDON OPHTHALMIC HOSPITAL, MOORFIELDS.

Among the Egyptians, Greeks, and Romans, the treatment of diseases of the eye was mostly in the hands of oculists. Hippocrates, Celsus, Galen, and the Arabian physicians describe many ophthalmic diseases well, and frequently give judicious rules for their treatment; but *medici oculariі* were at the same time numerous, and have continued so in modern times, to the latter part of the last century.

At this period, the anatomy and physiology of the eye were generally neglected byp hysicians and surgeons; and the treatment of its diseases was left to oculists, men, for the most part, very imperfectly educated, who relied almost entirely on external applications, and treated the eye as if it was unconnected with the rest of the body, and uninfluenced by the state of the circulation, and the condition of the digestive organs.

Germany first attempted to recall the attention of the profession to the neglected science, by the production of works of the highest merit, by university lectures, by opening ophthalmic wards in the General Hospital of Vienna, and by clinical instruction. Scarpa also greatly advanced the science by his labours in Italy.

In England a few distinguished surgeons, as Pott and Hey, had a well-merited reputation for their skill in operating on the eye; and Cheselden had, still earlier, added to his fame by giving sight to a young man supposed to have been born blind: but the first public institution for the treatment of Diseases of the Eye originated with John Cunningham Saunders in 1804.

Mr. Saunders was educated at St. Thomas's and Guy's,—at that time united hospitals. Here he studied ten years; during eight of which he was demonstrator of anatomy at the former hospital. In October 1804 he published the first proposal, made in England, of founding a dispensary for the cure of diseases of the eye and ear: and the proposal being sanctioned by the physicians and surgeons of the above-named hospitals, and encouraged by the public, the London Dispensary for curing Diseases of the Eye and Ear was opened in Charter-house Square on the 25th of March 1805; and patients were received under the care of Mr. Saunders and Dr. Farre. In 1808, however, the treatment of diseases of the ear was relinquished, and the name of the institution altered to that of the London Infirmary for curing Diseases of the Eye.

In founding the Infirmary, Mr. Saunders had two objects in view; to apply his knowledge of ophthalmic disease to the relief of the afflicted poor, and to communicate instruction to the medical student. In accordance with these views, the institution has, from its foundation, been open to all indigent patients, without any restriction; and, in 1811, pupils were publicly admitted to observe the diseases, and their treatment by the medical directors.

The institution had only enjoyed the benefit of Mr. Saunders' valuable services five years, when his incessant application destroyed him by apoplexy, in the thirty-seventh year of his age. His short career allowed him little opportunity of communicating his experience to the profession. He published, during his life, a work on diseases of the ear, and a paper on iritis; but the principal part of his recorded observations and opinions was edited, after his death, by his friend and colleague Dr. Farre, in a *Treatise on some Practical Points relating to Diseases of the Eye.* This valuable work contains essays on inflammation of the conjunctiva in infants; on inflammation of the iris, and the use of belladonna; on some of the more important terminations of ophthalmia, etc.; to which is added an account of the author's method of curing congenital cataract, by which he had succeeded in giving sight to 52 patients out of 64, of whom 38 were from two months to seven years old at the time of operation.

Dr. Farre has the merit of having taught the application to diseases of the eye of the same general principles of treatment, by which similar morbid

processes are controlled in the organs, and especially of introducing the mercurial treatment of iritis. Mr. Travers, Mr. Lawrence, and Mr. Tyrrell, in turn, succeeded to the chair from which Saunders had been removed by death: and the writings and lectures of these distinguished men, and the information acquired and communicated by their pupils, have accomplished, to a great extent, one of the grand objects contemplated by the founder of the institution, and have spread the knowledge of ophthalmic disease, and the benefits of that knowledge, over three parts of the globe. One of the most beautiful and accurate works that has yet appeared on diseases of the eye, is now in course of publication by Mr. Dalrymple, the present consulting surgeon of the hospital. It has more than once been introduced to the favourable notice of the readers of the London Journal of Medicine.

The number of patients has progressively increased from the opening of the institution to the present time. During the last four years the average annual increase has been 577, and during the last year 786.

NUMBER OF PATIENTS.

In 1805..... 600	In 1830.....5483	In 1849.....8686
1810.....2907	1840.....5520	1850.....9437
1820.....3704		

The total number of in and out-patients admitted from the opening of the institution in 1805, to December 31, 1850, is 217,706. The number cured of cataract and closed pupil during the same time is 2,361, including 306 born blind; no patient being entered a second time as a new case during the whole period of his attendance, however long. This is a tolerably large amount of good effected by a small institution in the city of London; but its utility is still more apparent from the good effected by its numerous ramifications. The total number of physicians and surgeons educated at this hospital to the end of 1850 is 1514. Many of these have themselves, or by their pupils, established similar institutions in Europe, Asia, and America. The first institution, on the model of the London Infirmary, was established at Exeter by Mr. Adams, afterwards Sir William Adams, on the joint recommendation of Mr. Saunders and Dr. Farre. The Royal Westminster Ophthalmic Hospital was opened after the death of Mr. Saunders in 1816, under the care of Mr. Guthrie, one of the earlier pupils. Others have since arisen in Dublin, Manchester, Birmingham, Salisbury, Bath, Brighton, Portsmouth, Plymouth, and in almost every large town in the kingdom. In 1850, the first Ophthalmic Infirmary was opened in Edinburgh; and in London itself two new Eye Infirmaries have in the last few years been opened and conducted by pupils of this hospital. In the year 1818, Mr. Richardson, one of its pupils, established the Madras Eye Infirmary, under the sanction and patronage of the Honourable East India Company, and during the first three years operated successfully on 381 cases of cataract. Subsequently Mr. Egerton and Mr. Jeaffreson were sent out by the East India Company to conduct similar institutions in Calcutta and Bombay. Assistant surgeon Richmond, of the 4th Light Dragoons, cured of cataract 789 inhabitants of Broach and Baroda in the short space of nine months.[1] Even in China, seven Ophthalmic Hospitals have been recently appointed. Meanwhile, other pupils have established the first Ophthalmic Institutions in the United States (New York), and in British and Spanish America.

In 1823, the Infirmary was removed from its original site to a new and more commodious building erected for it in Moorfields; and in 1837, the Queen having become its patroness, it was named the Royal London Ophthalmic Hospital. The present building is capable of accommodating eighteen in-patients. Nearly all the in-patients are admitted for operations, the majority being cases of cataract. Operations for cataract are usually performed on Friday, from the beginning of May to the end of October.

The hospital is supported by voluntary contributions, and is open daily to all indigent persons that require and seek its assistance. The average

[1] Bombay Courier, March 1827.

expense of each patient is less than two shillings; and the total expense of 1850 does not at all exceed the average total expense of the last ten years, notwithstanding the number of patients has nearly doubled in that time. But the income of the hospital falls far short of its necessary expenses, which have seriously encroached on its small permanent resources. The deficiency of 1850 is stated to have been nearly £250. An earnest appeal has therefore been made to the public by the committee, with the view of obtaining such support as will maintain the hospital in a state of efficiency, and meet the increasing demands on its resources.

NORTH LONDON EYE INFIRMARY.

Clinical Notices. The *changeable weather* which has characterised this spring, has kept the cases of rheumatic and catarrhal affections above the average. Simple treatment by purging, counter-irritation, and astringent collyria, have generally sufficed to cure the latter; but in two cases, obstinate ulcers ensued, and complicated the case; eventually, the eyes recovered under the use of bark and soda, nitrate of silver collyrium two grains to the ounce, night and morning, and a blister kept open behind the ear.

The preparations of *super-phosphate of iron*, prepared by Mr. Greenish at the suggestion of Dr. Routh, have been tried with decided advantage. It appears to be a mild tonic, and possesses the peculiar recommendations of neither discolouring the fæces nor constipating the bowels.

Hordeolum, or "stye", has been singularly rife; Mr. White Cooper has had twenty-six cases of this description in public and private, in the last two months, and all sufficiently bad to cause the patients to seek advice. Frequent fomentation with infusion of poppies, to which a portion of extract of opium has been added, and hot poultices with the same addition, afford the greatest relief; and where there is evidence of matter, the stye should be opened; this should be done with a sharp lancet, and quickly, as the part is exquisitely sensitive.

Many persons are subject to small *tarsal tumours*, which cause them much annoyance. They appear to be due, in some instances, to constitutional derangement, one succeeding another with provoking pertinacity; but they are not unfrequently a consequence of hordeol. If the troublesome little boil so called does not fairly suppurate and discharge its contents, the inflammation will pass away, leaving a small hard swelling; the parietes of this are sometimes so tough as to require some force to pierce them with a sharp knife. The treatment in use at this Infirmary is to evert the lid, lay open the cyst, and rub its interior with a small button of nitrate of silver at the point of a fine probe; some inflammation follows, with suppuration, and the cyst disappears. In small cysts, subcutaneous excision with a cutting needle answers well, and is less painful than the other proceeding.

Very bad cases of *lippitudo* occasionally present themselves, but yield to the following treatment. The raw ulcerated margin of the lid is lightly touched with nitrate of silver once or twice, and subsequently with sulphate of copper two or three times, at intervals of a few days; the lids are anointed night and morning with the diluted ointment of the nitrate of mercury, and the general health attended to; which latter is a matter of importance. The alum collyrium, four grains to the ounce, is a useful adjunct to the other treatment. Lippitudo and tinea are common disorders among the lower orders of the Hebrew persuasion.

It is a matter of importance not to use the tartar emetic ointment on the temple, as it occasionally leaves indelible marks, which are unsightly, especially in females. The croton oil liniment is preferable; but that also occasionally produces considerable discomfort, by the irritation extending to the lids and face, and puffing those parts considerably. Blisters, the size of a shilling, applied to the temples, cause sufficient irritation for ordinary cases, are manageable, and can be repeated at short intervals. Albespeyer's paper,

and Brown's cantharidine tissue, are useful especially with the higher orders, who often have much repugnance to the application of an ordinary blister. With children a few threads of worsted, smeared with blistering ointment, and placed behind the ear, is a useful and efficacious mode of exciting counter-irritation.

Collodion. Mr. Bowman has spoken of the advantage afforded by collodion in the treatment of wounds in the neighbourhood of the eye. In this, Mr. White Cooper fully concurs, having seen the greatest advantage follow its use in operations for entropion. The following is an example. Mr. G., a large, stout farmer, seventy-three years of age, consulted Mr. C. for entropion, in 1849. It had existed during eight months, and the irritation of the lashes against the eye was very distressing. There was a redundancy of puffy, loose skin about the lower lids ; and the deformity was entirely removed by pinching up a fold of it. On the 2nd of July 1849, an elliptical piece of integument was cut away from the right lower lid, the edges carefully approximated, and two sutures inserted. The skin being then dried, collodion was applied ; as it dried, the contraction of the integument was most marked. On the 5th instant, only three days after, the collodion was removed, and the wound found to be healed, except at the points of the sutures. A similar operation was performed on the left eye, and three days sufficed for the union of that wound also.

The only objection to collodion is the acute smarting it causes when first applied to a wound ; but, as that passes away in a few minutes, it is a matter of little consequence. The great tendency to evaporate, which is characteristic of collodion, is best counteracted by turning the bottle down, with its neck in water.

MORTALITY IN THE LONDON HOSPITALS.

The following very valuable article appears in the instructive weekly publication of the Registrar-General for May 17th.

"The table below illustrates two methods of exhibiting the mortality of hospitals and public institutions with rapidly changing populations. The cases which passed through each hospital were returned by the resident officers ; the average number of resident sick was deduced from five quarterly enumerations ; and the mean term of residence, in days, was obtained by multiplying the hospital population into 365, and dividing the product by the number of cases.

"It will be observed that in 1850, 11 of the general hospitals of London had 2736 resident patients, and that 2200 deaths took place in the year ; the mortality on the population was therefore more than 80 per cent. The patients only remained, on an average, 34 days in hospital ; 29,161 passed through the wards ; and the mortality was therefore 7·54 per cent. in the 34 days. About 92 in 100 who enter leave the London hospitals alive.

"The average number of lunatics, in eight of the large asylums, was 3,451 ; the deaths in the year 1850 were 380 ; the *annual* rate of mortality was therefore 11 per cent. But the patients remained more than two years (2·21) in these asylums ; and only 1,565 were discharged recovered, relieved, unrelieved, or dead ; consequently 24 in 100 cases terminated fatally, and of 100 who enter, 76 leave the asylums alive.

"In the *Fever Hospital* there were 19 deaths to 100 cases under treatment on an average 26 *days*, which implies that the rate of mortality was 256·76 deaths annually to every 100 patients constantly resident (100 occupied beds). In the *Consumption Hospital* 23 deaths occurred in 100 cases under treatment about 107 days ; the rate of mortality implies, therefore, that among a population consisting exclusively of persons labouring under consumption, the mortality would be 78·82 per cent. *annually.*

"The one column (5.) shows the mortality of such cases as are sent to hospitals, not during their whole course, but during the term of treatment : the

other column (6.) exhibiting the mortality out of a given number of sick during a given time (a year), indicates the intensity of the mortality in different diseases and hospitals.

"All the cases of illness in the army, slight as well as severe, are treated in the military hospitals: to the civil hospitals only cases of some severity are admitted; the mortality is therefore very different. Some of the differences in the mortality of other hospitals arise from the same cause; others are accidental.

REPORTS OF SOCIETIES.

MEDICAL SOCIETY OF LONDON.

March 15, 1851.

Edward W. Murphy, M.D., President, in the Chair.

The Mammillated Condition of the Legs in Certain Cases of Dropsy. By T. Nunn, Esq. In certain cases of dropsy, especially in those depending on chronic heart-disease, towards the closing stage of that malady, when the legs have become infiltrated with fluid, and when the distension of the skin has arrived at a pitch which seems to threaten its vitality, it will be found that the cuticle gradually cracks, and an exudation of serum takes place. The skin does not retain the waxy whiteness of anasarca, but changes to a reddish hue, or the cuticle separates from the true skin, and serum is poured forth. The surface next becomes uneven, and, within a few weeks, the whole leg, from the ankle to the knee, is studded with elevations, varying from the size of a pin's head to that of a pea; and in some parts they are grouped together, so as to form larger protuberances. They are moist and shining; around their base is a whitish pasty secretion, and serum oozes from their surface. A brownish-green staining encircles the limb above the tuberculated part in some cases. This state is a result of anasarca, widely different from the ulceration following the formation of bullæ, or the large open sores produced by the separation of sloughs. It is attended with a great deal of pain and smarting. When the tuberculisation of the limb is fully established, a profuse discharge of serum takes place. The fluid secreted has a peculiar faint sickly odour; it amounts to many ounces in the twenty-four hours. In proportion to the extent of the tuberculisation, and the amount of the discharge, is the relief experienced from the oppression of the vital symptoms, particularly of the respiration. When the discharge is checked from any cause, even for a few hours only, it is followed by cerebral disturbance and congestion, and by uneasiness about the cardiac region. In course of time, the mammillations shrink, the exudation becomes scanty, and at last entirely ceases, the leg being covered with a dryish scurf. Mr. Nunn believed this process of mammillation to be an effort of nature for the relief of the patient.

March 22, 1851.

Edward W. Murphy, M.D., President, in the Chair.

Prison Discipline. By Forbes Winslow, M.D. This paper contained an elaborate examination of the various systems of prison discipline, and of their influence on the bodily and mental condition of the inmates.

March 29, 1851.

Edward W. Murphy, M.D., President, in the Chair.

Symptoms, Diagnosis, and Treatment of Functional Diseases of the Uterus. By T. Snow Beck, M.D. This paper appears as an original article at p. 417 of our last number.

April 5, 1851.

Edward W. Murphy, M.D., President, in the Chair.

Excision of the Astragalus and Os Calcis. By Thomas H. Wakley, Esq. After some remarks on the subject of excision of joints, Mr. Wakley related the case of William Brown, on whom he performed, in December 1847, the operation of removal of the astragalus and os calcis for caries of these bones. The man recovered perfectly, and could now walk well. He was shewn to the members of the Society by Mr. Wakley a few evenings before the reading of this paper.

April 12, 1851.

Edward W. Murphy, M.D., President, in the Chair.

Diagnosis of Inflammatory Diseases of the Cervix Uteri; Use of Potassa Fusa, or Potassa cum Calce. By J. Henry Bennet, M.D. This paper appears as an original article at p. 448 of our last number.

April 19, 1851.

Edward W. Murphy, M.D., President, in the Chair.

Symptoms of Pulmonary Consumption. By John Hutchinson, M.D. The author desired to direct attention to three points: 1. Loss of weight; 2. Diminished breathing movements; 3. Morbid breathing sounds.

Loss of weight is a constant and primary sign; and there is no evidence of phthisis when the weight is undiminished. A person may lose weight and not have consumption; but he cannot have consumption without losing weight. The chest next changes in form and movement in respiration. The healthy chest is erect; the shoulders point backwards, and the deep inspiration is symmetrical, and swells out plentifully under the hand when laid over the upper ribs. The phthisical chest is not *erect;* the shoulders incline inwards and forwards, and the movement in respiration is more limited and pinched, as well as often non-symmetrical. The volumes of air expired were shewn to vary greatly in the healthy and in the diseased cases.[1] The morbid sounds are primarily of two kinds: sounds affecting the volume of air entering, as harsh, deficient, feeble; and, secondly, sounds produced by morbid secretions.

Loss of weight, diminished chest mobility, and morbid sounds, appeared in regular order: the third cannot exist without the second, nor the second without the first sign. They might exist without phthisis; but, when indicative of phthisis, their character was well-marked.

MISCELLANEOUS INTELLIGENCE.

Society of Apothecaries. The Court of Examiners of the Society of Apothecaries of London have lately come to a resolution, which is likely to exert a most considerable and a most beneficial influence upon the education of the general practitioners of this country. They have evinced their willingness to abandon the ordinary practice of testing the classical acquirements of their candidates in Celsus and Gregory at the termination of their medical studies, and have substituted a general classical and mathematical examination at the commencement of them. Students are to be admissible to this examination at any time, from the date of their apprenticeship to the termination of their first winter course of lectures. The object of this regulation appears to be twofold; first, to ascertain whether the student possesses sufficient general knowledge to enter upon the career of medical study, or whether he should not rather devote some months longer, or another year, to the acquisition of preliminary information; and secondly, to supersede the necessity of directing the student's attention to the Latin language, at a time when he has many other matters of more consequence to occupy his time. The subjects of the examination will be taken from those preliminary studies which are taught at every good school, and an attention to which is generally considered to be indispensable to the education of a gentleman. The subjects at present chosen are, the New Testament in Greek, the First Book of the Æneid, the Oration of Cicero pro Milone, the First Book of Euclid, and the principles of Arithmetic and Algebra. With the senti-

[1] See article "Thorax", in Cyclopædia of Anatomy and Physiology.

ments expressed in this Journal on the subject of the education of the Medical Profession, it is quite impossible for us to do otherwise than to accord to this plan our warmest commendation ; and our only regret is, that some such plan has not been adopted long ago. Admission into the church can only be gained through the portals of literature and science : and classical or mathematical examinations, or both, are now rendered imperative upon those who wish to enter the army, the navy, the East India Company's service, or even the merchant service ; and we should blush to think that our own honourable profession should lag behind in the general march of knowledge. A contemporary has remarked upon the extraordinary circumstance that the Court of Examiners of this Society, with the prospect of their own extinction before their eyes, should be devising and carrying out schemes for the amelioration of the profession : but we see no more anomaly in their doing so, than in a man making a just and equitable distribution of his property before he leaves the world. The Apothecaries' Society may or may not be abolished as an examining body; but the examiners deserve credit for sowing good seed, the fruit of which may probably be reaped by others. We are bound to say that their efforts are praiseworthy ; and whoever may be the parties who may eventually carry out their designs, we heartily wish them success. We ought to mention, that the Examiners of the Society intend to conduct the examination themselves ; that the first examination will be held on the third Saturday in October of the present year; and that no fee whatever will be required from the student.

The Resolutions above alluded to are the following :—

"At a Meeting of the Court of Examiners held at Apothecaries' Hall, March 10, 1851. It was Resolved unanimously,—

"1. That a preliminary examination for the junior students of the medical profession would be desirable, as an important auxiliary to their subsequent medical studies.

"2. That such examination should comprise an inquiry into the student's knowledge of the Latin and Greek languages, and of the elements of mathematics.

"3. That students should be admissible to such examinations at any period from the date of their apprenticeship to the completion of the first winter session of their curriculum.

"4. The such examination should, in the first instance, include the following subjects,—viz.:

"I. The First Book of Virgil's Æneid and Cicero's Oration for Milo.

"II. The Greek Testament, to the end of the Acts of the Apostles ; or, the First Book of Xenophon's Anabasis, at the option of the candidate.

"III. Algebra, as far as simple equations.

"IV. The First Book of Euclid's Elements.

"5. That students who pass this examination satisfactorily, should not be subject to any subsequent examination in Latin, except the *Pharmacopœia Londinensis* and prescriptions.

"6. That students who have not passed this examination should, for the present, be allowed as heretofore, to undergo the preliminary examination in Celsus and Gregory, after they have completed two winter sessions of their medical studies."

Liberal Proceedings of the Council of the Royal College of Surgeons. We are happy to lay before our readers the following resolutions adopted by the Council of the College of Surgeons on the 19th and 24th of March 1851. It is a remarkable coincidence that the Resolutions of the Court of Examiners of the Apothecaries' Society should have been passed only about a week before those of the Royal College of Surgeons. We have reason for believing that neither of these bodies was aware of what the other was doing. The steps taken by the Council of the College are meritorious ;

and as their present liberal conduct is in complete contrast to their celebrated manifestoes, issued hardly a year ago, we accord to their present proceedings a double meed of praise. We doubt, however, the necessity of handing over the General Practitioners to be examined by the College of Physicians, as we think that there are a sufficient number of fellows and members of the College of Surgeons, who are competent to act. We regret to find that not a syllable is mentioned of any preliminary examination ; a matter which we hold to be of the highest importance. We see no reason why Greek, Latin, and mathematics are to be reserved for the Fellows and withheld from the Members, any more than we could understand a system for giving classical and mathematical knowledge to bishops, and denying it to the parochial clergy.

The following are the RESOLUTIONS referred to :—

"1. That in the opinion of this Council, such parts of the charters and bye-laws of the College as restrict the eligibility to the Council to fellows residing and practising surgery within five miles by highway or road from the General Post-office in St. Martin's-le-Grand, should be abrogated.

"2. That in the opinion of this Council, such parts of the charters and bye-laws of the College as restrict the eligibility to the Council to fellows not having during the five preceding years practised *midwifery or pharmacy*, and require a certificate thereof by three fellows, should be abrogated ; and that instead thereof, a certificate by *three fellows*, and a declaration by *himself*, that the person nominated to be balloted for as a member of the Council does not practise as *an apothecary*, be required.

"3. That it is the opinion of this Council, that the medical qualifications of those about to engage in the *practice of surgery*, or in general practice, should be tested by the Royal College of Physicians.

"4. That the Council of this College are prepared to form and superintend a Board of Examiners in midwifery, or to cooperate with the Royal College of Physicians in the institution of examinations for testing the qualifications of practitioners in midwifery. (By order),

"EDMUND BELFOUR, Secretary."

CALDER MARSHALL'S STATUE OF JENNER. At length there is a prospect of a suitable monument being erected, in London, to Jenner,—one of the brightest ornaments of the medical profession, and one of the greatest benefactors of the human race. All honour to our Wellingtons and our Nelsons, and let them have the homage of the nation for which they so nobly fought and conquered ; but it is not one, but all nations, who have, and shall have, to bless the achievements of an Edward Jenner. Most fitting, therefore, is it to find the work of Mr. Marshall adorning one of the main avenues of the Great Exhibition of the Industry of all Nations ; and bearing upon it, that it is to be erected, in bronze, by contributions from the men and women of every country and of every clime. We believe that a most influential committee is at the head of this movement ; but we fear that no adequate means have yet been taken to correctly and widely apprise the public, and the medical profession, of what is contemplated. We would suggest that a public meeting be convened, under the presidency of one of the noblemen or gentlemen who sit in the committee ; and that a number of places be immediately appointed in London for the reception of subscriptions. The rates should perhaps be limited to a few pounds, and the smaller contributions of the masses be greatly relied on. The larger contributors might receive a miniature copy of the statue. A complete list of all the contributors, with their occupations and residences, should be kept, and printed. As more than the necessary sum may be raised, the possible surplus should at once be destined for some appropriate object,—say the formation of a fund for granting annuities to decayed members of the medical profession, to be called "THE JENNER FUND". We hope the committee will, without delay, inform

the public of the exact amount required for the erection of Mr. Marshall's statue in bronze, and of what they propose doing with the surplus, should such remain after the completion of their enterprise. We shall be glad to receive and publish the necessary information on these points. Dr. John Conolly, of Hanwell, is Acting Chairman of the committee; and George Vere Irving, Esq., of 10, Ampthill-square, is the Acting Honorary Secretary.

Resolutions unanimously adopted by the Royal College of Physicians of Edinburgh, regarding Practitioners of Homœopathy. We have much pleasure in giving publicity to the subjoined Resolutions. We hope that the London and Dublin Colleges will see the necessity of issuing similar manifestoes; *and of acting up to them.* Does Dr. William Henderson —the Homœopathic Professor of Pathology—still hold his Fellowship in the Edinburgh College of Physicians? We believe that a technical difficulty might interfere with any attempt at ejecting him from the University which he disgraces; but surely the College of Physicians has the power of expelling him from their body, if he do not voluntarily retire.

Resolutions. "At Edinburgh, and within the College Hall there, the 9th day of May 1851, an Extraordinary Meeting of the Royal College was held, pursuant to a Resolution agreed at the last Quarterly Meeting, and of which Extraordinary Meeting due notice was given.

"The President in the Chair. The following Resolutions were moved, seconded, and unanimously agreed to:—

I. That the Royal College of Physicians of Edinburgh did, several years ago, publicly express its opinion of Homœopathy and Homœopathic Practitioners, by peremptorily declining to admit into its body a Candidate for its Fellowship who belonged to that denomination; and, consequently, that no Fellow of the College can possibly be ignorant of the light in which all those who practise Homœopathy are regarded by the College.

II. The College regrets that, notwithstanding this decided expression of its opinion, more than one of its Fellows, after being admitted in a different character, have endangered the reputation of the College by becoming Homœopathic Practitioners; and the College expresses an earnest hope that these Fellows, seeing they have thus virtually separated themselves from the College, will spontaneously sever their further connexion with an Institution which repudiates them, and from which they can derive, as merely nominal Fellows, nothing else than a false position and a spurious credit.

III. The College feels the more bound thus to express its opinion, seeing that those Fellows who have become Homœopathists, and any other Medical Practitioners who follow Homœopathy, must necessarily be aliens to the other Fellows, and to the profession at large; inasmuch as no Fellow of this College, or any other Physician can, by any possibility, without derogating from his own honour, and from the honour of the profession, meet Practitioners of Homœopathy in consultation, or co-operate with them in the other common duties of professional life.

IV. That although the College has not thought it expedient hitherto to take any active steps for disclaiming those Fellows who have become Homœopathic Practitioners subsequently to their admission to the College, nevertheless, since it has the power of dealing summarily with those who act in a manner so unbecoming the character of a Physician, it reserves its right to exercise that power when it shall be so advised.

Signed in Name, and by Authority, of the College,

J. Y. Simpson, *President.*"

Next Meeting of the Provincial Medical and Surgical Association. The attraction of the Crystal Palace is so universally felt, that it is necessary to remind our readers that in making their engagements to see its contents, they should not forget the Anniversary Meeting of the Association, to be held at Brighton, on the 13th and 14th of August next. To those who can only leave home for a limited period, we would observe that the two objects may easily be combined, as Brighton is now reached from London in a couple of hours. (*Prov. Journal*, 28 May.)

Medical Students, and Unqualified Assistants practising Medicine. The Manchester Medico-Ethical Association have directed attention to this wide-spread abuse. We believe that the druggists of the present day, who prescribe, and who drive so lucrative a trade, commonly endeavour to obtain a smattering of knowledge by serving as visiting assistants with general practitioners: and many of this class first get into practice by fourpenny draughts and counter consultations; and then, if the neighbourhood require it, they whitewash themselves by passing the College or the Hall. Many unqualified practitioners are regular readers of new medical works, especially of the lighter medical periodicals. We think the profession might do something towards protecting themselves from the abuses referred to in this paragraph.

Sydenham Society. The Anniversary Meeting was held on the 1st May at half-past eight p.m., Mr. Phillips, F.R.S., Vice-President, in the chair. The Annual Report stated that there were about 2,000 subscribing members. The balance in hand was about £700. Mr. Rogers inquired as to the duties of the Secretary, and remarked on the large salary paid him, while the secretaries of the other medical societies of the metropolis served gratuitously. Some points of pecuniary importance he next touched upon, more especially with reference to £495 : 17 : 6 having been expended in one year in editorial charges. He finally commented on the fact, that few, if any, General Practitioners were on the Council, although the Society was mainly supported by them. This spirit of exclusiveness was owing, he thought, to their unwillingness to admit fresh blood into the corporation. The Secretary said, the average expense of editing was £100 per volume, and that of the twenty-four members of Council, five were General Practitioners. Dr. Copland spoke highly of the Secretary's services, and said he revised the productions of the Society before going to press. The following is the list of the new officers of the Society :—President, Sir James Clark, M.D., Bart., F.R.S. Vice-Presidents : W. P. Alison, M.D., F.R.S.; Sir John Richardson, M.D., F.R.S., K.C.H.; R. Cusack, Esq., M.R.I.A.; J. A. Paris, M.D. F.R.S., President of the Royal College of Physicians; J. A. Symonds, M.D.; B. Phillips, Esq., F.R.S.; R. Dunglison, M.D.; J. Hodgson, Esq., F.R.S.; C. Locock, M.D.; T. Shapter, M.D.; Sir C. Hastings, M.D.; A. D. Anderson, M.D.; T. Turner, Esq.; Professor Miller; A. Robertson, M.D., F.R.S. L. and E.; T. Watson, M.D., F.R.S. Council: E. F. Lonsdale, Esq.; E. L. Birkett, M.D.; A. B. Garrod, M.D.; W. R. Basham, M.D.; Golding Bird, M.D., F.R.S.; W. D. Chowne, M.D.; T. G. Balfour, M.D; Marshall Hall, M.D., F.R.S.; James Copland, M.D., F.R.S.; H. Powell, M.D.; R. P. Cotton, M.D.; John Forbes, M.D., F.R.S.; R. Quain, Esq., F.R.S.; E. Headland, Esq.; J. Hilton, Esq., F.R.S.; W. F. Barlow, Esq.; W. J. Iliff, Esq.; J. Pereira, M.D., F.R.S.; O. M'William, M.D.; C. C. de Morgan, Esq.; E. H. Sieveking, M.D.; J. W. Woodfall, M.D.; D. Maclachlan, M.D.; R. Partridge, Esq.

Royal Medical and Chirurgical Society and the Great Exhibition. At the close of the meeting of this Society on Tuesday last, the President announced that the Council had authorised him to admit foreign medical men visiting the metropolis, on the recommendation of a Fellow of the

Society, to attend their meetings during the remainder of the session, and also to avail themselves of their extensive library and reading-rooms.

Recent Prevalence of Small-pox throughout England. From the Registrar-General's Report of the first quarter of 1851, just issued, we transcribe the following illustrations to prove this prevalence, as likewise to show how much yet remains to be accomplished, ere the great benefits of vaccination are diffused throughout the entire population. From the above document it appears, that in St. Mary's District, Shrewsbury, amongst 13 fatal cases of small-pox, only one had been previously vaccinated. In Willenhall, Wolverhampton, out of 22 deaths by the same disease, 16 were unprotected. In Rowley Regis, Dudley, small-pox was also very prevalent, and the Registrar states, in no death by this disease had the patient been previously vaccinated. In another district of Dudley, out of thirteen deaths, ten were unprotected; whilst in a third division of the same town, among 58 deaths by variola, 30 were without previous vaccination. Again, in St. Mary's, Birmingham, amongst eighteen deaths by small-pox, only two or three were protected. In Aston, twelve deaths are likewise reported, nearly the whole being without vaccination. In Runcorn, out of forty fatal cases by variola, only three were vaccinated. Further, in one district of Oldham there were twenty-five deaths by small-pox, the greater portion of whom were unprotected; and, in the north division of Leeds, out of thirty-eight fatal cases twenty-six were never vaccinated; whilst in one district of Rochdale, all the eight deaths, registered from variola, never had been vaccinated. Other illustrations, of the same description, might be quoted; but it is superfluous to pursue the subject farther, excepting to observe, that in various localities there appears, it must be admitted, something more than want of attention on the part of parents in neglecting to take their children to the parish medical officers to be vaccinated, so prejudiced do they still seem against cow-pox, and also exceedingly doubtful with regard to its prophylactic virtues. It is, however, satisfactory to mention, on the other hand, that exceptions to the above lamentable ignorance, regarding the real value of vaccination, are occasionally met with; thus, in one district of Stockport, the local registrar reports, "It is now more than three years since I registered a death from small-pox, out of a population of between 12,000 and 13,000; which I attribute to the appointment of public vaccinators, and the attention parents now pay to the vaccination of their children". This fact is refreshing to hear, and ought to be held up for general imitation; for, if followed, variola might disappear, or, at all events, be of very rare occurrence.

APPOINTMENTS.

Gill, Dr. William, elected, by the Subscribers, Physician to the Nottingham General Hospital, on the 24th April, on the resignation of Dr. J. Calthorp Williams.

Massey, Dr. Isaac, appointed, on the 26th April, by the Magistrates, Surgeon to the Nottingham County Goal, in room of Mr. Henry Attenburrow, resigned.

Wright, Dr. Thomas, elected, by the Subscribers, Surgeon to the Nottingham General Hospital, on the 24th April, in room of Mr. Henry Attenburrow. resigned.

OBITUARY.

Baker, Dr. Edward, late of Walcot Terrace, of consumption, on the 17th May.

Kennedy, Dr. James, of Woodhouse, Leicestershire, at 24, Great Russell Street, Bedford Square, on the 9th May, aged 70. Dr. Kennedy had retired from practice.

Marshall, Dr. Henry, on the 12th May, after a protracted and painful illness. Dr. Marshall was born at Kylsyth, near Glasgow, in 1775. He studied medicine at Glasgow, and in 1803 became Surgeon's Mate in the navy, a service which he soon left; and, in 1805, was appointed Assistant-Surgeon to the Forfarshire regiment of militia. In 1806, he became Assistant-Surgeon to the 1st battalion of the 89th regiment, and proceeded with it to Ceylon, in which island he remained till the spring of 1821. In the same year, he was appointed to the staff, and stationed at Edinburgh. After two years, he went to Chatham, and from thence went to Dublin, as Surgeon to the recruiting depôt; from that time till 1830, Dr. Marshall was actively engaged in his public duties. He was then gazetted as Deputy Inspector-General of Army Hospitals, and retired on half-pay. About this time he settled in Edinburgh, where he remained till his decease. Dr. Marshall was the instrument of many useful reforms being adopted with reference both to the moral and hygienic management of soldiers. His contributions to statistics and to military medicine are of great value. Besides numerous monographs in periodicals and Parliamentary Returns, he was the author of the following works: *On the Medical Topography of Ceylon; On the Enlisting, Discharging, and Pensioning of Soldiers; The Military Miscellany; Description and Conquest of Ceylon; On the Feigned Diseases of Soldiers*, etc., etc.

Phillips, Richard, F.R.S.L. and E., F.G.S., on the 11th May, aged 72, having outlived most of his contemporaries in the field of chemical science. He was the friend and associate of Davy and Wollaston, and enjoyed the personal acquaintance of the most celebrated of the continental chemists; and he has been placed at the head of British analysts, by the venerable Professor of Chemistry in the University of Glasgow. In 1805 he published a memoir on the Bath waters, which attracted much attention, and this was followed by the examination of other mineral waters. The scientific publications of that day contain frequent and valuable papers on the composition of many rare minerals, and critiques on works on chemistry and pharmacy, contributed by him. From the year 1821, he was the conductor of the *Annals of Philosophy*, and when that serial was incorporated with the *London, Edinburgh, and Dublin Philosophical Magazine*, his services were secured as one of the editors of that journal—a post he held till his death. He was successively Lecturer on Chemistry at the London Hospital, at the Government Military College at Sandhurst, at Grainger's School of Medicine in Southwark, and at St. Thomas's Hospital. He also delivered several courses of lectures on chemistry at the London Institution, and lectured occasionally at the Royal Institution, and elsewhere. In 1839, Mr. Phillips was appointed Curator of the Museum of Practical Geology, now in Jermyn Street, which office he held until his death, which event unhappily occurred on the day previously to the opening of that institution by His Royal Highness Prince Albert. In 1822, he was elected a Fellow of the Royal Society, of the Council of which Society he was a Member for some years before his death. He was one of the founders of the Geological Society, and, for the last two years, held the office of President of the Chemical Society of London. In 1824, Mr. Phillips published his first translation of the *Pharmacopœia Londinensis;* and was subsequently consulted by the College of Physicians respecting the *Pharmacopœia* of 1836. Of this latter edition he published a translation, enriched with copious and valuable notes, which work ran through several editions. For the last few years he had been again engaged, in conjunction with a committee of that learned body, in experimenting, under their direction, upon the chemical preparations of the *London Pharmacopœia*, recently issued; and on a translation of this, he was employed a few evenings before his death. To the collection of additional information for this publication, he had devoted much labour and research, which we rejoice to find will not have been expended in vain; as we hear that a portion of the work has already been printed, and that its publication will soon take place. Valued and respected by all who enjoyed the pleasure of knowing him, for the frankness, and the simplicity of his character, as well as for his scientific attainments,

Mr. Phillips has closed a busy and active life, whilst yet both mental and bodily powers were undecayed, to the deep regret of a large circle of scientific friends, many of whom followed his remains to the cemetery at Norwood, where he was interred.

Shillito, Dr. Charles, late of Putney, at York Terrace, Regent's Park, on the 16th May, aged 69. Dr. Shillito became an Army Hospital Mate in 1799; a Member of the College of Surgeons in 1803; and an M.D. of Heidelberg in 1840. He was at one time a Member of the Court of Examiners of the Apothecaries Society.

TO CORRESPONDENTS.

Placenta without a Fœtus. We quote the following from a letter, dated March 29th, 1851, received from Mr. Thomas Underhill, Junr., of Tipton, Staffordshire. We do not feel able to give any explanation of the case; and we are also unable to refer to any one resembling it.

"I attended a very singular midwifery case some weeks since. The woman was in the ninth month of pregnancy, and had occasional gushes of hæmorrhage for the last three or four weeks, which led me to suspect placental presentation. When labour commenced, the hæmorrhage continued; and, as the os uteri dilated, I found the placenta occupying nearly the whole extent of the orifice. I punctured the membranes; a large quantity of liquor amnii flowed away, but I could not then ascertain the presenting part of the child. Labour proceeded, and in about two hours the placenta was expelled, with the bag of membranes nearly entire, and containing two large coagula, *but no sign of any fœtus.* I examined carefully the placenta; it was perfect, full-sized, had no funis attached, but merely a knotty prominence in the place where the funis should have been attached. The woman is now quite well. The case is, I believe, without parallel; at least I have never met with a similar one on record."

Medicines by Dry Inhalation. In reply to our correspondent who writes from Croydon, Surrey (as well as in reply to others who have asked for information on the same subject), we have to say, that formulæ for medicinal cigarettes are given by Dorvault, in his work entitled, *L'Officine ou Répertoire Général de Pharmacie Pratique.* The edition now before us—not the latest, we believe—was printed at Paris in 1844. We may afterwards give some extracts from this work.

The Great Exhibition contains numerous objects of much interest to our profession; and to some of them we propose to direct attention.

Communications for the Editors must arrive free of all charge at the Publishers'; or at the Printer's, Mr. Richards, 37, Great Queen Street, Lincoln's-Inn-Fields, London.

Foreign Works are received by M. Victor Masson, Rue de l'Ecole de Médecine, Paris; and also by any of the booksellers in Germany in correspondence with Messrs. Williams and Norgate, of Henrietta Street, Covent Garden, London.

LONDON JOURNAL OF MEDICINE,

A MONTHLY

Record of the Medical Sciences.

JULY 1851.—No. XXXI.

ORIGINAL COMMUNICATIONS.

OBSERVATIONS ON SOME OF THE COMPLICATIONS OF HERNIA; AND ON OBSTRUCTION OF THE INTESTINE WITHIN THE ABDOMEN.

By R. R. ROBINSON, Esq., M.R.C.S.Eng., late President of the South London Medical Society, and formerly Surgeon to the London Dispensary.

(Concluded from page 447 of May Number, 1851.)

PART SECOND.

OBSTRUCTION OF THE INTESTINE WITHIN THE ABDOMEN.

After the able papers upon Internal Intestinal Obstruction, published by Dr. Crisp[1] and Mr. Phillips,[2] and the interesting cases recorded by Dr. G. Bird, Mr. Hilton, and Mr. Druitt, it may seem presumptuous in me again to advert to the subject. As, however, the basis of this paper was written many years ago; as in many points the cases which have come under my care tend to confirm what Mr. Phillips has advanced; and as some points which I shall consider have not been so fully alluded to, either by him or the other authors whom I have quoted, I have determined to submit the following paper to the notice of the profession, in the hope that it will not be found entirely devoid of interest.

The most perfect classification of these maladies, with which I am acquainted, is that of Rokitansky. He has divided internal strangulations into three species:—

1st. The narrowing or complete obliteration of the canal of a piece of intestine, resulting from pressure exerted upon it at one or more spots, by a larger or smaller portion of intestine or its mesentery, so as to compress it against the opposite side of the abdomen.

2nd. The rotatory species; which consists of the rotation of one part round the axis formed by some other part. In this class he in-

[1] Lancet, 1847.

[2] Med. Chir. Trans. vol. xxxi, p. 1..

cludes three sub-species: (*a*) rotation of a portion of intestine round its own axis; (*b*) round an axis formed of mesentery; (*c*) where a portion of intestine forms an axis, round which another large portion with its mesentery turns, so as to touch the periphery of the axis at every point.

3rd. That caused by some peculiar arrangement of parts, the results of original malformation or of previous disease.

These strangulations of the intestines, he observes, occur in circular or fissured spaces formed (*a*) by fibres or bands of cellular membrane running from one organ to another; (*b*) by adhesions of the free end of the vermiform appendix to some part of the walls of the abdomen, or to a portion of intestine or mesentery; (*c*) by adherent diverticula; (*d*) by the adhesion of two convolutions at a single point; (*e*) by perforations in the mesentery, or by fissures in an omentum altered by disease.[1]

It is not, however, my intention to enter into a consideration of all the conditions which may cause internal intestinal obstruction, but to confine my observations to the following points:—

I. Obstruction from contraction of the intestine.

II. Obstruction from membranous bands.

III. Obstruction from the calibre of the intestine being girt round by the omentum or the mesentery, one portion of intestine being twisted upon another.

IV. Obstruction from a combination of the two last-mentioned causes; a twisting of the bowel, and preternatural adhesion by membranous bands.

I purpose to consider the subject under the following heads:— 1. The appearances met with on dissection. 2. The Causes. 3. The Symptoms. 4. The Cause of Death. 5. The Prognosis. 6. The Diagnosis. 7. The Treatment.[2]

MORBID APPEARANCES.

I. Contraction of the Coats of the Intestine. Contraction is not an unfrequent morbid condition of serous membranes. It is frequently seen in the pleura, especially where vomicæ, situated near the exterior of the lung, have discharged themselves and cicatrized. It is occasionally seen in the spleen, and very often in the peritoneal coat of the bowels. I have also remarked it in those who have died a few days after the operation for strangulated hernia; in Case XII, the very great contraction observable in the ileum was apparently owing solely to this cause. The following is an abstract of the dissection in that case. The jejunum and upper part of the ileum were enormously distended, partly by yellow liquid fæcal matter, but principally by flatus; a stricture (Fig. 1), formed apparently *by contraction* of the peritoneal coat, without any thickening, existed in the ileum, near its middle: the calibre of the gut in this situation would not admit a large pea. The lower half

[1] Chelius' Surgery, by South, vol. ii, p. 94; and Rokitansky's Pathological Anatomy; translated for the Sydenham Society by Dr. Sieveking, vol. ii, pp. 51-2.

[2] Although, for the facility of description, I have arranged my remarks in the form of a general essay, I am desirous of stating, that the inferences I have drawn have been derived solely from the cases appended to the paper, and those to which I have from time to time alluded; and I wish them to be applied generally *only* in so far as more extended experience shall justify this application.

of this intestine was exceedingly contracted. The convolutions of the intestines were united together by bands of lymph; they were also adherent to the abdominal parietes, and were in many places approaching a sphacelated condition; for, on gently separating the unnatural adhesions, an opening was made into the gut. There was also an unnatural contraction of the muscular fibres in the centre of the transverse colon, but, by pressure, this part could be made as capacious as others. A question arises here,—did this contraction, met with in the ileum, exist at the time the patient was first attacked by peritonitis; or did it occur as a sequel to that affection? I incline, myself, rather to the first supposition, as the bowels were naturally costive, and as there was no thickening of the coats of the intestine, nor any *old* adhesions. I am the more strengthened in this view by a case which I have examined lately; in which a lady, dying at last rather suddenly from fright, after suffering long from phthisis and interlobular emphysema, was found to have the great omentum firmly united to the left side of the parietes of the abdomen; the greater part of the transverse colon was very much contracted throughout its whole length, and the descending colon was contracted precisely in the way in which the ileum was contracted in this case. There was no alteration in the tissue, and no apparent impediment to the passage of the motions; for although she had latterly been of a very costive habit, she had never had any obstinate constipation, and there was nothing like accumulation above the constricted part.

Fig. 1. Stricture of the bowel from contraction of the peritoneal coat.[1]

II. Obstruction from Membranous Bands. Of all the causes of internal obstruction, the formation of false membrane girting some part of the bowel, or preternaturally fixing it to the abdominal parietes, appears the most frequent. This is no doubt the result of inflammation existing some time previously. In Case xiii it will be perceived, that a considerable portion of the ileum towards its lower part, and not far from its termination, was surrounded by two false membranes, one of them of *extreme tenuity*, not much thicker than a thread, and in parts of a *black colour*. (Figs. 2 and 3.) This completely surrounded the gut, and very considerably diminished its area here. In Case xiv also, it is stated, that some of the folds of the ileum were agglutinated together, and tightly bound down to the peritoneum, covering the right iliac fossa, by strong and apparently long-standing membranous bands. In most cases, the adhesions seem to have been of old standing, especially

[1] The wood-cuts which illustrate this paper have been executed by Dr. Westmacott of King's College, from preparations in my possession, with the exception of Fig. 1, which is sketched from memory, and Figs. 2 and 3, taken from drawings by Mr. Hurst, from a preparation in Guy's Hospital Museum, through the kind permission of the Treasurer.

in those appended to this paper, and in Mr. Hilton's case;[1] but in that detailed by Mr. Druitt,[2] the inflammatory action was of more recent origin. It appears also, that *partial* is more likely to produce obstruction than *general* peritonitis; for where all the convolutions are glued together by false bands, although in some a *tendency* to constipation may ensue, in many cases no apparent interruption to the passage through the canal takes place. I remember a remarkable

Fig. 2. Portion of ileum surrounded by membranous bands.

Fig. 3. Opposite view of the same preparation.

[1] Med. Chir. Trans., vol. xxx, p. 51. [2] Ibid., vol. xxxi, p. 245.

instance of this in a strong, healthy-looking old man, who underwent the operation of lithotomy, which proved fatal, and in whom all the convolutions were firmly bound together by strong old adhesions, but in whom no inconvenience had ever been complained of with respect to the bowels; and in Fig. 4, which represents general adhesions of the convolutions to each other, the result of strumous inflammation, leading to tubercular as well as albumino-fibrinous deposit, there was no constipation; and towards the close of life *diarrhœa* supervened.

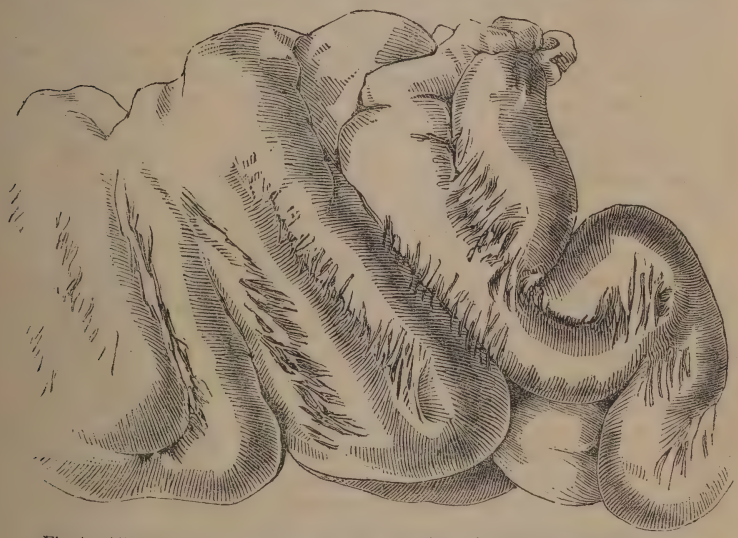

Fig. 4. All the intestinal convolutions agglutinated together by strumous peritonitis.

The *situation* of these bands is an important point for consideration. In all the cases which I have seen, and in most of those of which I have read, the bands have been around the ileum or jejunum, especially the former; but no doubt they may occur elsewhere. It is natural to suppose that they would be more likely to be attended with urgent symptoms when embracing the small than the larger intestines; and the higher the obstruction, the greater *(cæteris paribus)* would be the distress produced, and the more imminent the danger; but experience does not altogether bear out that view.[1]

III. Mesenteric and Omental Obstruction. It occasionally happens that the bowel is twisted upon itself; and in that case, one portion of intestine is girt round by the mesentery of another, and the confusion of such folding is sometimes very great. No well-marked, uncomplicated case of this kind has occurred to myself: but in Case xv, for which I am indebted to a medical friend, it was found, after death, that a portion of omentum had grown around a knuckle of small intestine (a portion of the ileum), and had occasioned strangulation; so that when the omentum was turned back, the intestine was dragged

[1] Vide Symptoms, p. 604.

back with it; and in the *Medical Gazette*, three very interesting cases, of what he calls dislocation of the sigmoid flexure of the colon, are mentioned by Mr. Mackenzie. In whatever manner, he observes, the displacement is effected, the result is remarkably uniform; the intestine is thrown from its natural situation towards the centre of the abdomen, and receives a twist at its termination in the rectum, which causes complete obstruction of the passage; the small intestines get coiled round it in such a manner as to strangulate the gut by the free margin of the mesentery. In Case I, on opening the abdomen, an enormous viscus, of a dark colour, in a state of extreme distension, occupying the centre of the abdomen, half buried among the small intestines, which were also distended with gas, came into view. This proved to be the sigmoid flexure of the colon; at its termination in the rectum, it was found to have received a twist upon itself, giving rise to complete obstruction. The transverse arch of the colon was pressed towards the right side; all the *intestines were more or less inflamed*, except the rectum and twisted portion; the sigmoid flexure was in a gangrenous state, and on being opened, was found *filled* with cranberries and bloody sanies. In Case II, there were the same morbid appearances as in the former, except that the dislocated intestine occupied the right side, concealing from view the descending colon; and, instead of being twisted, it was tightly embraced by a turn and a half of the mesentery, by the free margin of which it was completely strangulated. A loop of small intestines had got entangled, and was also strangulated and gangrenous; the mesocolon lay in the shape of a long appendix amongst the intestines, quite saturated with extravasated blood. In Case III, the morbid appearances were precisely as in Case II, the sigmoid flexure being thrown to the centre of the abdomen, and at its termination in the rectum, being strangulated by a turn of the mesentery. The small intestines were found in a state of extreme distension, equalling the normal size of the colon, and highly inflamed, whilst the colon was found of normal size; the small intestines were perfectly empty, even of gas, and quite free from inflammation.[1]

IV. Obstruction from the Mesentery and Membranous Bands. It occasionally happens, that both of the causes last-mentioned above, occur in the same individual, and the difficulty and danger of the case are thereby increased. In Case XVI (Fig. 5), such a complication will be seen. The lower part of the ileum, towards its termination in the colon, was in a complete state of strangulation from bands and mesentery; the portion incarcerated consisted of two convolutions united together by bands of lymph, and that portion of the mesentery by which the principal stricture was formed, although very tightly embracing the bowel, was softened, and had *in part given way*.

Effects of Obstruction. Several ill consequences follow as the effects of stricture of the intestine. It may be so tight as to produce, not only congestion of all the tunics of the bowel some way above the constricted part, but softening, ulceration, and perforation,—hypertrophy, and distension of the bowel above the stricture—atrophy and contraction of all the portion below it—and partial or general peritonitis.

[1] Medical Gazette, vol. xli, p. 407.

Congestion of the Bowel above the Stricture. In only two of the cases (XIV and XVI) is there a distinct mention of congestion of the coats of the bowel above the stricture; but it is probable it might have existed in the others in so slight a degree as to escape notice. This appearance will much depend upon the tightness and duration of the obstruction, and the nature of the treatment to which the patient has been subjected.

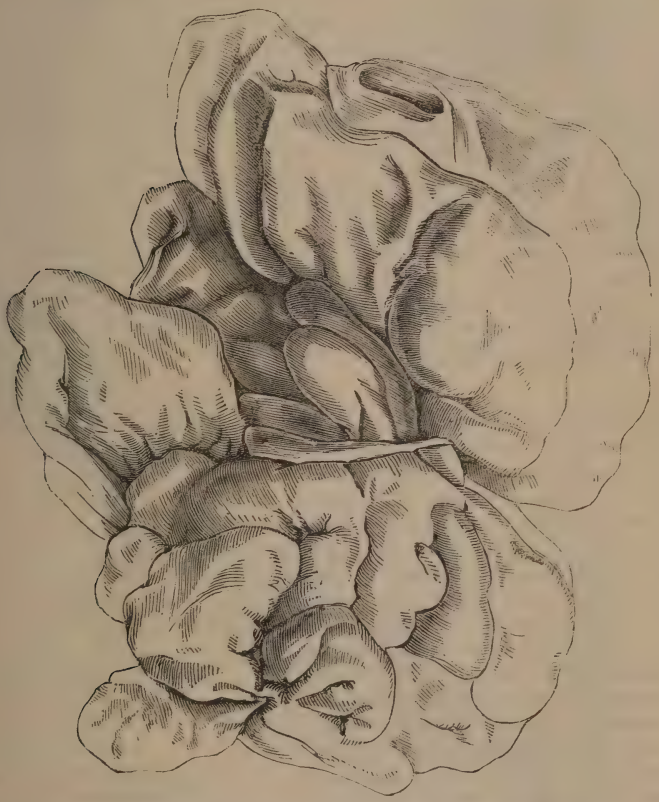

Fig. 5. Convolutions of the bowel strictured by false membrane and mesentery. A, the part above dilated; B, the band of mesentery forming the stricture.

Softening of the Mucous Membrane will be noticed in some of the cases appended to the paper; in one also, the mucous membrane is said to be ulcerated; but in none of the cases does perforation appear to have happened *before* death. No doubt it may occur from this as it does from other causes, but it is by no means usual; for the inflammation set up around the diseased part produces adhesion to the surrounding textures, and this effectually prevents it. It is more common, therefore, for all the parts to be softened, so as upon the least touch to give way, as happened in Case I, alluded to in the preceding page.

Hypertrophy and Distension of the Bowel above the Stricture. The same evidences of obstruction as are seen in other organs are seen in

Fig. 6. Hypertrophy of the muscular coat of the bowel, to such an extent as to allow of its being torn into two layers.

the intestinal canal, not, however, to the same extent as in the heart and bladder when obstruction occurs. In the first instance, an effort is made to overcome the obstruction, and by the continuance of that, there is an increase in the muscular power of the bowel, or genuine hypertrophy, as is recorded in Case XVI, illustrated by Figs. 5, A, and 6. Hypertrophy failing to overcome the obstruction, a great augmentation of calibre occurs, which is owing partly to the accumulation of the contents interrupted in their passage, and partly to the decomposition of them, by which much gas is generated. Sometimes the distension is very great, as in Case XII, where the ileum is described as measuring *nine inches* in circumference. I have no preparation of this particular condition; but in Figs. 7 and 9, copies of preparations of imperforate anus, the same thing is very well illustrated.

Fig. 7. Imperforate anus, with rectum distended above it.

Contraction and Paleness of the Bowel below the Stricture. There is a great contrast between that portion which is above and that below the stricture; the latter is generally pale, shrivelled, and smaller than natural, especially where the contraction has existed any time. In Case XIV it is stated, that this part was only *one-fourth* the size of that above it

Peritonitis may be general, or confined to some part; the latter appears to be most common, and sometimes it does not take place at all, as in Case XV, where it is mentioned that there was neither fluid nor any other inflammatory product. In most, it will be seen, that the effusion of fibrin was partial, and in only two of the cases was there any fluid found in the abdomen; in Case XVI there were two ounces only of serum; and in Case XIII, eight ounces of dark brown fluid, without lymph, were found in the general cavity. Sometimes, however, the peritonitis goes on to the purulent stage, the matter being occasionally confined in a circumscribed cavity, as in Case I, where it is recorded, that there was a large collection of pus in the right iliac fossa, which was contained in a distinct cyst of false membrane, formed by the agglutination of the lower part of the ileum, the cæcum, and the peritoneum, covering the right transversalis and iliacus internus muscles.

Fig. 8. The rectum of a full-grown fœtus in a natural state.

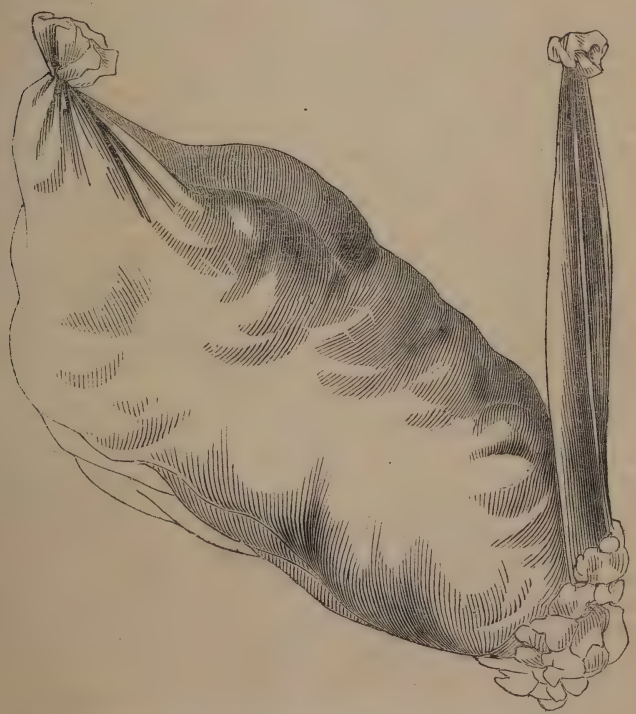

Fig. 9. Another preparation of imperforate anus, with the bladder in front. The distension of the bowel above the stricture is greater than in Fig. 7.

CAUSES.

Although contraction of the bowel and formation of bands, etc., are the *real* cause of obstruction, they are not the *sole cause;* for in many cases there is reason to believe that they had been in existence *some time before* the serious interruption to the canal took place; other causes must therefore exist to bring them into operation, and these are, for the most part, sudden and violent exercise, and errors in the quantity or quality of the food. Thus, in Case XIV, the symptoms showed themselves after lifting a weight; in Case XVI, while the man, a sawyer, was at his work as usual; in another case, soon after exposure to cold when dining out; and in Mr. Mackenzie's cases, the imprudent use of raw, indigestible substances, as cranberries, turnips, cabbages, etc., was suspected as the cause.

Age. Obstruction of the bowel from internal causes may occur at any age; yet in the cases which have come under my notice, and in others to which I have referred, the middle period of life has been that in which it was most frequently seen. Thus, two cases occurred at 20 years of age; one at 34; three at 40; one at 55; and one at 60.

SYMPTOMS.

I shall, in the next place, consider the symptoms to which the morbid conditions described give rise. This is a task both difficult and important; difficult, because it will be seen that they vary considerably in different cases; and important, because, unless the symptoms are clearly made out, the *diagnosis* can hardly be correct; and without a correct diagnosis, anything like operative interference can scarcely be undertaken,—certainly not *early* enough to give it a fair chance of success. In considering this branch of the subject, two things are to be borne in mind: first, the symptoms which show themselves; and, secondly, the *order* in which they appear; the latter, I think, is as important as the former.

A very good summary of the symptoms is given by Mr. B. Cooper, in his valuable lectures, published in the *Medical Gazette;*[1] to which, as they are well known, I shall content myself with alluding. As a closer examination of the symptoms may be attended with advantage, I will enter more into detail. The symptoms may be divided into two classes—the premonitory, and the actual.

Premonitory Symptoms. In some of the cases, nothing particular occurred to call for notice till the time the attack actually began; but in others, *all the life through*, there was a tendency to constipation; and in Dr. G. Bird's and Mr. Hilton's case, the patient, although a youth, seldom got any relief at all without the aid of purgatives. Others had symptoms from time to time of ordinary dyspepsia; others, pains of a colicky nature; and others, again, had had an attack of decided enteritis, which had been actively treated; others had been the subjects of genuine peritonitis; and others, again, had been subject to a complication of abdominal maladies, as in Mr. Hilton's case, where, in addition to habitual constipation, there had been in early life a tendency to, if not actual, mesenteric disease.

---

[1] Medical Gazette, vol. xlii, p. 607.

Actual Symptoms. In describing the symptoms which mark internal intestinal obstruction, I will enumerate them in the order in which, I believe, they most frequently occur.

Pain. This varies in kind, degree, and extent, in different cases. In some instances, it is described as a dull, heavy sensation; in some, as in Case xv, there is no pain at all; in others, it is universal; in some it appears to come and go, and is relieved by pressure, after the manner of colic; at others, it is constant and severe, as where the inflammation of the peritoneum is most active. In some instances, there is pain increased on pressure; but in others, that circumstance has not occurred. In some cases, there is a general uneasiness rather than pain; in other cases, the sensation is that of dragging; and in some *(a circumstance specially to be noted)*, there is pain in a situation *away* from the obstructed part; and again, there is pain both there and elsewhere.

Constipation. In almost every case there is constipation: but constipation is very often unattended to, as there is great difference in different persons in respect to the frequency with which the bowels are opened. This has been very well illustrated by Dr. Heberden, who says: "Homines frequentiâ alvum exonerandi plurimum inter se differunt. Alteri semel tantum singulis mensibus venter solutus est; alteri *duodecies* quotidie descendit per *triginta annos*, uti ipse mihi narravit, et dein septies quotidie per septem annos".[1] In these cases, however, the constipation cannot generally be overcome. It is true that by means of injection a small quantity of fæcal matter is brought away, but this is nothing more than sufficient to tinge the injection; now and then a large portion of hardened fæcal matter, which had been long resident in the large intestines, escapes, and then there is no other action; and occasionally, as in Case xii, the bowels have been freely opened, and yet there is a fatal result.

Vomiting has occurred in every case. In the commencement, it is merely the return of matters taken; but as the disease advances, it is said to put on a stercoraceous character. It is generally, however, if not always, the matter resident in the small intestines which passes from the mouth; as, in most of the cases, the obstruction has been in the small intestines, which would as effectually prevent the passage of the contents of the larger bowels *upwards*, as it does the removal of the contents of the upper part of the canal *downwards*. In one remarkable instance (Case xv), the matter vomited was of a very fluid nature, and amounted in a very short time to the extraordinary quantity of *ten pints*.

Abdominal Distension has occurred to a greater or less extent in almost all the cases. In some it sets in early and proceeds rapidly; in others, even when the disease has lasted some time, there is scarcely any distension. Thus, in Mr. Hilton's case, it is stated, so late as the eighth day, "abdomen flat and collapsed".

Hiccup. There is great uncertainty about this symptom; it does not occur in every case, nor, indeed, in the majority; for out of the total number to which reference has been made, it is only mentioned in three of the cases.

---

[1] Heberden, Commentarii de Morbis, p. 14.

The Countenance was natural in all of the cases at first, and remained so throughout in some; in one it was florid; in others, however, distress and anxiety were depicted; and in one of Mr. Mackenzie's cases, though the disease was seated in the *large* intestines, the face was reported to be hippocratic and expressive of intense suffering, and here the amount of inflammation was not great.

Pulse. This varies considerably in different cases, and at different periods of the malady. It is generally slow at first, quickens when inflammation sets in, and becomes excessively rapid as irritation advances; in some, it is described as about 68; in others, between 80 and 90; and in others, again, it was as high as 120. In character, also, the pulse varied considerably; in some cases, it was described as natural; in others, as full and wiry; and in others, as exceedingly feeble. These variations have seemed to bear some ratio to the extent of obstruction,—the length of time the disease has lasted,—the amount of inflammation present,—the original constitutional powers of the individual,—and the impression which the disease has made upon the system generally.

Tongue. There has been noticed great variety in the appearance of the tongue. In some cases, it remained clean, even to the last; in others, it was white; in others, brown; in others, red; in others again, it was very dry; and in one case, and one case only, was there noticed an aphthous state of the tongue and mouth.

Skin. In some cases the skin was cool; in others, hot; in some, dry; in others, covered with warm perspiration; in others, the surface was bedewed with a clammy sweat.

Urine. It is worthy of remark, that, in some of the cases, there was a copious secretion of urine, showing that a part of the function which should be carried on by the bowels, was, in a measure, compensated for by the kidneys, when the bowels were no longer capable of acting. In *none* of the cases was an analysis of the urine made, but nothing of an abnormal nature appears to have called for attention. In one case there was *dysuria;* but that arose from a mechanical cause,—a stricture at the bulb of the urethra; and, in one case, there was *retention of urine*, requiring the use of the catheter, but that appears to be referrible to spasm about the neck of the bladder, produced by a blister.

Sleep was procured in most cases, especially in the commencement of the malady; but, towards the close of the case, restlessness, more or less extreme, was manifested. *Delirium* was also observed in one or two cases, towards the close of life; but that was not a symptom observed in the majority of instances.

Dyspnœa is mentioned in one case. It did not arise from any affection of the thoracic viscera, but was owing to abdominal distension thrusting the diaphragm upwards, and thus contracting the area of the chest.

Rigors were also apparent in two or three cases; and, in these, were precursors of inflammatory action about the peritoneum.

The duration of the disease, it will be observed, varied very much. One case was fatal within a few hours, another in three days, another on the fifth day, another on the seventh, and another on the eighth; one on the tenth, one on the fourteenth, and one on the sixteenth day.

CAUSE OF DEATH.

In most instances, the death of the patient is to be referred to exhaustion, consequent on the suffering to which he has been exposed, and the total interruption to the function of the intestinal canal. In some instances, it would appear to be attributable, in great measure, if not entirely, to inflammatory action. In two instances, I think it can scarcely be denied, that death was hastened by the operation performed for the liberation of the stricture; and, in one case, death appeared to be almost instantaneously brought about by the discharge of very large quantities of fluid by vomiting.

PROGNOSIS.

In respect to the prognosis, a few words will suffice, as, so far as we know, all cases are fatal, and therefore the opinion given in regard to them must be very unfavorable. The principal chance of a successful issue seems to depend upon finding out the cause of obstruction, and removing it by operation before the powers of life are too much exhausted.

DIAGNOSIS.

In the earlier stages, it is not easy to say accurately the nature of the affection; but, towards the close of the malady, when it resists all remedies suggested for its removal, there can be little doubt about it.

The maladies most likely to be confounded with internal strangulation, are, colic, enteritis, stricture, malignant disease, and introsusception. In the beginning, it will be perceived, by reference to the cases, that some of them much resembled *colic*. There was pain of intermitting spasmodic character, in some part of the abdomen, not increased on pressure; constipation of the bowels, and absence of fever. As the disease advanced, however, the pain became more violent and more constant; vomiting supervened, at first of the contents of the stomach, but, ultimately, so-called stercoraceous vomiting. The entire failure of all remedial means plainly showed that colic was *not* the disease under which the patient labored. From *enteritis*, it may be distinguished by its comparatively slow progress, by the absence of intense pain and fever, and by the distension of the abdomen not appearing so early as in that disease. As *stricture* occurs most frequently in the lower part of the rectum, examination by the finger will generally enable us to distinguish between the two; and constipation and stercoraceous vomiting are not so often seen in the former as in the latter case. From *malignant* disease, it may be diagnosed by the countenance, by the rapidity of its course, and by the constipation being more persevering than in that disease. From *introsusception*, I know of no symptoms by which it can be *clearly* and *unerringly* distinguished; but as it has not been my lot to see much of this latter affection, and as what I have seen has been principally in children, I cannot, from experience, speak to this point.

Respecting the mode of distinguishing one kind of obstruction from another, great difficulty must, necessarily, be felt. If I may draw any inference from one case (and I am very unwilling to do so), I should say that the free relief of the bowels, the result being nevertheless fatal, would serve to distinguish obstruction, the effect of contraction of

the peritoneal coat of the bowel, from strangulation, resulting either from the twisting of the mesentery, or the formation of false bands. According to Mr. Mackenzie, the following will serve to diagnose dislocation of the sigmoid flexure of the colon: "In these cases, while all the symptoms of strangulation and obstruction of the bowels are present, there is one symptom never absent, which, respect being had to the history of the case, leads to a correct diagnosis, viz.—that it is impossible to throw up injection, per rectum, in any quantity; for, as soon as the gut is filled up as far as the twist, which is always low down, the fluid injected flows out as fast as it is thrown up, independent of any action of the intestine itself. Besides, the introduction of the long tube is impracticable, being always arrested at the obstruction."[1]

Dr. Barlow, in an interesting paper in Guy's Hospital Reports,[2] endeavours to diagnose the *situation* of stricture of the alimentary canal, by the *amount* of the secretion of urine, and cites cases in point. "It seems," he says, "that where there existed a perfect obstruction in the upper part of the small intestines, there was almost a total suppression of urine; where there was a diminution of the calibre of the canal, in the same situation, the urine was diminished in quantity; and where the small intestines were free, and the obstruction was seated in the colon, the urine was very abundant." Should future experience confirm these statements, a very valuable diagnostic mark will be obtained; but in Dr. G. Bird's case, and in some of those which I have related, the obstruction was seated in the ileum, and yet there was no perceptible diminution of urine, so that more facts are wanted to establish this point. At present it seems probable that where the *duodenum* is the intestine affected, non-secretion of urine will be noticed.

TREATMENT.

In the treatment of this dangerous malady, the following indications present themselves:—1, to open the bowels; 2, to subdue inflammatory action; 3, to support the strength; and, 4, to remove the obstruction.

1. *To open the Bowels.* As constipation is one of the most constant, and, at the same time, earliest symptoms, to relieve the bowels is certainly the first indication; and this may be attempted by,—*a*, purgatives; *b*, injections; *c*, the warm bath; *d*, nauseating remedies; and *e*, bleeding.

a. Purgatives. Great judgment is, I think, required in the selection of purgatives, as, if they do not effect their object, they do much mischief; for it is questionable whether the ulceration met with in the mucous membrane, in many cases, may not be in part owing to the unsuccessful use of drastic and violent purgatives. Had I grounds for suspecting that a case was one of intestinal obstruction, from any of the causes mentioned, I would endeavour to liquefy the motions, so that, if possible, they might pass the stricture in a fluid form. For this purpose, I would give one large dose of calomel, to be succeeded every two hours, if the stomach would permit it, by drachm doses of sulphate of magnesia, in peppermint water; and, did these not succeed,

[1] How far this *is* diagnostic I think admits of question.

[2] Vol. ii, New Series, p. 396.

I would rub croton oil on to the abdomen, or try one drop of croton oil internally. Should these fail, I would give up the use of purgatives, feeling assured that the obstruction was much too complete to be overcome by their means.

b. Injections. Purgatives failing to procure action from the bowels, recourse is naturally had to injections, which should, in the first instance, consist of the compound extract of colocynth, dissolved in water; but when a tympanitic state of the bowels occurs, turpentine, or the tincture of assafœtida, is to be preferred. So far, however, as my experience goes in these cases, injections avail but little; and I shall hereafter relate a case where seventy-two injections were administered without any apparent beneficial result.

c. The Warm Bath is a remedy which it would be very proper to use in the earlier stages; but, as the disease advanced, the strength of the patient being much exhausted, would scarcely justify its trial. Fomentations, often useful, and always soothing, should be used in all cases, especially where there is pain.

d. Nauseating remedies, in a strong and robust individual, might deserve a trial. Of these, perhaps, the two best are tartarized antimony, and the tobacco injection; but I should not be very sanguine of obtaining success by their means.

e. Bleeding may be now and then resorted to, in the earlier stages, in the robust and plethoric; but bleeding, carried to any great extent, I consider objectionable, for reasons to be stated hereafter.

2. *To remove inflammation* is a point to which particular attention should be directed; and, perhaps, there is but one thing of more consequence than this, for if it be allowed to go on unchecked, it may destroy the patient; and yet, if too vigorously attacked (by reference to the cases it will be seen that, in some, it was entirely absent, and, in almost all, limited, and by no means severe), the patient may sink from other causes. I think, therefore, that general bleeding will seldom be called for on this account; the application of leeches, fomentations, and the administration of small doses of calomel and opium, will be all that is required for removing or controlling peritonitis brought about by this cause.

3. *To support the strength.* I am very anxious to lay great stress upon this point, because I do not think it has been sufficiently attended to in practice; and I feel sure that patients have been largely bled, who would have had a better chance, had the vital fluid been less unceremoniously abstracted. If the bleeding be not sufficient to effect its object, either in opening the bowels by its depressing effect, or by removing the peritonitis by its antiphlogistic power, it must, if carried to a great extent, do infinite harm, as it will tend to depress the vital powers, already at a low ebb, and thus take away, I may say, every chance, either from the efforts of nature, or the resources of art. In the absence of fever, and where the stomach would allow of it, I would give, from time to time, barley water and chicken broth in small quantities. Where there is great restlessness and want of sleep, and where I had failed in the use of purgatives, and determined no longer to administer them, I would certainly advise the administration of opium, as, by so doing, I should hope to tranquillise the nervous system; for nothing tends to exhaust the frame so much as long-continued nervous irri-

tability; and cases are on record showing the good that has been done with it occasionally. If I employed opiates, I should prefer solid opium to every other form,—first, as being more likely to be retained by the stomach; and secondly, as possessing a stimulating as well as sedative property, which, I think, would, in these cases, be decidedly advantageous.

4. *To remove the obstruction* is one of the most important and difficult questions connected with this subject, and one upon which much difference of opinion exists. It is clear that this can only be done with certainty by means of an operation; and two cases have lately occurred, in which encouragement has been given to this plan. In one of the cases (Mr. Hilton's), the bowel was so far liberated, that the intestinal contents passed through the obstructed part. In neither of the cases, however, did the patient long survive. In considering this subject, four points are to be entertained: A, the likelihood of finding and removing the obstruction; B, the place of performing the operation; C, the time at which it should be undertaken; D, the chance of success that may attend the attempt.

A. *The likelihood of finding and removing the obstruction.* Upon this point, there can be no doubt that there is great uncertainty; for although, in both the cases to which I have alluded, the obstruction *was* detected and removed, yet in one (Mr. Hilton's case) very considerable difficulty was experienced; and in case XVI, had an operation been undertaken, the incision would, in all probability, have been made to the *right* of the umbilicus, as a decided induration was evident there, and not elsewhere, and a pouch immediately above it. It was natural, therefore, to suppose that this was the point of obstruction; whereas, on dissection, this proved to be merely hardened scybala; and the fatal incarceration was situated in the upper and posterior part of the *left* side of the pelvis.

B. *The place of performing the operation.* Mr. Phillips says: "There are some cases where the seat of obstruction is so clearly indicated, that *no doubt* remains. In such cases, I apprehend the rule is evident, —the incision should be made as near as is prudent to that point. But supposing the point of obstruction to be only obscurely marked, or indeed not discoverable at all, then I consider the incision should be made on the median line, because an opening in that situation may be found most convenient for liberation, if that be practicable; or, for the establishment of an artificial anus, supposing liberation of the intestine be not accomplished." The case, however, to which I have just alluded, induces me to think the central incision, as recommended by Dr. Crisp, preferable in all cases where the obstruction is seated in the small intestines.

C. *The time at which an operation should be undertaken.* It is very difficult to lay down any decided rule for this. Mr. Phillips says, that interference by surgical operation is justifiable when three or four days have passed without any relief from the bowels by ordinary means, providing constipation be complete, and fæcal vomiting continue. I scarcely think we are justified in operating so soon; partly because persons have recovered from constipation of twenty-three days' continuance, and partly for reasons which will appear in the sequel.

D. *The chance of success* I regard as a very important consideration

before undertaking any operation; and I cannot think that cases of internal intestinal obstruction, even under favourable circumstances, offer much chance of a successful issue from operation.

In the cases to which I have referred, it has been said, that, had an operation been performed earlier, a different result might have been obtained; and no doubt, in both cases, delay was caused by the unwillingness of parties interested to give their consent. Can that be a matter of wonder, when it is recollected, that if an operation be undertaken, both the patient and surgeon must be prepared to go *all* lengths? The obstruction may *not* be at the part suspected; it may be *some way* from where the operation was commenced, and a *very large abdominal section* may be required to complete the operation; and it may possibly not be completed at all. How can this be undertaken without very considerable risk? How can such an operation be *proposed early?* And how can any better justification be urged for such a proceeding, than that long since advanced by Celsus: "Satius est anceps remedium experiri quàm nullum?"

If it be true, that great difficulty attends the finding these obstructions, and great danger follows the attempt at removing them by the knife, so that we cannot conscientiously recommend it but as a forlorn hope, it is but reasonable to inquire, whether any other expedient can be resorted to for a similar purpose. And this naturally induces me to ask whether nature ever produces a cure, or whether spontaneous relief is ever obtained? Several cases are on record, where persons with the symptoms I have described, and, to all appearance, sinking from internal obstruction, were suddenly relieved in the bowels, and gradually recovered. A case is alluded to by Mr. Cooper where this happened. An elderly lady, residing at Norwich, was under the care of Mr. Colman, suffering from constipation of the bowels, having had no evacuation for four days. The usual purgative remedies were prescribed, but without effect; enemata and more drastic cathartics were tried, but still ineffectually; vomiting and immense distension of the abdomen supervened; the symptoms became more and more urgent, and, on the twelfth day from her attack, she had had no relief from her bowels. Dr. Alderson was then called in, and asked *what purgative* he would recommend; to which he replied—"None; but a large dose of opium". It was given, and *in a few hours* the bowels were freely opened, and the patient recovered.[1] What was the precise condition of this lady must ever be open to doubt; but I venture to suggest that this might have been a case where the bowel was strictured by false membrane, that inflammation and ulceration of this band ensued, and that then the gut was liberated; and I am the more inclined to think so from what is observable in Fig. 5, in which the band seems to be undergoing the ulcerative process; and I feel convinced that, had the patient lived a little longer, it would have entirely given way, and the patient might possibly have recovered. It is this conviction which makes me lay so great stress upon keeping up the strength of the patient; for as newly-formed parts are less organized than those formed originally, there is a hope, if the strength of the constitution be kept up, that the band may give way before the bowel, and the patient's life be saved. It is from this case that I particularly recommend the

[1] Medical Gazette, vol. xlii, p. 608.

renewal of the old plan of metallic mercury; I think its use has not been rightly understood. That it will remove an introsusception, or enable a portion of bowel to be drawn out of these bands, I agree with Mr. Hilton, is not at all likely to happen; but that it might in favourable cases (Mr. Hilton's was not one of that sort), by exciting a pressure upon the bowels, break through a false band, I verily believe; and I am more strengthened in this idea by the good that has occasionally followed its use. I have heard of a case, which I believe was of this kind, where metallic mercury appeared to remove a very obstinate constipation, and the patient recovered; and my friend Mr. Lawrence of Brighton has mentioned to me, and kindly allowed me to make public, the two following instances, which are cases in point. In one, a boy, æt. 10, was seized, without any apparent cause, with constipation of the bowels, but with no sign of inflammation. He was bled, leeched, took drastic purgatives, and had seventy-two glysters administered. On the twenty-first day of the disease, no motion having been procured, ʒiij of metallic mercury were swallowed; no effect following, the same quantity was repeated on the twenty-third day, after which he felt great weight and pain in the abdomen, and voided, with much forcing, an immense quantity of fæcal matter, and all the mercury, minus ʒss; almost fatal syncope followed, but the boy eventually recovered. The other was a case of similar kind, of shorter duration; it occurred in an elderly lady. All purgatives proving unavailing, two doses of metallic mercury, of ʒiv each, were given; several motions (and all the mercury, minus ʒj) followed its exhibition after six hours, but the exhaustion and the depression occasioned were such as to destroy the patient. For these reasons, I think metallic mercury again worthy of a trial; it *can* do no great harm, and *may* do good. That it will often fail, I have not the least doubt, especially where the obstruction is low down, and has been so great as to ulcerate or destroy the coats of the bowel; but where, on the contrary, the band is thin, and high up in the canal, where the constriction is not so great as seriously to engorge or injure the part constricted, where the system does not sympathise much with the local malady, and where the powers of life remain vigorous, I am not without hope that it may *occasionally* succeed; and if *but one case* should occur in which, from what I have said, a trial of this remedy should again be made with success, I shall consider my observations not altogether out of place, and I hope I may with truth be permitted to say—"Est quiddam prodire tenus si non detur ultra".

Case xii. Former Enteritis--Obstruction of the Ileum from Contraction of the Peritoneal Coat—Softening and Ulceration of the Bowel—General Peritonitis—Circumscribed Abscess in the Right Iliac Fossa. J. T., ætat. 40, came under medical care on January 28th, 1832. He had been subject to flatulence and constipation, and had been seized three months previously with obstinate constipation, and with marked symptoms of enteritis; but recovered by bleeding, croton oil, and purgative enemata. When I saw him, he complained of violent pain in the situation of the transverse colon, relieved by pressure; it had existed only a few hours; there was slight tension of the abdomen. He had had three motions on the preceding day, and one that morning; he had no fever. He was ordered to be bled to ʒxvi; to have a drop of croton oil immediately, and 4 grs. of scammony every four hours until the bowels were opened.

Jan. 29th. Blood not sizy: no pain: no fever: no motion. To have a drop of croton oil immediately, and to have it repeated if required.

Jan. 30th. No motion. Two drops of croton oil, and an ounce of castor oil were taken, and injections frequently given. A bougie was passed into the rectum, and met with complete resistance at four inches. The croton oil and enemata were repeated.

Jan. 31st. After great efforts, a very hard portion of fæcal matter passed, as large as an egg, yesterday afternoon, which afforded great relief; three or four loose motions followed. Pain recurred this morning in the transverse colon, and there was great rigidity of the abdominal muscles. Half a drachm of castor oil was given; an opiate liniment was used; and the enemata were repeated.

Feb. 2nd. Leeches had been applied to the abdomen, and several enemata and purgatives administered. No motion until last night. Some urine passed. He is easier, but the abdomen is still tense. A dose of salts and senna was given, and fomentations were applied to the abdomen.

Feb. 3rd. Many foul fæcal stools, with some lumps, and griping; belly less tumid, and softer; pulse natural; tongue clean. He was directed to take a grain of Barbadoes aloes every night.

Feb. 4th. Vomited yesterday afternoon; several motions; abdomen, notwithstanding, hard and full, especially on the right side.

Feb. 5th. Diarrhœa; vomited at times yellow matter, of fæcal smell; belly soft and easy; pulse good; tongue clean, but red. The enemata were repeated; and he was ordered to take twice daily a pill, of a grain of calomel, half a grain of opium, and four grains of compound extract of colocynth.

Feb. 6th. No motion; no vomiting; exceedingly restless; hiccough; pulse very feeble; an aphthous state of the throat. To have a cathartic draught occasionally; the injections to be repeated.

Feb. 8th. Four motions, some figured; abdomen full; aphthæ increased; pulse lower; light-headed; sinking.

Feb. 12th. He died.

Dissection, forty-eight hours after death. The skin covering the abdominal parietes was undergoing putrefaction; the abdomen tense; no air nor fluid in the general cavity. The jejunum and upper part of the ileum were enormously distended (measuring nine inches in circumference), chiefly by wind, but partly by yellow liquid fæcal matter. There was a stricture, formed apparently by contraction of peritoneal coat, without any thickening, in the ileum, near its middle; the calibre of the gut in this situation would not admit a large pea; the lower half of this intestine was exceedingly contracted. The convolutions of the intestines were united together by bands of lymph; they were also adherent to the abdominal parietes, and in many places approaching to sphacelus; for, on gently separating the unnatural adhesions, an opening was made into the gut. There was an unnatural contraction of the muscular fibres in the centre of the transverse colon; but, by pressure, this part could be made as capacious as others. There was a large collection of pus in the right iliac fossa, which was contained in a distinct cyst of false membrane, formed by the agglutination of the lower part of the ileum, the cæcum, and the peritoneum covering the right transversalis and iliacus internus muscles.

Case xiii. Former Peritonitis—Enteritis?—Strangulation of the Ileum by Membranous Bands—No Ulceration—Death on the Sixth Day. I was invited by a medical friend to witness the *post-mortem* examination of a gentleman, æt. 40, who had been attended by Dr. Davis, Mr. Key, and himself. This gentleman, in the year 1830, had been seized with constipation of the bowels, to which succeeded peritonitis. He was largely bled, treated in the usual way, and recovered. For three years he enjoyed very good health, except being occasionally subject to constipation, which easily yielded to aperients. On the 4th September, 1833, he had as usual a natural motion in the morning; but, after eating a mutton chop for dinner, he felt an uneasiness and fulness of the abdomen, for which he took a blue pill, and a mild aperient draught. The uneasiness continuing, leeches were applied to the abdomen, and croton oil and other purgatives administered, together with enemata.

Sept. 5th. No motion having been procured, the uneasiness continuing, and sickness supervening, with tension of the abdomen, the purgatives were continued, and the enemata repeated; the latter returned, only slightly tinged with fæcal matter.

Sept. 6th. After taking a mild aperient draught, he had one scanty motion; felt much less distension; and the vomiting abated. Towards the afternoon, however, the uneasiness increased, the sickness returned, and he had no further motion. The purgatives and enemata were continued; a blister was applied to the abdomen; and an opiate was ordered to be taken at bed-time.

Sept. 7th. There were more distension and uneasiness of the abdomen; the vomiting was stercoraceous; the bowels were still confined.

Sept. 8th. He was much the same, with the exception of retention of urine (probably owing to the blister), requiring the catheter.

Sept. 10th. Hiccough supervened; the stercoraceous vomiting continued; and he died at ten o'clock at night.

Dissection. Decomposition was commencing. About eight ounces of brown serum was found in the abdomen: there was no other evidence of recent peritonitis. The liver, gall-bladder, spleen, and stomach were healthy. A little flatus, and much yellow fæces, occupied the small intestines, the muscular coat of which was in a state of hypertrophy. The hypertrophied appearance increased towards the lower part of the ileum, where, not far from its termination, a considerable knuckle was surrounded by two false membranes, one of them of extreme tenuity, not much thicker than a thread, and in parts of a black colour; this completely surrounded the gut, and very considerably diminished its area. The surrounded portion was of a pale colour, and flaccid; and the mucous membrane, in various parts of the intestine, was soft, pulpy, and of a chocolate colour, but nowhere ulcerated. The large intestines were healthy. The bladder was empty.

Case xiv. Former Peritonitis—Obstruction from some folds of the Ileum being adherent to the Abdominal Parietes—Mucous Membrane softened and ulcerated—Death on the Ninth Day. A man, æt. 34, in lifting a weight, overstrained himself; shortly after which, he felt a pain in the bowels, and, although this continued, he did not for six days apply for medical advice. On the 6th day, he complained of some pain in the abdomen, which was

tense, but not very tender on pressure; his bowels had not been opened since the strain; he had constant vomiting, occasional hiccough, and some dyspnœa; his countenance was florid; his tongue covered with a brown fur; his pulse was regular, full, and wiry; and there was dysuria from stricture about the bulb of the urethra. Twenty ounces of blood were taken from the arm; twenty leeches, and fomentations, were applied to the abdomen; and ten grains of calomel and an effervescing draught were given.

Five hours afterwards, I found him much the same. He had vomited frequently, but the calomel had staid down; there was rather more pain upon pressing the abdomen; he had slept a little, but he had had no motion; the tongue was moister, but the countenance was much shrunk; the pulse was 97, small and thready; there was very great general debility, and the skin was covered with a cold clammy perspiration. Five grains of calomel and one of opium were ordered, together with castor oil and enemata.

7th day. Some sleep during the night; less pain, but more tenderness of the abdomen; vomiting and hiccough continue; no motion; in a state of complete collapse. Extract of colocynth, croton oil, port wine, and quinine were given him; the fomentations continued; and a turpentine enema administered.

8th day. The matter vomited assumed the fæcal character; there was no motion, although some of the enemata, which had been frequently given, were slightly tinged with fæcal matter. The collapse became more perfect; and he died in the afternoon.

Dissection, sixteen hours after death. The muscles were very rigid: the abdomen was tense: the thoracic viscera were healthy. A great portion of the small intestines were immensely distended with flatus; the vessels of their peritoneal coat, as well as of that lining the abdominal parietes, were much congested: some of the folds of the ileum were agglutinated together, and tightly bound down to the peritoneum covering the right iliac fossa, by strong and apparently long-standing membranous bands. The mucous membrane of the constricted part was in a state of ulceration; and the coats were so completely softened, that they all gave way, upon the convolutions being laid hold of. The folds of small intestine below the constriction, were only one-fourth the calibre of those above. The muscular coat of the bladder was very much thickened, owing to a stricture which existed at the bulbous portion of the urethra.

Case xv. Internal Hernia—Strangulation by Omentum—Vomiting of Ten Pints of Fluid—Death within Three Days of the Seizure. A medical man was called one morning to a gentleman, æt. 58, who was said not to be quite well. He had slept indifferently, and complained of a little sickness, or rather a slight feeling of it; his bowels were somewhat uneasy, and had not been relieved since the previous afternoon. Although the message was not urgent, the surgeon went immediately, and found his patient in bed. He expressed surprise at seeing him so early, and regretted that he had given himself so much trouble for so little cause. His pulse was 68; skin cool; tongue clean; abdomen rather too full, but quite soft; there was no pain upon pressure, but a feeling of soreness. Blue pill and compound rhubarb pill were prescribed for him. At five in the

afternoon he was much the same, having taken at noon a draught with rhubarb and decoction of aloes. The draught was ordered to be repeated every four hours, and the patient was left, without any reason to be anxious about the issue. The following morning, early, the symptoms were not aggravated, except that the abdomen was somewhat larger; there had been no motion, although three doses of rhubarb and decoction of aloes had been taken. A pint and a half of warm water, with some oil, were injected into the bowel; five grains of calomel were put upon the tongue; and, after an interval of two hours, a teaspoonful of castor oil was administered. At 12 at noon, his pulse was not quickened; but his abdomen had become somewhat larger. At 3 p.m. an active enema was administered, without benefit; and a pill composed of calomel and soap was ordered to be given every two hours. At 5 p.m. the pulse had become quicker, and the abdomen larger. At 8 p.m. he was seen by a physician, whose opinion was unfavourable, notwithstanding that there was no evidence of inflammation, and no effusion, and that no hernia was discoverable. He advised that croton oil should be added to the pills, and a turpentine enema administered. At half-past 12 P.M. the patient was quite calm; his intellect quite clear. He was thankful for everything done for him; and stated his belief that there was some alteration of structure, which could not be overcome. About 3 the following morning (the third day), he began to vomit; and, raising himself on his elbow, fluid to the amount of *ten pints* passed from his mouth, as from the spout of a pump, without the least effort; during this, he fell over on his side, and expired.

DISSECTION, TWELVE HOURS AFTER DEATH. Upon turning up the omentum, the cause of death was immediately evident. A portion of omentum had grown round a knuckle of the small intestine (ileum), and occasioned strangulation; so that when the omentum was turned back, the intestines were dragged back with it. It appeared as if this fatty growth had been in progress for some time: it was pervading the intestines generally. They were also very much narrowed in two or three places. There was no fluid in the abdomen, neither were there any evidences of inflammatory action.

CASE XVI. ILEUM STRANGULATED BY FALSE BANDS AND MESENTERY—THE LATTER NEARLY ULCERATED THROUGH—DEATH ON THE NINTH DAY. John Anthony, æt. 21, was admitted a patient of the London Dispensary, under the physician, on May 11, 1833. He was by trade a sawyer. He was of costive habit, and had overstrained himself some years ago. He was at work as usual on the 8th inst., when he suddenly felt a sensation as if his bowels were drawn up in knots: he soon became sick, and had since had no motion. He had been twice bled, with relief, and leeched upon the abdomen; and he had taken calomel, jalap, and scammony.

On the 16th he was transferred to me. The blood taken from the arm was neither cupped nor buffed; he was much exhausted and emaciated; features very much shrunk; abdomen very much distended, and tympanitic. There was something resembling a pouch to the right of the umbilicus, and below this an induration, which was very tender when touched. Pressure upon any part of the abdomen gave pain, but more especially in the before-mentioned part, and in the course of the

descending colon. With the exception of two days, vomiting had been constant from the commencement of his illness: this morning a large quantity of very offensive stercoraceous matter was brought up. He lay with his legs drawn towards the abdomen, being easiest in that position; no rigors; no sleep; tongue brownish, and like raw meat in the centre; pulse soft, 108; skin perspiring; rectum, upon examination, healthy and empty. He was ordered to have a common enema immediately, and two grains of calomel and a quarter of a grain of opium, and a drachm of Epsom salts in peppermint water every two hours; and to have a turpentine injection in the evening.

May 17th. The injections soon returned, only slightly tinged with fæcal matter; the vomiting continued urgent; the matter rejected was yellow, and seemed to come from the small intestines; the abdomen became more distended. He became delirious, and died at eleven in the morning.

Dissection. There were about two ounces of serous fluid, but no air, in the general cavity of the abdomen. The small intestines were excessively distended, partly by yellow inodorous fluid, and partly by flatus. The coats of the small intestines were hypertrophied; the lower part of the ileum, towards its termination in the colon, was in a complete state of strangulation, both from bands and mesentery. The portion incarcerated consisted of two convolutions, united together by bands of lymph, in a state of great engorgement; the mucous membrane appeared softened, and on the eve of bursting; and the portion of mesentery by which the principal stricture was formed, although very tightly embracing the bowel, was also softened, and had in part given way. The portion strangulated was lying in the upper and posterior part of the left side of the pelvis; the cæcum had been somewhat dragged from its situation. The liver was healthy; the gall-bladder distended with green bile; the right kidney was healthy, but its ureter was dilated to the size of a goose-quill. The thorax and head were not examined.

CONCLUSIONS.

I. The ileum is that part of the intestinal canal where internal obstruction is most likely to occur.

II. Membranous bands (probably the result of former peritonitis) are the most frequent cause of obstruction.

III. Partial is more likely than general peritonitis to lead to obstruction.

IV. All the convolutions of the intestines may be united together without obstruction.

V. Mechanical, although the direct, is not the sole cause of obstruction, as there is reason to suppose the mechanical cause has been in existence some time before the symptoms show themselves; other causes must therefore arise to produce them, and the most frequent of these are sudden and violent exercise, and errors in the quantity or quality of food.

VI. It is *possible* for a spontaneous cure to arise from inflammation and ulceration of an obstructing band.

VII. The same consequences are seen in internal intestinal obstruction as are seen in other obstructed canals—viz. hypertrophy and dilatation above the stricture; atrophy and contraction below it.

VIII. The symptoms vary considerably in different cases.

IX. The order in which the symptoms arise is as important as the symptoms themselves.

X. There are no symptoms by which one obstructing cause can be clearly distinguished from another.

XI. The duration of the disease varies much in different cases.

XII. The strength of the patient should be maintained.

XIII. Bleeding should be employed with great caution.

XIV. The seat of obstruction may be very apparent, and yet deceptive.

XV. An operation is only justifiable as a forlorn hope.

XVI. As a rule, when an operation is resorted to, the central incision is to be preferred.

XVII. There is reason to believe that metallic mercury has proved useful; and it is in obstruction from membranous bands chiefly, if not solely, that benefit is to be expected from its use.

Camden Row, Camberwell, April 1851.

OBSERVATIONS ON THE FORM AND MOVEMENT OF THE CHEST IN PHTHISIS.

By RICHARD PAYNE COTTON, M.D., Assistant-Physician to the Hospital for Consumption and Diseases of the Chest.

AN absence of symmetry both in the form and movement of the thorax is very apt to be considered as a necessary condition to the diagnosis of Consumption; and I have seen many cases of phthisis overlooked, in consequence of a well-formed and, to all appearance, healthy chest, having been deemed incompatible, not only with the existence of pulmonary tubercles, but even with the tuberculous diathesis. It is the object of the following observations to correct this misapprehension; and I shall commence with a few remarks upon the relation of the form of the chest to the *development* of consumption.

The form of the thorax appears to have little or nothing to do, primarily, with this disease, for it is equally common to see phthisis attacking persons of fine and well-proportioned chests, as those who are the subjects of some congenital or acquired thoracic malformation. The life-guardsman, the pugilist, the blacksmith, etc., notwithstanding the fully-developed chests which their several occupations induce, are, *cæteris paribus*, quite as liable to the inroads of phthisis, as the mechanic or artizan, whose daily task leads to the opposite result; the truth being that, in every instance, the origin of the disease is not attributable to any peculiar conformation of chest, but to the various circumstances under which such conformation has arisen; the impure atmosphere which has been breathed; the excesses which have been indulged in; the violation of sanitary laws; or, the inherited scrofulous taint. It is very questionable whether even the evil practice of wearing stays has been justly accused of bringing on phthisis in the female sex. M. Louis considers the popular belief upon this subject

as nothing more than matter of assertion, wholly unsupported by proof; and the very circumstance of consumption being so much more prevalent in London amongst males than females,[1] might be fairly used as an argument against it. Without doubt, this habit, which fashion has so mistakenly inflicted upon women, has its penalties; but phthisis can scarcely be included in the list.

The varieties of deformed chests, which are sometimes congenital, but oftener, perhaps, acquired during infancy in consequence of imperfect nutrition, are much less frequently seen amongst consumptive patients than might be anticipated. In phthisical children they are very common, but not so in adults; which probably arises from the circumstance, that whenever the deformity proceeds from the early development of scrofula, the little patients' career is very liable to be cut short by some form of tuberculous disease; but when it arises from causes which are only temporary, the health may be restored as these are overcome; and although the form of the chest may ever afterwards retain the evidence of early derangement, it does not expose its possessor, on that account, to any unusual chance of becoming phthisical. Whether or not this may be a satisfactory explanation, the fact remains, that the pigeon-breasted chest is not of very frequent occurrence amongst phthisical adults, whilst it is common enough to observe persons so affected in the enjoyment of perfect health.

The deformity arising from angular curvature of the spine is extremely rare, and has only once fallen under my observation amongst more than two thousand consumptive patients; and this is the more singular, from the affection being, in nearly every case, of scrofulous origin. Lateral curvature, on the contrary, is very common, and the loss of symmetrical form and motion of the thoracic walls which it generally involves, is liable to be mistaken for an indication of pulmonary disease, if the condition of the spine should escape notice; but this deformity has no relation to the development of phthisis, beyond that of exhibiting a defective state in the general health, which may have induced the tuberculous diathesis.

Continued observations upon phthisis in all its multiform characters, have led me to the following conclusion:—that the best formed chests afford no security against the onset of the disease, whilst those which are comparatively ill-developed, or even deformed, do not appear, on that account, more liable to become the seat of tubercle.

I now pass on to some remarks upon the form of the thorax as influenced by phthisis in its commencement and progress; and these will be better understood by a brief reference to the relationship existing between phthisis and tubercle.

There is a period of the disease, sometimes well-marked, but equally often so short and ill-defined that it escapes detection, which may be termed the *preliminary* stage; it might be called with more propriety the *first* stage, but this title has been too long applied to a somewhat later period to admit of being changed. Consumption has now commenced. The tuberculous elements exist in the blood, but are not yet separated from it in the form of tubercle. This period passes into the tubercular or *first* stage; in some cases the tubercle is formed very

[1] First Medical Report of Brompton Hospital for Consumption, p. 8. London: 1849.

rapidly; but in others, it may take months, or even years, for its accumulation to any notable amount.

The tubercular deposit consequently should be considered as the *effect* of phthisis, and as bearing precisely the same relation to this disease as the lithate of soda does to gout; and, just as a patient may be gouty without having the movements of his joints affected by "chalk-stones", so may any one be phthisical without having the functions of the lungs interfered with by tubercle. The really phthisical symptoms, at the commencement of the disease, depend, not npon the state of the lungs, but upon the morbid condition which has produced it. It is true, that in the latter stages, much of the patient's suffering is a direct consequence of the pulmonary disease; but, at an earlier period, the general features of the malady—the weak and quickened pulse—the languid expression—the perspirations, etc.—depend entirely upon the *phthisis*, not upon the tubercle.

From this view of the subject it must follow, that phthisical symptoms may present themselves in connexion with every possible degree of pulmonary disease,—from a few scattered tubercles, which are scarcely appreciable, to their accumulation in considerable masses; and that *incipient* phthisis is not *always* discoverable by a physical examination of the chest. If this had been more fully admitted by writers upon these subjects, the stethoscope would have been often spared unmerited discredit.

We will assume, however, that the disease has fairly reached its *first* stage, and that the tubercular deposit is sufficiently abundant to interfere with the proper functions of the lung. In what manner is this exhibited by physical signs? Are the form and movements of the chest necessarily altered? These are questions which cannot be answered by an appeal to individual cases, on account of the well-known Protean character assumed by the disease, and are only to be met by continued observation upon such a scale as an hospital, like that at Brompton, can alone afford.

As a general rule, the form of the chest is unchanged, and the action of its two sides is symmetrical. In a few instances, there is a slight bulging over the diseased part, but, owing either to its rarity, or the shortness of its duration, it is not very often to be detected. Auscultation and percussion are now the sole guides to the condition of the lungs—points, however, upon which it is not my present object to enter.

I have always been aware that such a statement may be met by the very plausible argument, that directly the apex of a lung becomes tubercular, it must necessarily lose some of its capability of being expanded, and, as a natural consequence, the portion of the thoracic walls corresponding with the seat of the disease, must undergo a change in form, and be less moveable than the opposite side. But I think it can be shown how it happens that, in most cases, neither of these alterations are immediately apparent, and that the chest may retain, for a time at least, its healthy form, as well as its long-accustomed habit of equal and simultaneous motion.

There are two ways by which it does so, viz.: 1. The movement of the healthy side becomes diminished to the same extent as the other, so that the ordinary breathing, instead of being partly costal, as we find it in health, is almost wholly abdominal. 2. The pulmonary cells

in the immediate neighbourhood of the tubercular deposit become enlarged, and by increased capacity for air, compensate for those which are disabled.

The first is less common than the other, but its occurrence may be witnessed in certain cases (of which I have seen many examples), where, although it is evident from other signs that one lung only is affected with tubercle, the thoracic movement upon both sides is small but equal, except on very deep inspiration, when the diseased side is less raised than the other. The second may be seen in the many cases of early phthisis, in which the respiratory sound upon the diseased side is actually louder than on the other, and in the still more numerous instances, in which the murmur at the tuberculous apex is scarcely audible in some points, and morbidly loud in others; both of which conditions must be familiar to every experienced auscultator. It is probable that the first takes place in cases where *miliary* tubercle is scattered throughout the greater part of the lung's apex; and the second, where the tubercular deposit is in somewhat larger masses, and accumulated in particular spots.

The occasional bulging over the diseased part, first observed by Dr. Chambers, is yet additional testimony in favour of the second explanation; for when the portion of the chest so altered is percussed, it is often found to be more resonant than the healthy side, apparently in consequence of an extreme degree of enlargement of the pulmonary cells, amounting to emphysema.

But, after a time, which varies very much in different cases, circumstances are entirely changed; the diseased portion of lung *begins to contract*, and the thorax undergoes an alteration in form, not only in the region of the clavicles, but in its whole contour. M. Fournet referred this contraction to secondary pleurisy; Dr. Stokes has attributed it to atrophy of the lung; and Dr. Walshe has added to these, the contraction of plastic matter exuded into the pulmonary tissues. It is probable that these different causes are sometimes associated; but one or more of them must be present, before the form and action of the chest can be materially interfered with.

In the majority of phthisical cases, their effects begin to appear towards the middle or latter end of the first stage; but examples are sufficiently numerous of their being completely absent until softening has commenced.

I shall describe the several changes which are thus produced, as they are seen when in their extreme; premising, that the greatest variety will be met with, both in the rapidity and extent of their development.

The vertebræ of the neck and back are inclined forwards, and the shoulders are rounded; the front of the chest is consequently contracted, and the stature of the body lessened, giving an awkwardness to the whole appearance, difficult to describe, but which any one accustomed to the external aspect of the disease, would at once refer to the *tubercular chest*. If the patient be looked down upon whilst he is sitting, two curves are distinctly visible; the one affecting the whole line of the cervical and dorsal vertebræ, the other crossing it, and formed by the two shoulders inclining forwards. A depression is visible beneath one or both clavicles, giving to these bones the appearance of

prominence; and, posteriorly, the supra-scapular region over the diseased part is more or less sunken inwards. During ordinary breathing, either there is no costal movement whatever at the upper part of the chest, or there is a difference in its extent upon the two sides; and, on forced respiration, instead of the peculiar *swelling* movement of the infra-clavicular regions which is so characteristic of health, either one side is elevated more than the other, or the entire chest is raised, as it were, in one mass, without being perceptibly increased in the antero-posterior diameter of its upper part. These latter changes are more conspicuous in females than in males, as the healthy respiration in our own sex is principally abdominal, whilst in females—owing to the restriction of stays, or for reasons which the obstetrician is the best able to appreciate, there is greater freedom of movement in the upper ribs, and the breathing is, to a much greater extent, costal.

The loss of symmetry and healthy movement take place simultaneously; so that, unless there is some depression in the clavicular or supra-scapular regions, there will be no diminution in the ordinary movements of these parts. M. Fournet was, I believe, the first who drew attention to this circumstance; and I have certainly never seen an exception to it.

The changes above described may occur at any period of phthisis, from that antecedent to softening, to that of large vomicæ; but they are very capricious guides to the actual stage of the disease; for persons with cavities in the lungs very often are less altered, in these respects, than others who have scarcely entered the second stage. The different amount of pulmonary contraction which must accompany different cases, will at once account for these varieties.

From the preceding observations, I think it must be evident that inspection and mensuration of the chest can seldom afford assistance in the diagnosis of *incipient* phthisis; although, as the disease advances, they may prove useful auxiliaries to other physical signs. But when it is remembered that a departure from strict symmetry is occasionally seen in healthy persons, as a consequence either of a congenital peculiarity, or of certain pursuits which influence the development of the thorax, it is obvious that much caution is always necessary in their employment.

I shall conclude with the following extract from M. Fournet's *Clinical Researches on Phthisis:*

"Il arrive assez souvent qu'une infiltration tuberculeuse *considérable* a lieu dans un poumon sans qu'aucune diminution dans le volume du thorax, aucune modification dans les mouvements de la paroi thoracique correspondante, se fasse remarquer. C'est le cas ordinaire de la tuberculisation *miliare disséminée*, et de la phthisie aigue. Dans ce cas, les mouvements de la paroi thoracique ne sont pas sensiblement modifiés. . . . . On voit, que la palpation des mouvements de locomotion n'est applicable qu'à une époque déjà fort avancée, de la première période de la phthisie, époque à laquelle le diagnostic ne peut plus être douteux, si l'on s'est servi convenablement de l'auscultation et de la percussion."

4, Bolton Street, Piccadilly, May 30th, 1851.

ON THE CAUSES, CONSEQUENCES, AND TREATMENT OF INFLAMMATION OF THE VEINS.

By HENRY LEE, Esq., F.R.C.S.Eng., Assistant-Surgeon to King's College Hospital, and Surgeon to the Lock Hospital.

(Concluded from p. 503 of last Number.)

The term Phlebitis, originally restricted to designate inflammation of one of the larger veins of the body, has gradually been extended so as to include all the consequences which are liable to result from it; and the idea promulgated by M. Cruveilhier, that all such secondary affections have their origin in inflammation of the capillary veins of parts at a distance from the original lesion, has been the means of gradually associating the term rather with the grave constitutional affections arising from a poisoned state of the blood, than with any local disease.

In my last paper, I considered some of the effects likely to arise in different capillary systems from the stimulating nature of their contents, and from the mechanical impediment to the circulation produced by the admixture of foreign substances. At present, I shall in like manner review some of the results produced by the presence in the blood of substances which have a tendency to alter its condition, either by producing its coagulation, or by causing its separation into its different parts.

III. Since the time of Ambroise Paré, different surgeons have, with greater or less accuracy, described the abscesses which form in the lungs and liver after injuries to other parts. These abscesses were observed to be peculiar, in the sudden and unexpected manner in which they make their appearance, and also in the circumstance of several of them forming at the same time, leaving the intervening structure of the organ in its natural condition. The want of knowledge of the real way in which they originate, was veiled by ascribing their formation to "sympathetic action", "metastasis", "constitutional irritation", etc, But as such words have been used without any distinct meaning, their place might, perhaps, be advantageously supplied by the term "translation", employed to indicate that the *materies morbi* is transferred from one part of the body to another, in the manner and under the circumstances which have been already pointed out.

John Hunter was the first, in modern times, to study the actual conditions under which abscesses formed in veins.[1] His observations proved that the internal coats of veins, like the internal surfaces of serous cavities, might become the seat of inflammation, and that such inflammation might terminate in suppuration. "From attentive examination of abscesses of the lungs, he found many appearances which served to confirm this supposition. He often observed the internal surface of veins leading from such abscesses, not only in an inflamed state, but, in many places, suppurated; and he could even distinctly trace the progress and termination both of the inflammation and suppuration."

[1] Medical and Philosophical Commentaries by a Society in Edinburgh, vol. iii.

It is not a little remarkable, that Hunter, having so closely traced the progress of inflammation of the larger veins in the extremities, and also of the smaller veins in the lungs, should have failed to recognise the relation which these so frequently have to each other. Almost all pathologists who have written upon inflammation of the veins, have, in fact, taken for granted, that the injurious consequences produced were necessarily transmitted by continuity of surface. It was therefore natural enough, that the investigation of the effects of inflammation of the veins should terminate with the appearances of irritation of their lining membrane; and as these could rarely be traced in the direction of the circulation so far as the heart, and never beyond it, the consideration of the disease naturally terminated at this point.

In the dissections which Hunter made, he usually found the abscesses which had formed in the course of the veins accurately circumscribed, being separated from the fluid blood by firm coagula. He, however, showed, in a preparation still preserved in the College of Surgeons, that the coagulum might be absent upon one side, and then, he conceived, the purulent secretion might become mixed with the blood. What the circumstances were which determined the formation of coagula in one case, and not in another, Mr. Hunter did not attempt to define; but the following case which he has left on record, leaves no doubt with regard to his having duly appreciated the important office which they perform.

Case xlii. A man was taken into St. George's Hospital with an inflammation of the arm, in consequence of having been bled in the basilic vein. He died suddenly at the expiration of eight days. Upon examination, the vein was found inflamed; the inflammation extended from the puncture which had been made by the lancet as high as the axilla; it went also some way down below the puncture. The orifice where the lancet had been introduced was yet open, and a probe could easily be made to pass through it. The coats of the vein were much thickened, and even the coats of the artery were affected in consequence of its vicinity to the diseased part. About the middle of the arm the vein had suppurated, and was divided by the abscess into two. Each extremity, like the internal surface of the abscess, was irregular and jagged. From the cavity of the abscess *there was a free passage into the axillary vein.* The cause of the patient's death was attributed to some accidental change in the position of the arm, by which the purulent matter was mixed with the refluent blood, and immediately carried to the heart.

In the dissection of horses which had died after bleeding, Mr. Hunter had traced the inflammation to the heart. To this he attributed the death; thereby giving origin to the notion, since so generally received, that the fatal symptoms arose from the extension of inflammation in a continuous and uninterrupted manner along the lining membrane of the vessels. In dissenting from this opinion, which has been followed by the very great majority of subsequent writers, it is necessary to remark, that in some of the most rapidly fatal instances, the inflammation has not extended far along the veins; and Mr. Arnott has, by a very careful collection of cases, clearly shown that it by no means generally extends to the heart.

It appears to us a most important fact in connexion with the patho-

logy of this disease, that wherever a coagulum is found to have occupied a vein for any length of time, there the coats of the vessel will be found thickened; but that, on the contrary, no change will be found to have taken place where the circulation has remained unobstructed.

In examining the veins of those who die of phlebitis, it is not at all uncommon to see such portions of them as have been blocked up with coagula, thickened by adhesive inflammation, while intermediate portions (which have contained no coagula, or where these have been only recently formed) remain in their natural condition. Specimens illustrating this point may be seen among Dr. R. Lee's preparations in the museum of St. George's Hospital; and the evidence which they afford is not the less satisfactory from the dissections having been made to confirm other and different opinions.

It must be evident, in such cases, that it is the stagnation of the vitiated blood in contact with the lining membrane of the vein, which produces the inflammation; and we submit, that it matters not at what intervals such stagnation may take place. The essential characters of the disease are the same, whether the poisoned blood coagulates through the whole of a vein, or in its different parts; whether in the vessel in which the vitiated secretion is first formed, or in some distant system of capillaries. It is, in fact, the poisoned condition of the blood, and not the extension of the inflammation to any particular part, which gives rise to the severe constitutional symptoms. The inflammation which is set up in internal organs, after bleeding, thus appears to have the same essential characters as that which affects the vein originally wounded. The disease is merely translated from one part of the venous system to another; and we have thus no difficulty in accounting for the multiform character of the secondary affections, of which, otherwise, it would be difficult to offer any rational explanation.

It is important, in the elucidation of the symptoms of this disease, that we distinguish between the coagula formed in veins by vitiated and by healthy blood. The former will irritate and inflame the coats of the veins; while the latter forms the most efficient barrier against the extension of the inflammation. In examining the veins of those who have died of phlebitis, it will sometimes happen that the lining membrane will appear "blood stained". This may occur either with or without any thickening of the coats of the vessel. It is not difficult to account for this appearance when a coagulum has remained in contact with the discoloured membrane; but it is occasionally observed where no coagulum is found upon dissection. It is extremely probable, in such cases, that the appearance is still due to a coagulum of blood having for some time occupied the vessel, and having subsequently been removed, either by the natural force of the circulation, or by accidental causes.

The following case from the Hunterian MSS. (Cases and Dissections) may illustrate this point:

Case xliii. Mr. —— received a blow on the right side of the face, which stunned him, but from the immediate effects of which he soon recovered. He was bled; but the opening in the arm opened, and he bled again. An inflammation came on in the arm, which was very severe; and a suppuration at the orifice took place. He was taken with stupor, sleepiness, and sickness at the stomach. It was,

at the time, doubted whether these symptoms depended upon the blow he had received, or upon the inflammation of the arm. He continued in much the same state until the twelfth day, when he was seized with a most violent shivering fit. He became as cold as possible, subsequently hot, and then covered by a profuse perspiration. He remained all day very low and debilitated, and his arm had less of the fluid red colour than previously. On the fifteenth day he became, in some degree, comatose, lost the power of speech, and died a day or two afterwards.

The preparation of the veins taken from this case, and preserved in the College, shows the cephalic distended through nearly its whole course by a firm clot. This, at the upper part, becomes smaller, and tapers to a narrow flat band, which adheres firmly, by one of its surfaces, to the adjacent wall of the vein. The walls of the vein at this and at the lower part appear healthy; but, in the intermediate portion, they are thick and tough. The median-cephalic and median-basilic veins, and the lower part of the basilic vein, are similarly filled with firm round clots. *The upper part of the basilic vein is pervious; but its inner coat is discoloured, being blood-stained.* An attentive examination of this preparation will, I believe, leave little doubt that the discoloration must have been produced by the contact of a coagulum, which, for a certain time, occupied the cavity of the vessel; and it is not improbable that the period of its dissolution, and its removal into the circulation, was marked by the grave accession of constitutional symptoms, which manifested themselves on the twelfth day. The intensity of the local and constitutional symptoms may not unfrequently bear an inverse proportion to each other. In the case just mentioned, the inflammation of the arm became less apparent at the very time that the really serious symptoms first appeared; and, on the other hand, the following case will show that the constitution may remain comparatively unaffected, even in the severest cases of local phlebitis.

Case xliv. Thomas Baker, a powerful man, of irregular and intemperate habits, was bled in the left arm, on the 28th of March 1851, having, a few hours previously, been thrown from a horse. He had been stunned at the time of the accident, had broken his collar-bone of the right side, and sustained other injuries about the head and chest. On the 7th of April, the wound made in bleeding, shewed a disposition to suppurate; a pad was, at this time, placed upon the vein, above the wound, and retained in position by a moderately tight bandage. The inflammation about the orifice now subsided, the wound healed, and no further attention was, for the time, paid to it. Ten days after this, the bandage from his arm having been removed, he got upon horseback. As the right arm was still disabled, from the fracture of the collar-bone, he was obliged to use the arm in which he had been bled freely. On returning home, he complained that his ride had "shaken" him.

On the evening of the 19th, a sharp pricking and smarting sensation was experienced about the upper and inner part of the arm. He felt uncomfortably warm, and, of his own accord, loosened the bandages that were about his shoulders. On the 22nd, a vivid red patch of inflammation, the size of the palm of the hand, had formed upon the upper and inner part of the arm. This was of a bright red colour,

becoming white for a moment upon pressure. Its outline was, in some parts, tolerably well defined; but, in others, it faded gradually into the colour of the surrounding parts. The inflamed part was very hot to the touch, and exquisitely painful upon pressure. The pulse was quick and full, but not hard; the skin hot, but not dry; the tongue coated with a yellowish brown fur, which was not unusual with him; and the bowels had been freely opened by medicine. The cicatrix of the wound made in bleeding, appeared perfectly well healed, and showed no signs of irritation. A pad was carefully adjusted, so as to make slight pressure over the upper part of the basilic vein; its lower border corresponded with the termination of the redness in the arm. He was ordered bark, with some *liquor ammoniæ acetatis.*

During the two following days, the inflammation extended downwards, in the course of the vessels, and indicated some disposition to spread to the back of the arm. He now continued the bark alone. On the 25th, the redness had extended below the elbow; several large vesicles had formed upon the arm, principally in the direction of the basilic vein; the cicatrix at the bend of the elbow discharged some dark coloured matter,—its edges were tumid and everted; the whole of the inflamed parts were exquisitely sensitive; pulse 108, compressible; he had some comfortable sleep. From this period, the inflammation gradually spread, involving the whole of the arm; the skin lost its bright red character, and became more livid, and abscesses formed slowly in succession, in every part. The inflammation, which spread so extensively in other directions, never encroached upon the situation of the pad, which had been placed over the upper part of the basilic vein. At the time when the inflammation was most intense, the patient became delirious for three or four nights; but this probably depended upon his having been denied his usual quantity of stimulus. With this exception, there occurred no symptoms to indicate that any vitiated fluid had entered the circulation. In this case no shivering occurred, either at its commencement, or at any other period; thus affording a strong contrast to the case last mentioned.

The extent to which the blood may coagulate in the living body, in similar cases, is remarkable. When the whole diameter of a vein is obstructed at any one point, a mechanical impediment is necessarily afforded to the circulation in the smaller veins which supply it. The blood, then, is placed under circumstances favourable to its coagulation in them also; and the same disposition is induced in them as in the larger vessels. The obstruction thus produced in veins will account for the tendency evinced, in some cases, for the inflammation to spread in a direction contrary to the natural course of the circulation; whereas, if no such obstruction exists, it will follow the course of the blood. It is evident that, under these circumstances, it may become an important object in the treatment to place a limb under those conditions which may favour the formation of a coagulum in the affected vein. The local inflammation may, by this means, be increased; but the constitutional affection is prevented. However severe the local symptoms may be, if there be fibrine enough in the blood to form a coagulum, and seal the vessel, the patient is comparatively safe. This observation applies with even greater force to cases of open or divided veins; such as present themselves after childbirth,

on the inner surface of the uterus; or, after amputation, on the suppurating surfaces of stumps.

IV. The difference between the effects produced by the introduction of foreign substances into the blood, when they are retained in the first system of capillaries to which they are conveyed, and those which result when they are allowed to circulate with the blood, is strikingly illustrated by the following experiments.

Experiment xxix. Fifteen grains of crystallized acetate of lead, dissolved without decomposition in rain water, were injected (a third part at a time) into the crural artery of a large dog. Each injection caused very great pain. The limb, after the operation, became completely paralytic, relaxed, and cold. The pulse and respiration were frequent, and there was a good deal of thirst. In the evening, the limb had swollen, but did not in the least recover its heat, its sensibility, nor its motion. The pain continued unabated. The animal died twelve hours after the experiment.

Post-mortem Appearances. All the organs in the interior of the body were healthy; but the limb was much swollen, emphysematous, and infiltrated with reddish serum. The muscles had become of a pulpy consistence, and of a reddish-black colour. The lighter structures had assumed a violet colour; and the whole limb had the appearance of having been affected with gangrenous inflammation.

Experiment xxx. Four grains of tartar emetic, dissolved in an ounce of water, were injected into the crural artery of a large dog. Some pain was apparently experienced during this operation; and the animal subsequently walked a little lame upon the affected leg. From the time of the operation, all food was refused; and violent retching and vomiting came on at the expiration of a quarter of an hour. Much discomfort and restlessness were now apparent. The pulse was small and feverish; but the limb, when handled, in no wise appeared preternaturally sensible (affording in this respect a strong contrast with the limb in the experiment last mentioned). An hour and a quarter after the operation, a kind of diarrhœa came on, accompanied by a repetition of the vomiting. These symptoms recurred occasionally until about three hours after the injection of the fluid, when the animal died.

Post-mortem Appearances. The limb upon which the experiment had been performed presented nothing unusual. The peritoneum was slightly injected, and contained some reddish serum. The stomach also was slightly injected, but only at its pyloric extremity. The mucous membrane of the duodenum throughout was livid, of the colour of the lees of red wine. This appearance was continued into the jejunum; but the other portions of the alimentary canal were apparently healthy. The liver was congested, and mottled upon its convex surface. In some situations its structure was so altered in consistence, as to break down upon very slight pressure. The gall-bladder was healthy, and full of bile, which was neither thick nor dark coloured. The lungs were studded here and there with a considerable number of petechial spots, or small black patches.

Direct experiment, in these instances, affords us the same information which we obtain from the more lengthened observation of cases as they occur in practice; viz. that foreign substances, when introduced

into the blood, in some cases being retained in the part, expend their influence in producing a local, although perhaps a most severe, disease; while in other instances, circulating more freely with the blood, they leave no trace of their entrance into the system, but produce a strictly constitutional affection.

The diseases which we have now to consider, belong principally to the last-mentioned class. It must, however, be remembered, that the two sets of symptoms continually present themselves, in every shade of intensity, in the same case; and that infected blood, which at one period of the disease goes the round of the circulation, may at another be arrested in some system of capillaries, and give rise to an apparently local disease.

Experiment xxxi. An ounce of fluid, resulting from the fermentation of some leaves of beet-root, in about an equal quantity of water, was injected into the jugular vein of a very little dog. At the expiration of an hour, the animal vomited. This was followed by evacuations of the bowels, at first of moderate consistence, but subsequently liquid, and consisting chiefly of mucus. Symptoms of dysentery now made their appearance. There was pain in the stomach upon pressure, difficulty of breathing, and expression of much uneasiness. Three hours after the injection, there were complete prostration of strength, inability to walk, or even to stand; and fresh evacuations of gelatinous mucus, tinged with blood. These symptoms were followed by renewed vomiting of glairy bilious fluid, and discharge of urine. The fluid evacuations from the bowels were now repeated upwards of five times, and were very fetid, tinged with blood, and black as if mixed with soot. Under the persistence of these symptoms, the strength became greatly impaired. The animal was affected with convulsive twitchings of the muscles, and died eleven hours after the injection.

Post-mortem Appearances. The body was opened while yet warm. The lungs were found somewhat dark and congested, but free from inflammation or petechiæ. The intestinal canal, from the pylorus to the anus, was covered with a muco-sanguineous fluid, resembling the lees of red wine. The mucous membrane of the intestine was, however, everywhere healthy, except in the duodenum, the commencement of the jejunum, and the rectum. In these situations it was of a violet red colour, and bore marks of having been inflamed in longitudinal ridges.

Experiment xxxii. Some beef and blood were allowed to decompose in water, at a temperature of about 80 Fahr. Five ounces of this fluid, which was quite putrid, were injected in divided quantities into the peritoneal cavity of a small dog. After the experiment, there was prostration of strength, vomiting, discharge of fæces with tenesmus, and increased sensibility of the stomach. At the expiration of an hour, the vomiting and evacuations, consisting of gelatinous mucus, recurred several times. The animal died nine hours after the operation.

Post-mortem Appearances. About a pint and a half of bloody serum was found in the peritoneal cavity. This was without smell, and of the colour of the lees of wine. The peritoneum was inflamed, of a violet red colour, and presented everywhere patches of ecchymosis or congestion. The inflammation appeared to have been very great, and was accompanied by the formation of dark patches along the course of

the vessels contained in the mesentery. The discolorations were also found at the attached margin of the intestine. The whole of the mucous membrane of the intestinal canal, from the stomach to the anus, was highly inflamed, and of a deep red, violet, or black colour. The folds of mucous membrane which projected into the cavity of the intestine were most discoloured; and in the stomach, these were the only parts inflamed. A glutinous but not bloody mucus was contained in the intestines. The muscular layer appeared in no way to have participated in the affection. The bladder was empty and contracted; it was inflamed on its peritoneal surface, but of its natural appearance within. The left pleura contained some bloody serum. The spleen and the lungs were studded with patches of congestion.

Experiment xxxiii. The last experiment was repeated on a large dog. Two ounces and a half of fluid, obtained from putrid beef, not so thick or fetid as in the preceding case, were thrown into the peritoneal cavity. Very great pain was immediately produced. This was followed by prostration of strength, aversion to food, fever without vomiting, alvine evacuations, and death at the end of ten hours.

Post-mortem Appearances. About two pints of bloody serum were found in the peritoneal cavity. The peritoneum itself was excessively inflamed, of a violet red colour, studded with black patches, and presenting here and there inflammatory adhesions and exudations. The bladder was of a deep red colour externally, but quite of its natural appearance within. The intestines were inflamed on their peritoneal surface, but still more so internally. The mucous membrane, from the pylorus to the anus, was thickened, of the colour of the lees of wine, and coated with mucus. Even those portions of the intestines which (in consequence of having been protected from the contact of the morbid fluid) were not inflamed on their serous surface, were nevertheless affected internally.

The general result of the presence of putrid fluids in the system, whether introduced directly into the circulation, or by absorption from serous surfaces, is, as evinced in the foregoing cases, to produce a remarkable affection, peculiarly characterised by congestion of the mucous membrane of the intestines. The evacuations that accompany this condition, are evidently an effort of nature to relieve the system from the vitiated fluids which have entered the circulation; and it is not a little remarkable, that the mucous membrane of the intestines should in these cases be exclusively affected. The appearances produced may be distinguished from the results of inflammation, in that no thickening or shrinking of the tissues is produced; but they are swollen, congested, and blood-stained, either in petechial spots, in larger patches, or over a continuous surface. The discharge from the intestines, in such cases, consists chiefly of mucus; but this may sometimes be accompanied by a kind of passive hæmorrhage, and occasionally the secretion may assume a puriform character, without any abrasion of the mucous lining of the canal.

We can readily understand, under these circumstances, that the appearances and symptoms which, a few years ago, were so often observed and described as forming a separate disease, under the name of gastro-enteritis, may frequently have been only the secondary results produced by an unhealthy condition of the blood.

When the actions produced by the introduction of putrid fluids into the body are fully developed, all the indications of putrefaction may take place even in the living body. Not only the fluids, but the so-called solids, pass rapidly into decomposition; and the former would appear, in addition to being extremely liable to decompose themselves, to have the property, under certain circumstances, of infecting other parts, and even other healthy bodies. Thus, we read, that during the plague of Marseilles, the bile taken from those who had died of the disease, uniformly produced death when injected into the veins of dogs.

After a putrid element has been introduced into the system, the blood is evidently altered in composition. It becomes black, viscid, and, in a great measure, deprived of its fibrine. After death, it is found fluid, of a very dark colour, and not unfrequently mixed with gas.

It might be, and, perhaps, generally is supposed, that putrid fluids mixed with the blood have the power of preventing its coagulation. The experiments which I have performed on this subject have, however, led me to an opposite conclusion. I have found that the addition of putrid fluids to healthy blood recently drawn promotes its coagulation. It is nevertheless true, that whenever there is manifested a tendency in the body to decomposition, the blood will be found to have lost its power of coagulation; but this effect arises from the continued circulation of vitiated fluid with the blood, and is not the immediate result of their admixture. It is probable, in this as in the former classes of cases, that the foreign substance gradually abstracts the fibrine of the blood, giving rise to small petechial spots, or small patches of congestion in different parts; and whatever may be the coagulating power of the blood when the putrid element is first introduced, it rapidly becomes impaired, or altogether lost.

Of all the substances with which the experiments have been tried, none possesses the power of coagulating blood so rapidly and so completely as pus. To this fact we attribute the formation of the larger patches of congestion found in internal organs when pus has accidentally entered the circulation; and with the more feeble influence of putrid fluids, or of mercury, we naturally associate the formation of the smaller and more circumscribed congestions, where these have given origin to the disease.

Two principal indications arise from the physiological analysis of these affections. *First*, in phlebitis, strictly so called, there may be, and generally is, a twofold disease, namely, a local inflammation, and a constitutional infection. These, although they occur together, give rise to very different symptoms, and may require very different plans of treatment. It may even be strictly in accordance with the soundest principles of pathology, to use remedies to subdue the violence of the local inflammation, at the same time that tonics are administered to support the general strength of the system. *Secondly*, we learn, by direct experiment, that where a putrid element is introduced into the circulation, the mucous membrane of the intestines and the liver are the principal channels by means of which the elimination of the morbid matter is attempted. The functions of the intestines would appear to fit them in a peculiar manner for this office; and it is probably some power connected with their natural action which determines so large a

flow of vitiated blood to their mucous lining. The congestions which arise in other parts, in consequence of a direct infection of the blood, may terminate in the effusion of serum, lymph, pus, or blood, either separately or mixed together in various proportions. In some rare instances, the secondary inflammation may terminate in resolution; of this the following case affords an instructive example.

Case xlv.[1] G. B., æt. 31, was admitted into St. George's Hospital for an aneurism in the left groin, for which the external iliac artery was tied. On the evening after the operation, the whole abdomen became painful and tender; the pulse was frequent, the skin hot, and the tongue dry and brown. The patient was bled, and on the following day the bleeding was repeated. The adhesions of the edges of the wound were destroyed, and gave exit to some sanious matter contained within. On the third day, none of the local symptoms were relieved, and the constitutional symptoms were much aggravated. The right shoulder now became affected with intense pain, accompanied by swelling and tenderness. Half a pint of wine was prescribed to be taken daily, with such nourishment as the stomach could receive. The pain in the shoulder, with some degree of swelling, continued for some time; but on the quantity of the stimulus being farther increased, this, as well as the other symptoms, gradually subsided.

This case is interesting, not only as showing that a secondary inflammation may terminate in resolution, but also as indicating the kind of constitution in which such secondary affections are likely to occur. Three months after the patient was discharged from the hospital as cured, the pulsation returned in the tumour, which again enlarged to a very considerable size. It is therefore evident that the coagulating power of his blood had from some cause been greatly impaired: for had this not been the case, the coagula which had been allowed such ample time to form, would have permanently closed the dilated vessel.

13, Dover Street, Piccadilly, June 1851.

HYSTERICAL AFFECTIONS OF THE HIP JOINT.

By WILLIAM COULSON, Esq., F.R.S.C.Eng., Surgeon to St. Mary's Hospital; and to the Magdalen Hospital, etc.

I was consulted in the case of a young lady, nineteen years of age, pale and delicate looking, of highly nervous and excitable temperament, on account of an affection of the right hip joint, for which she had been under surgical treatment, and for a considerable time confined to the recumbent position. The frequent application of leeches, and the employment of counter-irritation in every possible form, had proved without avail; she lay helpless and bed-ridden, complaining of severe pain extending over the whole lower extremity, and impressed with a firm conviction that she would remain a cripple for life. She shrunk from the slightest attempt to examine the limb, declaring that the pain she experienced was insupportable. My attention, however, was

[1] Related by Sir Benjamin C. Brodie in the *Medical Gazette*.

directed to the fact, that her general health had not suffered to an extent corresponding with what might have been anticipated from the severity of the local suffering, and the duration of her illness and confinement. The head of the femur was evidently in the acetabulum; there were no evidences of thickening or of disorganisation of the structures composing the joints; the pain was diffused, and her exaggerated complaints seemed as much excited when the integuments were lightly touched, as when firm pressure was made over the bones. No persuasions of mine could induce this patient to leave her bed, or to use the limb. I ordered her different preparations of steel, quinine, and other suitable remedies, but there was no perceptible change for the better. She was lying in this helpless state, when intimation was sent her that her father had been suddenly taken ill, and was not expected to live. She was conveyed in an invalid carriage to a distant part of the country, where the family resided, and arrived in time to see her father expire. By this loss, the means of living became much reduced; the family, which was large, could no longer pretend to their former state of affluence, and the different members were called upon, for the first time, to exert themselves to meet their calamity. This young lady upon being made acquainted with the particulars—for misfortune it was none to her—one day suddenly rose from her couch and walked. She exerted herself much, both mentally and bodily, for the good of those around her, seemed to forget her long illness, and has ever since remained well. That the joint was not affected with any organic change is clear from the result of the case. The disease was one of those obscure hysterical affections, more common among the rich than the poor, during which the impression of pain is in a morbidly excited and perverted state, and the power of the will over a certain group of muscles is suspended.

A limb was removed by a surgeon from a patient, whose symptoms, in many respects, corresponded with those in the case I have above related. The girl was in humble life, but well brought up, and was much noticed by some ladies who superintended the school where she was educated. She was of pale complexion, with dark hair and eyes, and of highly excitable temperament. Without apparent cause, severe pain came on in the right knee; the leg became flexed upon the thigh, and the slightest effort at extension excited impressions of intense suffering. She became an interesting object of pity; numerous professional opinions were asked by her patronesses, and frequent visits were paid to her by different surgeons. All, however, urged the necessity of her leaving her bed and using the limb; a measure to which she professed herself unequal. At the expiration of three years, during which her condition varied but slightly, a surgeon was induced, upon her representations, to recommend the amputation of the limb. To this she assented; the operation was performed, and the wound healed without any unfavourable symptom. Upon examination, the joint was found to be perfectly healthy. The synovial membrane retained its normal delicacy and transparency; the articular cartilage was slightly thinned, as is usually the case in a limb which has been long disused; the bones were light and easily sawn, but otherwise healthy; and there were no morbid changes in any of the surrounding structures.

It has been calculated, that at least four-fifths of the females among

the higher classes of society, supposed to be suffering from diseases of joints, are, in truth, affected with hysteria, and with nothing else. As, in the one case, absolute rest is requisite to effect a cure; and in the other, the patient must be urged, nay, even forced to take exercise, in spite of complaints of pain, it is important that the surgeon should be familiar with everything that will assist him to form an early and accurate diagnosis.

In hysterical affections of the hip joint, the patient from the first complains of pain in the part, and not in the knee, as is frequently the case when organic changes are commencing in the joint itself. The pain which the patient describes as most severe is not limited to one spot, but extends over the buttock to the lumbar region, and down the thigh. It is this general diffusion of pain which constitutes one of our most useful distinctions between this affection and disease of the hip joint. From the commencement, the patient complains of such aggravation of pain by pressure and motion, that she confines herself to one position of the limb; and yet upon occasions, when the mind is otherwise occupied, or during sleep, she will move it without complaint. The sensibility of the limb to the touch is frequently so great, that the slightest pressure on any part of the hip or thigh will cause the patient to scream; she shrinks involuntarily from the mere approach of the hand, but nevertheless, upon a careful examination, these morbid conditions will be found to exist more in the skin than in the deep-seated parts. As Sir Benjamin Brodie, who first directed attention to these important affections, observes: "If you pinch the skin, lifting it at the same time off the subjacent parts, the patient complains more than when you forcibly squeeze the head of the thigh bone into the socket of the acetabulum."[1] The more the patient's attention is directed to the part, the more the pain is increased; but if her attention be directed otherwise, she will hardly complain, and the pain does not interfere with her rest. In disease involving the structures of the joint, there is nothing of which the patient complains so much as the inability to sleep at night. Just as "Nature's soft nurse" comes to soothe the suffering and exhausted frame, a sudden start, or pain, or cramp, banishes sleep, and the patient dreads again to close her eyes. In hysterical affections, on the contrary, the sleep is calm and refreshing; and this, perhaps, is a great reason why the general health so slightly suffers, even in long-protracted cases. The pain is anomalous in its character, and different from the result of inflammation, or other organic changes. It may not be always easy to arrive at the truth, for such is the morbid constitution of the mind, that when leading questions have on a previous occasion been put, the patient will, as it were, take the hint, and symptoms, for which we previously may have in vain inquired into, will now actually present themselves. As for the motives for such deception, "to become an interesting object", says Dr. Prout,[2] "is an innate and characteristic feeling of the human mind; and if in early life this feeling in its natural and legitimate form has been thwarted or disappointed, it is almost sure to deviate into some other channel; and the ruling passion is displayed in attempt-

[1] Brodie, Sir B. C. Lectures on Local Nervous Diseases, p. 88.
[2] Prout, Dr. Diseases of the Stomach and Urinary Organs, p. 385.

ing to excite pity and commiseration, when she cannot excite erotic sentiment."

In some instances, there is no visible alteration about the joint or neighbouring parts of the limb; in others, there is general puffiness and tumefaction of the whole hip. The swelling, however, is rarely considerable, and depends on the effusion of fluid into the surrounding areolar tissue. It corresponds with what may be observed in some other neuralgic cases; thus Sir Benjamin Brodie relates a case of facial tic douloureux, attended with severe pain and swelling of the face, although there could be no doubt that the seat of the disease was not in the nerves, but in the brain itself. I have seen similar cases. In one, severe paroxysms of pain, attended with considerable œdema over those parts of the face supplied by the first and second divisions of the fifth, was the result of some obscure disease of the brain, in a man otherwise healthy, of temperate habits, and of powerful frame. When the tumefaction is limited to the immediate neighbourhood of the hip joint, it increases the difficulty of distinguishing this affection from organic disease, more especially as, in some forms of scrofula, the muscular excitement of a subacute character, dependent possibly upon irritation caused by the deposit of tubercle, spreads to the neighbouring parts, producing an undefined fulness and puffiness. In these cases, however, the swelling eventually is more defined, and proceeds from the formation of matter within the joint; in hysteria, the interior of the joint is quite sound.

I have often witnessed the periodical change of temperature mentioned by Sir Benjamin Brodie (*Op. cit.* p. 284), affecting either the joint, or even the whole limb. In the morning it is cold, pale, and shrunk; towards evening there is evidence of a more active circulation, and the surface of the skin is evidently red, hot, and shining. During the night, the heat and redness subside; and these alternations are as regular as the paroxysms of an ague. A patient who was some time under my care, was extremely susceptible of changes of temperature in the part; the knee, the part affected, was usually colder than the opposite joint; but towards evening it became warm, and quite damp with perspiration.

In all these cases, there is a great tendency to muscular contraction, and the limb is thrown into that position which it would assume after the influence of the will is removed, as in sleep. The thigh is bent upon the pelvis, the leg is bent upon the thigh; and, unless means be taken from the commencement to counteract this deformity, it gives the surgeon more trouble than the original complaint. The muscles undergo a sort of atrophy, and become paler than natural; the tendons contract cellular adhesions with parts around, so that very considerable and continued force may be requisite to free the limb, and to bring it to its proper bearings. I have known it necessary for the surgeon to perform the operation of the subcutaneous division of tendons, in the case of a contracted limb in an hysterical girl. Both the outer and the inner ham-string tendons were divided, when the leg was readily extended, and the patient recovered the use of the limb. The muscles about the hip, arising from the pelvis, do in some cases contract in such a manner, as to prevent the patient putting the heel to the ground on a level with that of the sound leg; and at times the limb is even so

much drawn out of its natural position, as to simulate dislocation of the femur upon the ilium.

A young lady, the subject of hysterical hip disease, came under my care, the case having previously been mistaken for disease of the joint, and moxæ applied. The knee was bent; the limb inverted; the thigh rested upon its fellow, and the head of the bone was preternaturally prominent. A superficial observer might have easily mistaken it for dislocation. The most positive assurance on my part could scarcely remove the impression which existed in the minds of the parents that there was no organic disease in the joint, and that there was no necessity to pursue the plan of counter-irritation and confinement. My patient was first directed to take out-door exercise in a carriage; with much trouble the limb was at length straightened; then she was persuaded to attempt to walk; and by these means she ultimately recovered.

Sir Charles Bell relates a case of this kind; and similar cases are not uncommon, in which "the knee was bent almost to the bursting of the ligaments, and the foot turned in so extraordinary a manner that the great toe lay close to the anus."

The age most liable to this affection is from fifteen to twenty; but when once developed, it may continue for a long period. I have met with cases in which the catamenia were irregular or scanty; but in other instances they have not deviated from health. The bowels are sometimes, but by no means invariably, constipated.

I will now sum up the symptoms by which this affection is distinguished from disease of the hip joint. In *the nervous affection*, pain is felt, from the commencement, in the hip, and extends to the loins and down the thigh; there is great general nervous excitability, and extreme sensitiveness in the part; and the patient is from the first unable to walk. Combined with this extreme amount of expressed suffering, the trochanter major retains its proper bearing to the spine of the ileum. There is not the characteristic wasting of the glutei muscles, and consequently no flattened appearance of the nates. Pressure in these situations, where the bone approaches almost the surface, does not excite greater pain than in the other parts. There are none of those involuntary startings during sleep, which cause the patient such intense agony. On the contrary, however loud may be the complaints of the painful condition of the limb while the patient is awake, no sooner is she asleep, than she rests well and calmly throughout the night. In *true hip disease*, the reverse is the case; for, when nature is exhausted by suffering, and the patient faint from want of rest, the sleep, if unaided by the administration of opium, is broken by sudden cramps, shooting pains, and frightful dreams, or vague anticipations of coming pain.

There is one circumstance attending this affection of the joint, which is calculated to mislead the inexperienced practitioner. I allude to its being often described as consecutive to a blow or other injury. In fact, many surgeons believe that there is generally some such cause, which determines the manifestations of these nervous phenomena in any one particular joint. I cannot say that I share largely in this view. Were local injuries alone the exciting cause, the pain would

be equally felt in such constitutions, in whatever joint were the seat of the accident; whereas, it is well known that, in by far the greater number of cases, the neuralgia is in the hip or knee.

As regards the pathology of these affections, we know little. The joint, the seat of pain, offers no abnormal deviations. It may, however, be asked, is not this affection seated in the spinal cord, or in the brain? Can we explain the phenomena of pain and muscular contraction, upon the supposition that the spinal cord, to which all motor and sensitive nerves are attached, is in a morbidly excited state, and that the brain responds truly to the impressions which it receives? Or is it that the functions of the brain are all perverted; and that an inquiry must be conducted upon the same principle as if we were seeking to investigate the reason why, as in the insane, objects are seen which do not exist, and sounds are heard which were never uttered? From the wonderfully sudden change which a strong mental impression can effect in one who is the subject of an hysterical affection of a joint, I am inclined to believe that it is to the sensorium we must mainly look as the organ morbidly affected; although I am fully aware that, in many instances, there are evident proofs of a highly sensitive and excited condition of the cord.

A young lady, nineteen years of age, complained of a constant gnawing pain in the knee joint; of stiffness and weakness, from which she feared a sudden fall. Her parents wished the joint to be strapped and bandaged; but feeling convinced that the disease was of a nervous character, this plan was not adopted. At the time of each menstrual period, the pain was more severe; and when seated at work, or engaged in reading, she was subject to a violent convulsion, without increase of pain, and incontrollable by the will, affecting the muscles of the whole body. It was a strongly marked instance of reflex action; the convulsion being so strong, that she would rise from her seat and forcibly grasp whatever object she was holding. The same phenomena would occur, if, at these periods, she was suddenly exposed to any risk of receiving a blow on the affected knee; the movement then being equally general and involuntary. There was, however, no increased pain; the sensation which the brain appreciated remaining unchanged, however violent the spasm of the leg.

"The existence," says Dr. Conolly, "of an original susceptibility in excess, in the nervous system of hysterical patients, is an assumption warranted, we conceive, by all observation. The natural or congenital constitution of the nervous system, and even of different portions of it, is most plainly discerned to be different in different individuals. From the very cradle may be observed a different degree of sensibility to impressions; and even a different countenance, impressed by the hand of nature herself, before human feelings have written their deeper lines upon it." "In the hysterical patient, we may observe the most intense development of susceptibility, connected with a singular proneness to irregular action, often arising from slight causes; the natural proportion designed to exist between the impressions of the external world, and the sensient human system, being in them not preserved."[1]

[1] Conolly, Dr. J. Cyclopædia of Practical Medicine, Art., Hysteria: vol. ii, p. 576.

With regard to the treatment of this affection, it is obvious that, if it be mistaken for organic disease of the hip joint, the surgeon will be led to adopt a line of practice, not merely useless, but positively injurious. The seat of the disease being in the nervous centre, little can be done locally, with any benefit or relief to the patient. We are, therefore, called upon to direct our remedies to the state of the nervous system generally. The patient must be persuaded to leave her couch as soon as possible. It is useless to wait until the painful sensations have subsided. She must take carriage exercise daily, be in the open air as much as possible, and in the society of lively and cheerful companions of her own age. The diet should be plain and nutritious. In the common forms of hysteria, I find the vegetable tonics more efficacious than the metallic; but, in that now under consideration, they possess no superiority. Their employment, however, is by no means to be laid aside; for in all cases where the tongue is foul, and there are other evident signs of derangement of the digestive organs, they are more beneficial than any preparations of the metals. But under different circumstances, as when the appetite is tolerably good, the tongue clean, and the bowels regular, then it is that the metallic tonics may be tried with great effect. In most neuralgic affections, the preparations of iron prove successful; and among these the carbonate stands justly preeminent. It may be prescribed in as large a dose as the stomach will bear without inconvenience. Among the medicines that directly soothe the pain, none are preferable to valerian; for though much less powerful than opium and belladonna, it neither constipates the bowels, nor enfeebles the system.

"The medicine which I have found the most useful," says Dr. Copland, "is the spirits of turpentine, prescribed in various modes, internally and externally, and administered in enemata; the preparations of iodine, alone, or with narcotics and camphor. These, however, should be associated with suitable adjuvants; amongst which, the several narcotics and antispasmodics are the most important. The warm or vapour bath, simple or variously medicated; mental excitement, and exercise taken regularly and energetically, and employment of the mind, are also important aids in the treatment. The affections of the joints are sometimes accompanied, or even alternated, with severe nervous pains in the extremities, and occasionally with tenderness in some portion of the spine. In such cases the treatment hardly requires any material alteration. In those which have come under my care, I have very frequently prescribed the spirit of turpentine, as already stated, and often repeatedly in enemata; and after two or three doses of it, I have commenced with the preparations of iodine, conjoined with henbane, opium, or belladonna. Whilst the iodine has been given, the turpentine has been administered in enemata, from time to time; and embrocations or liniments assiduously employed."

When the pain has been extreme and almost insufferable, the local abstraction of blood by leeches has afforded relief; but it has been only temporary: and, as the effect of the loss of blood necessarily is to weaken the frame, their application cannot be often repeated without producing permanent mischief.

Counter-irritants, such as blisters, setons, stimulating liniments,

mustard-poultices, and the like, all aggravate instead of relieving the pain. The belladonna or opium plaster, and sedative liniments, are the only local applications which I employ.

It may, however, be fairly questioned to what extent medical treatment in these cases is productive of good, unless there exists some evident derangement, against which our remedies may be directed. Far more is to be effected by moral treatment. Those absurd fancies to which young women of the present day are peculiarly susceptible, and which prevent their giving way to the vivacity and buoyancy of spirits suited to their age, should be carefully checked. The mind should be trained to regain its elasticity, instead of brooding over melancholy forebodings, or seeking to excite sympathy and compassion. The patient (cruel as it may seem) should not be allowed the privileges of a sick-room; nor should she be permitted to recline upon the sofa during the day, an interesting object of solicitude to her friends, and of care to a medical attendant. By being compelled to move the limb, and enter into society, patients have been known to recover, after the complaint had resisted every other kind of treatment.

The time of cure varies. Sometimes it is instantaneous; at other times it is slow. The time, however, does arrive, when this morbid state of the nervous system passes away, and the patient begins, though somewhat late in the day, to feel grateful to those to whose judgment and perseverance she owes her recovery. Above all, let it be remembered, that in this affection, the power of motion is present from the beginning; but the will to exercise it lies dormant, until called into action by some sudden emergency, or excited by moral and remedial means.

REMARKS ON THE NATURE AND TREATMENT OF HAY-FEVER.

By F. W. MACKENZIE, M.D., Physician to the Paddington Free Dispensary for the Diseases of Women and Children, Fellow of University College, etc.

It is well known that the respiratory mucous membrane is in some persons peculiarly susceptible to certain impressions, and readily disposed to take on morbid action in consequence. The perfume of particular flowers in one,—the effluvia from ipecacuanha in another,—the emanations from hay and grass in a third,—the smell of certain animals in a fourth,—and the presence of minute quantities of dust in the atmosphere in a fifth,—will give rise to much irritation of this membrane, and in some cases to severe consecutive constitutional disorder. In what this peculiar susceptibility consists, we neither know, nor shall probably ever discover; but the fact itself is undeniable, and in a practical point of view is one of extreme interest.

In the different instances which have been mentioned, it is probable that a similar state of the mucous membrane is induced in each; and that although the causes may differ, their ultimate action is the same; that this is primarily upon the nervous system, or those parts of it which are more immediately connected with the respiratory mucous

membrane; and that nervous irritation precedes and gives rise to those alterations in the secreting functions of the membrane, together with the other local and constitutional derangements by which the disease when fully developed is characterised.

It would thus appear probable that, however the symptoms, as well as the exciting causes, may differ in different cases, these affections depend upon the same proximate cause, and are amenable to the same general principles of treatment. It is more particularly, however, to the derangement of the mucous membrane produced by the effluvia from hay and grass, that the following remarks are intended to apply.

In designating this disorder, various terms have been used, having reference chiefly to the cause or to the nature of the local or the constitutional derangement. Hay-asthma, hay-fever, hay-catarrh, summer-cold, summer-catarrh—are terms ordinarily in use; but they express very imperfectly the nature of the disorder, and are otherwise not altogether free from objection. The local as well as constitutional symptoms will vary materially in different persons, according to the localisation of the irritation in the mucous membrane, its severity, and the susceptibility of the patient: thus, the portion of membrane lining the frontal sinuses, that of the eyes and eye-lids, the Schneiderian membrane, the mucous membrane of the throat, or that of the trachea and bronchi, may be principally or solely affected in different persons, and accordingly the symptoms will approximate in different cases to those of cephalalgia, ophthalmia, coryza, cynanche, bronchitis, or asthma.

With regard to the pathology and treatment of the affection, it may be remarked, that very little is known; and many persons annually suffer severely from it, who have failed to derive benefit from any treatment that has hitherto been devised. Such was the case in the instance of a gentleman who consulted me about two years ago, and who had relinquished all hope of getting relief from medicine, in consequence of the number of remedies which he had tried ineffectually.

From the state of the mucous membrane in his case, I was led to think that *arsenic* might be beneficial, and more particularly from the analogy which appeared to me to subsist between its pathological condition and that of the skin in some forms of prurigo. It was certainly given with advantage, and the results of its employment in this and other cases have been such as to lead me to think very favourably of it. Whether, however, its efficacy be such as to justify its general employment in these affections, my experience is as yet too limited to enable me to say; but I cannot doubt that it is worthy of a further and more extended trial.

Case. Mr. A. S. had for many years suffered during the summer months from hay-asthma, or rather catarrh; but his present attack had been of unusual severity, partly from the extreme dryness of the season, and partly from his having been obliged to live a great deal in the country during the summer, and consequently much exposed to the emanations from hay and grass. He had been suffering from this attack for many weeks before I saw him, and its severity had told painfully upon him. The whole of the respiratory surface, from the frontal sinuses to the bronchi, was excessively irritable, and in some parts inflamed; the eyes were blood-shot and suffused; the nose pain-

ful and tumid, and the nostrils inflamed and almost excoriated; his throat was dry and rough, and throughout there was a copious defluxion, with lachrymation and coryza. In addition to the local, the constitutional symptoms were severe. The pulse was quick, the skin hot, the tongue furred, the appetite bad, and the secretions from the liver and intestines scanty and unhealthy. The patient was restless at night, and had very little uninterrupted sleep. The continuance of these symptoms had very materially changed his appearance; he had become emaciated, pale, and haggard, and altogether was in a very pitiable condition.

Having learnt that he had consulted many persons, and taken various remedies without benefit, and having no particular treatment to suggest, I had intended leaving without prescribing; but it struck me, during my visit, that there was a close resemblance between the state of the respiratory mucous membrane in his case, and that of the skin in some forms of prurigo; and having often seen the beneficial effects of arsenic in the latter affection, I was led to think that it might be serviceable in the present case. Thus, in both there appeared to be a peculiar or specific irritation of their respective surfaces. Both appeared to depend primarily upon nervous rather than upon vascular disturbance, and each to consist essentially in an exaltation or perversion of nervous action,—the one of the organic, the other of the sensory nerves. Impressed with this view, I recommended a trial of this medicine. It was commenced on the 11th of July, in five-minim doses of Fowler's solution three times a day; and by the 16th nearly every vestige of the complaint had disappeared. The patient, however, was so sceptical in regard to medicine, that he was unwilling to believe that his improvement was attributable to it. He rather thought that the complaint had worn itself out, and this view was favoured by the lateness of the season: my own impression was otherwise; but I was willing to let the matter rest, to be decided by further investigation.

During that year, I saw no other cases of the disease; and it was not until the following summer that I was enabled to make any further observations in regard to it. I had then the opportunity of trying the medicine in several cases, and in all with encouraging success. A professional friend, whose experience and judgment are very great, has also given it, at my suggestion, with much benefit: and it has been given successfully by a practitioner of extensive practice in the country. These facts, so far, are favourable to its employment in these cases; and it is with the view of drawing attention to it, and of eliciting the results of more extended observation, that I am led to publish the present communication.

Of the precise pathological nature, or the proximate cause of hay fever, we are, as has been stated, altogether unacquainted; and we are therefore unable to deduce from a consideration of it any satisfactory method of treatment, and so far must be content to adopt either empirical measures, or such as analogy may suggest. I have remarked that the more obvious symptoms of the disease appear to depend upon, or to be connected with, a morbid irritability of the organic nerves of the respiratory mucous membrane; and that in this respect it presents some analogy to a kindred affection of the skin, characterised by extreme

irritability of the cutaneous nerves, and one at the same time in which arsenic is extremely efficacious. Upon this ground, I was more particularly first led to employ it; but there are other considerations which recommend it to our notice. In the first place, the *origin* of this complaint is very similar to some in which it has been given with much benefit, such as remittent and intermittent fever, neuralgic affections, and some forms of rheumatism, which, in common with hay-fever, are traceable to malaria, miasmata, or vegetable effluvia of various kinds; whilst in the more specific actions peculiar to these, and in the morbid condition of the nervous system which prevails, we see much that is analogous in all. But independently of these more specific diseases, we have many and undoubted proofs of the utility of arsenic, in correcting or controlling irregular nervous actions, and morbid conditions dependent upon them; and its remedial powers in chorea and epilepsy, in prurigo, lepra, psoriasis, and many other cutaneous diseases, may be cited in illustration. Within certain limits, most writers agree in considering it as a tonic; and as such, its action is especially marked upon the skin and the mucous membranes. An eminent practitioner remarked that, for strengthening and giving tone to the former, he knew of nothing equal to it; and in regard to the latter, it has evidently a specific action upon that of the whole respiratory tract. Hence its administration, when given too largely, or for too long a period, is occasionally followed by redness and irritation of the eyes and eye-lids, coryza, dryness of the throat, cough, and symptoms of pulmonary irritation; and, on the other hand, in moderate doses, it has been given beneficially in various irritable and morbid conditions of this membrane, such as is met with in asthma, hooping cough, catarrh, ophthalmia, etc.

Mr. Wm. Simmonds, of Manchester, gives the following report of its employment in hooping cough, in a letter to Dr. Duncan, published in the second volume of the *Annals of Medicine* for 1797, p. 393. "For upwards of three years, I have given arsenic in the hooping cough with the most salutary effect. In general, it has put a stop to the disease in about a fortnight; and it has never failed to moderate it in a few days. I have administered it in one unsuccessful case only, and even then it afforded considerable relief; and had I been called in earlier, or had I been permitted to pay the attention the case required, I am of opinion it would have succeeded in that also. I have used it in the form of the mineral solution of Dr. Fowler; and in the dose, and with the precautions recommended by him in his work on Intermittents, etc., children of a year old may take it with safety. Previous to, and during its use, bleeding, blisters, and emetics may be employed, according to the indications, particularly the latter. It should be continued until the disease is subdued; and then leaving it off for a week, it should then be had recourse to for a week, to prevent a return. Should exposure to cold occasion a relapse, it has hitherto put a stop to it, upon being taken for a few days."

In some forms of ordinary catarrh, I have myself given arsenic with the best results; but more especially in those cases in which the affection has been of a local character, and there has been an absence of inflammatory action, as well as of febrile disturbance. These circumstances forbid its employment; and it is because they so frequently occur in connexion with catarrhal complaints, that it is for the

most part inappropriate. Where, however, there is irritation of the mucous membrane rather than inflammation, as is especially the case in hay-fever, it may be employed with much advantage; as is shown in the following instances.

Case. Rebecca Lord, aged 45, applied at the Paddington Free Dispensary, October 8, 1850, suffering from catarrhal symptoms—sneezing, coryza, lachrymation, cough, and slight fever; tongue furred and unpleasant; bowels open. ℞ Liq. pot. arsenitis ʒj; vini ant. tart., vini ipecac., liq. potas. āā ʒiiss; aquæ distil. ad ʒxij. M. Fiat mistura cujus sumatur ʒj ter die. On the 11th, she was perfectly well; all the catarrhal symptoms had left her. She took eight doses of the mixture: but in twenty-four hours she was relieved of all uneasiness of the mucous membrane.

Case. Mary Ann West, aged 15, applied at the Paddington Free Dispensary, July 26th, 1850, suffering from catarrhal symptoms—coryza, lachrymation, defluxion, cough, sore throat, and slight febrile disturbance. ℞ Liq. pot. arsenitis ♏iiij; liq. potassæ ♏x; aquæ distil. ʒiss. M. Ft. haust. ter die sumendus. July 30. She was free from all catarrhal symptoms, and felt perfectly well.

Case. Margaret Liddon, aged 55, applied at the Paddington Free Dispensary, August 13, 1850, suffering from catarrhal symptoms, together with constrictive pain of the chest, dyspnœa, and cough. She had been troubled with these latter symptoms for some time; throat dry; tongue unpleasant and furred in the morning; bowels constipated; appetite bad. ℞ Liq. pot. arsenitis ♏xxv; liq. potassæ ʒj.; tincturæ hyoscy. ʒij; aquæ distil. ad ʒviij. M. Fiat mistura cujus sumatur pars sexta ter quotidie. Sumat pil. hydrarg. gr. v. August 23. She was entirely relieved of cough and all pulmonary irritation.

In catarrhal ophthalmia, and more especially in those forms which are of a passive, subacute, or chronic character, or where the irritability of the conjunctiva is excessive, arsenic has a very beneficial effect. I might subjoin cases in illustration of this fact, were it not well known to oculists, and referred to in systematic treatises on diseases of the eye.

Lastly, in intermittent headaches, brow ague, cephalalgia, and other affections in which the mucous membrane of the frontal sinuses appears to be the seat of pain, arsenic has proved efficacious. These facts are all of importance, in connexion with the subject of the present communication.

The cases of hay-fever in which I have seen it most serviceable have been of a catarrhal rather than of an asthmatic character; and I have given it, on an average, in doses of five minims of Fowler's solution three times a-day. Where, however, the attack has been slight, or the medicine has been given with the view of improving the tone of the mucous membrane rather than of correcting morbid action, three-minim doses, or even less, are preferable; whilst, on the other hand, if the irritation has been excessive or resists these, larger doses may be given, and their action modified or assisted in different cases by remedies of a kindred character.

Dr. Fowler, to whom we are indebted mainly for our knowledge of the efficacy of the medicine, was in the habit of prescribing it much more largely than is done at the present day. To adults, he gave his solution in doses averaging from ten to sixteen minims twice or thrice

a-day. He mentions that fifty minims were taken by mistake, within the space of nine hours, by a patient, without any very serious consequences ensuing; and that, in one case, twenty drops were taken three times a-day, with speedy and permanent advantage.

Dr. Brown (*Cyclopædia of Practical Medicine*, vol. ii, p. 228), who gave it in many hundreds of cases, states that he never saw any permanently ill effect arise from it. These facts are adduced, as showing the harmlessness of the medicine when properly given, and as meeting an objection which might otherwise be urged against its use.

Arsenic is best given, in this affection, in moderate doses, and I should propose smaller than those recommended by Dr. Fowler, whose experience led him to lay down the following rules for its administration: "Patients from two to four years," he says, "may take from two to four drops of the solution; from five to seven years, may take from five to seven drops; from eight to twelve years, may take from seven to ten drops; from thirteen to eighteen, may take from ten to twelve drops; and from eighteen and upwards, may take twelve drops as a dose." He advises that doses proportional to the age of the patient should be administered three times a-day for five days; then omitted for two or three days; and then repeated for three days, to prevent a relapse. These doses are mentioned with especial reference to the cure of intermittent fevers. They are much too large for the cases under consideration; for which, from one to five minims of the mineral solution may be considered as an average dose, and beyond this it will seldom be necessary to carry it, while positive harm may result. Seeing, indeed, that the state of the mucous membrane is one of morbid susceptibility to impressions, and that the medicine has a specific action upon it, it is important to keep within due limits and so avoid any severe or unfavourable reaction.

When the medicine alone fails to do good, its use may be alternated with quinine, or the two medicines may be given concurrently. Dr. Fowler found this practice successful, in the treatment of intermittent fevers, when either bark or arsenic, singly administered, failed to remove the disease. He observes: "if the solution and Peruvian bark have been given separately, and have failed, it will sometimes be advisable to try the joint power of the medicines at the same time, but in doses rather smaller than usual. In these cases, the solution should be given at stated hours three times a-day, and the Peruvian bark may either be given combined with it, at the same periods or between the fits, in as frequent doses as the stomach can bear." Another useful addition to arsenic, when the irritation of the mucous membrane is severe, or the stomach is unpleasantly affected by it, is opium, in small doses: indeed, its general employment in conjunction with arsenic has been recommended by many practitioners, as being calculated to render its action not only more certain, but less disagreeable to the stomach; and in cases like the present, where the irritability of the part more immediately affected is excessive, its use is otherwise appropriate. It is best given in small doses, not exceeding two or three minims of the tincture or of Battley's solution; and should it derange the stomach, or interfere with the secretory functions of the liver or other organs, some other sedative may be substituted. I have seen very favourable effects from the Indian hemp in cases of morbid irrita-

bility of the nervous system, and these would lead me to recommend a trial of it in the present disease. The most efficacious preparation is the ætherial tincture.

Lastly, when the irritation is most marked in the pulmonary portion of the mucous membrane, and the symptoms are of an asthmatic rather than catarrhal character, ipecacuanha, antimony, squills, or some other expectorant, may be given concurrently with it, if circumstances indicate the employment of such remedies.

But in addition to the more specific treatment of the disease, much may be done in the way of prevention, by invigorating the nervous system, and improving the tone of the respiratory mucous membrane; and measures that fulfil these objects should be perseveringly employed by persons who are subject to these attacks. In particular, the daily use of the shower bath, the application of cold locally to the chest, neck, and shoulders, and the use of cold collyria and gargles, may accomplish much good. The diet and regimen also should be subservient to these ends; and, if there exist an undue irritability of the nervous system, depending on a defective condition of the blood, steel in some appropriate form should be also given.

I would further observe, that when the disease is fully developed, and the irritability of the mucous membrane is very great and distressing to the patient, it may be very much mitigated by the occasional application of the vapour of warm water. By holding the face over a large basin of boiling water, and retaining the steam by means of flannel thrown over the head and shoulders, it is readily and directly brought in contact with the whole respiratory branch, and affords very striking relief to the irritation which exists. Of medicated vapours I have no experience; nor have I seen any benefit derived from the topical application of lotions of the nitrate of silver, etc. Indeed, seeing that the disease is seated rather in the nervous system than the mucous membrane, I should anticipate less benefit generally from local than from constitutional treatment.

These, then, are the principal points to which I would direct attention, in the treatment of hay-fever:—1. to preventive measures, comprehending, more particularly, tonic treatment in every available form, both local and constitutional; 2. to specific treatment, comprising more especially the administration of arsenic, and modified or assisted in the manner proposed, according to the requirements of individual cases; 3. and lastly, to soothing or palliative treatment, which is not inconsistent with the former, but may be advantageously combined with it.

In adverting to these points, and indeed, in treating the subject generally, I have endeavoured to confine myself as much as possible to such deductions as observation and careful reflection would warrant; but the subject is one so imperfectly understood, that I have engaged in it with some hesitation, and rather with the view of offering suggestions than of announcing positive conclusions.

Chester Place, Hyde Park Gardens, June 1851.

BIBLIOGRAPHICAL RECORD.

A Practical Treatise on Diseases of the Urinary and Generative Organs in Both Sexes. By W. Acton, late Surgeon to the Islington Dispensary, and formerly Externe at the Female Venereal Hospital, Paris. Second Edition. pp. 693. London: 1851.

Mr. Acton's well-known book has been so modified and enlarged, as to be virtually a new work; and as such we shall review it. It is divided into two parts; in the first, *Non-specific* diseases following sexual intercourse are treated of; and the second is occupied by *Syphilis*.

In an introductory chapter, Mr. Acton discourses of the origin of syphilis, (which he leaves precisely where he found it—in perfect obscurity); of the frequency of venereal diseases, (which is very great, more so than many imagine, nearly one in five being the subject of them in the army, one in seven in the navy at home, and one in three in the merchant service); and of the necessity of public measures in reference to the sanitary condition of prostitutes. We agree with much that he states, and are quite at one with him as to the worse than folly of refusing admission into our large hospitals to syphilitic patients; but we greatly doubt the possibility of effective legislative interference, and confess to share in the general repugnance which is felt in this country to the adoption of any system of registration, like that which obtains in Paris. That it does not check the prevalence of venereal disease in that metropolis, the source of much of our author's experience abundantly testifies; and that it has, at least, the *appearance* of legalising vice, is also evident. We think, also, that Mr. Acton's sketch of the "harlot's progress" is painted in far too favourable colours; and till we receive better evidence than that adduced, we shall hesitate to believe that well-doing mechanics, clerks, and petty tradesmen, seek their wives among discarded mistresses and the haunters of brothels. Mr. Acton must forgive us for withholding our assent from such a statement; and of expressing our belief that it is a mere fancy or gratuitous assertion of his own.

Blennorhagia is the term which our author applies to those discharges from the genito-urinary apparatus and from the conjunctiva which result from venereal disease. He limits the term *gonorrhœa* to those cases in which the discharge proceeds from the male urethra, employing it then only in deference to long-established use. The microscopic character of this discharge has been investigated by Dr. J. W. Griffiths. "'The secretion of the mucous membrane affected with gonorrhœa consists of muco-pus, but it varies somewhat in character according to the period of duration of the morbid action. In the very earliest stage, it consists of a simple white watery mucous fluid, but in a very short time it becomes yellow,[1] and this condition, in an unchecked gonorrhœa, lasts for some time; ultimately it loses some of the yellow tint, becoming more watery, and remains as gleet. During the very earliest period it consists of simple mucus, and under the microscope exhibits epithelial scales and their débris. During the second stage, it also contains these substances, but, in addition, albumen in solution, which is coagulable by heat, the precipitate not being dissolved by acetic acid; and the microscope detects very numerous pus-corpuscles, upon the presence of which the yellow colour is dependent, together with epithelial scales. In the latter and chronic stages, the number of pus-corpuscles is proportionably dimin-

[1] "In some cases the discharge is milky white, or nearly so, in the two first stages. In these, the corpuscles are of that kind which has been denominated *mucous*, exhibiting the molecular motion, etc."

ished, that of the epithelial scales increased, and the albuminous impregnation is diminished, or disappears.

"'The urine (excluding the gonorrhœal deposit) in gonorrhœa does not differ essentially from its normal state; it is, however, usually of lower specific gravity, and very commonly contains small crystals of oxalate of lime. The pus-corpuscles increase the density of the deposit, which subsides by repose, so that the latter appears to the eye to contain a more copious and denser deposit than in health. The pus-corpuscles are also somewhat different in appearance from those of normal pus, being rather larger, less granular, more transparent, and less rapidly acted upon by acetic acid; in some the molecular motion is seen, in others not; the former properties depend upon the imbibition of the urine, the latter upon their being surrounded by the mucus, which defends them for a time from the action of the acid. They ultimately yield the same nuclei as normal pus. The urine in gonorrhœa also contains slightly more pavement epithelium from the bladder than the natural fluid; but I have not been able to detect the cylinder epithelium from the urethra to any amount. However, the presence of the pus-corpuscles, without excess of the vesical or renal epithelium, might guide in the diagnosis of the source of the pus.'" (pp. 26-7.)

BLENNORRHAGIA IN THE MALE.

Balanitis, or Gonorrhœa Preputialis. This consists in inflammation and patching excoriation of the glans penis and lining of the prepuce, accompanied by a muco-purulent discharge. The predisposing cause of this complaint is the existence of the prepuce; it does not occur in the circumcised. The exciting cause can be usually traced to the application of some irritating secretion, such as menstrual fluid, blennorrhagic matter, etc. It may arise from inattention to cleanliness. It is also met with in persons who have had abscesses close to the frænum, which have left little fistulæ through which the urine exudes. The only way to cure it in them is to heal the fistulæ. Balanitis may be complicated by abscesses which point at the upper part of the penis. The prepuce may also become gangrenous. Chancre is a very frequent complication, and eczema, particularly in old subjects. Simple balanitis never gives rise to secondary symptoms, as has been shown by M. Ricord's experiments by inoculation.

The treatment of the uncomplicated disease is very simple: it consists in washing the parts, carefully drying them, and by means of dry lint, accurately placed between the glans and prepuce, separating the two surfaces. If a slight inflammatory condition of the parts exist, it will be well to pass a stick of caustic over them, simply to whiten the surface, which should be previously dried by lint. The affected parts should be washed twice daily with a lotion of zinc and tannin, one grain of each to the ounce, then dried, and lint applied as before. When phimosis exists, lint wrapped round a probe should be carefully introduced between the glans and the prepuce, to wipe away all secretion; the prepuce then being gently drawn forwards, a solid stick of nitrate of silver may be introduced and brushed quickly over the surface, warm water being afterwards injected; or a strong solution may be injected, instead of using the solid caustic. If the phimosis be irremediable, the operation of circumcision must be performed. The following is Mr. Acton's method. "Without employing any traction, I trace in ink a line on the prepuce, which follows the circumference of the base of the glans, and is a little in front of it. This being done, the prepuce should be drawn forward and fixed between the blades of a pair of dressing forceps placed in front of the glans, and behind the line of ink traced on the prepuce; let the forceps be then held in this position by an assistant. Let that portion of the prepuce which is in front of the forceps be now drawn forwards by the left hand of the surgeon, while, at the same time, he with the right divides it in the oblique direction of the forceps, which thus protects the glans. In this operation the skin alone is removed, the mucous membrane is not drawn

forward with the skin, and remains intact; if we do not wish to see the phimosis recur, this portion of mucous membrane must be removed. To effect this, I employ a pair of scissors, slitting up the thin layer of mucous tissue as far as the base of the glans; the two portions should then be successively held apart by a pair of forceps, and removed by dividing them at the base of the glans, as far as the frænum, which is divided the last. I generally employ torsion of the arteries in these cases, to check the bleeding; lint dipped in cold water is then applied, and it may be advisable to administer an enema containing opium in the evening, or to prescribe camphor pills to prevent erections. A perfect cure takes place about the twentieth day, and the result is very satisfactory; there is no deformity, nor have we to dread a consecutive paraphimosis." (pp. 76-7.)

Gonorrhœa, or Urethral Blennorrhagia. We need not occupy either time or space by any notice of the progress or complications of this form of disease; our attention will be directed to the treatment, and here we shall quote our author's words.

"When a patient applies to me in the early stages of gonorrhœa, before scalding in making water has come on, or when the acute symptoms have passed, I at once employ a strong solution of nitrate of silver; but, as this efficient mode of treatment may become a very dangerous agent, I always inject the solution myself. The manner in which I proceed is as follows:—Having a solution of the crystallized nitrate of silver at hand, in the proportion of ten grains to the ounce, I desire my patient to make water; and, placing him in an erect position against the wall, I inject a glass syringe full (about two drachms) of the solution into the urethra, and by pressure retain the fluid in contact with the mucous membrane a few seconds. It is as well, in doing this, to suddenly distract the patient's attention by some remark, otherwise the passage of the fluid along the whole length of the canal may be impeded by spasm or contraction of the organ. I then desire the patient to sit down for ten minutes or a quarter of an hour in an arm-chair, and to withstand the desire of making water, which, for the first few minutes, sometimes is very violent.

"The effect of the injection on different individuals is very striking. Some scarcely feel any pain; others suffer for a few moments most acutely; but usually the agony goes off in three or four minutes, and is replaced by mere temporary soreness, so that the patient is able to walk about. I, however, generally recommend him to lie down on the sofa for an hour or so, and keep quiet.

"The quantity of discharge, like the amount of pain, differs greatly in different individuals. Sometimes no further *discharge at all* is seen, and the patient gets perfectly well. More commonly the injection is immediately followed by a large quantity of serous or shreddy exudation, which soaks through the lint. This exudation is followed by a stringy yellow discharge. In a few hours, this gradually becomes again serous, until it completely ceases, and redness of the meatus alone remains, which disappears in a few days.

"Of course, considerable pain would be felt did the patient make water immediately after the injection; but as the bladder has been previously emptied, micturition is not required, and the patient has only to combat for the first few minutes the desire to attempt it, and many hours will elapse before urine will be required to be passed, and by that time the effects of other treatment have been brought to bear, so that scalding is seldom, or never complained of by the patient.

"I have now no fear of leaving my patient, having applied a suspensory bandage, or what answers equally well, a handkerchief passed round the loins, and another tied in front and behind to support the testes, with strict injunctions to abstain from any kind of fluid whatever, so that the urethra should enjoy a few hours repose. On the next morning the discharge has either alto-

gether ceased, or a drop only is to be seen, and in the course of the day a mere weeping from the urethra occurs. The patient may now take fluids in moderation, consisting either of tea or soda-water; but coffee should be strictly prohibited, as well as wine, beer, and spirits. In some cases, towards the afternoon, the discharge returns again. If this becomes green or yellowish, I have no scruple in repeating the injection, with similar precautions; but I seldom have recourse to a third, and my patient is quit of a troublesome complaint in a very few days.

"The effect of nitrate of silver in a strong solution is very surprising, as may be judged of from the previous description. It appears to possess a specific action in changing the vitality of the mucous membrane, substituting for the original inflammation a new one, whose principal characteristic is its short duration: it destroys, likewise, the morbid element.

"Out of the large number of cases that have been treated on this plan, I have never yet seen any ill consequence arise, not even hæmorrhage or retention of urine. I may mention, however, that I have never employed the treatment except in private practice, where I have had the assurance that my patient would implicitly follow my directions. I should not recommend the treatment among out-patients at public institutions, nor, in fact, have I any expectation that any abortive plan will generally succeed with them, but, on the contrary, be attended with such consequences as would soon prevent a surgeon from employing the treatment in private.

"I must, however, confess, that this treatment has not, in my hands, been successful in the treatment of the first attack of clap in young men. In private practice, a consulting surgeon does not attend, generally speaking, very young men with their first attack. Shyness, or not knowing where to apply for advice, perhaps, is the cause; but of the fact there can be no doubt, that I am comparatively rarely consulted for first attacks. When consulted, the complaint has perhaps commenced several days, and the treatment is therefore no longer efficacious. From these circumstances, I am perhaps hazarding a wrong opinion; but, speaking from my personal experience, I would not advise caustic injections to be applied in cases of first attacks. No dangerous symptoms arise with common care; but I have not met with those certain results which have attended my treatment in persons previously affected." (pp. 88-91.)

But with these means Mr. Acton combines the use of copaiba, or cubebs, or both.

In Mr. Acton's experience, as we have seen, this plan has been eminently successful and safe; but that it is not always either the one or the other, is evident from a lecture of M. Ricord's which is quoted, and in which we find a formidable list of evils which may arise during its progress.

When the inflammatory stage has set in before the patient is seen, or when the abortive treatment has been tried and failed, the author adopts the ordinary antiphlogistic treatment, until the acute symptoms have subsided, and then has recourse to specifics and astringent injections. In reference to the last means, we would strongly recommend Mr. Acton's remarks to the notice of our readers, because we feel assured that one great cause of the failure of injections, is the very inefficient way in which they are usually employed.

Chronic Gonorrhœa, or Gleet. The chief point of interest in this section, is the view put forth by the author, that the cause of gleet is the existence of a granular condition of the mucous membrane of the urethra, analogous to that which the speculum reveals in the vagina, in cases of old standing discharges. In the treatment, he examines the passage by a wax bougie, No. 6 or 8. If an irritable unequal surface be detected, he uses the strong caustic injection, and gives copaiba or cubebs; following up by injections of zinc and tannic acid. If incipient stricture is detected, the nitrate of silver is not advisable; but bougies should be passed every other day, astringent injections being used in the intervals.

We pass by the three next sections, which include Stricture, Extravasation of Urine, and Fistula, because, though well worthy of perusal, they present nothing remarkably new to our notice. We may merely mention that Mr. Acton has a somewhat more favourable opinion of cauterisation, in the treatment of impermeable stricture, than we have been led to entertain; and that he has successfully treated the small fistulæ which often form just below the glans penis, by placing the smallest possible quantity of Vienna paste in the external opening. A little slough forms, blocking up the fistula, and cicatrisation follows in a few days; or it may be necessary to re-apply the caustic, on each occasion employing less and less of it.

Affections of the Prostate Gland. The following is M. Ricord's description of acute inflammation of that organ and the vesiculæ seminales:—

"This is a rare complication, depending either on too great intensity of the inflammatory symptoms, or on faults committed during the time the patient is under treatment. When the prostate is affected, all the symptoms become aggravated. There is augmentation of the perinæal pain, throbbing, difficult and painful micturition, or retention of urine, a tendency to constipation, with pain on going to stool, particularly when fæculent matter passes. When the patients attempt to sit down, if they cross their legs, the pain becomes intense, constituting symptoms of inflammation of the prostate. It has been said that a deep indentation on the upper part of the fæcal mass (which it has been asserted is caused by the impression of the enlarged prostate in the rectum), is one of the symptoms of the disease; this mark, however, would be impressed on the semi-solid motion, at the time that it passes the prostate, and those who advance this symptom seem to forget that the fæcal mass has subsequently to pass the anus, a portion of the rectum much smaller than that opposite the prostate, consequently any impression made by the prostate must be effaced. Examination with the finger introduced into the rectum is of great service in the diagnosis; it may determine the degree of swelling of the organ, and whether fluctuation exists, should either be suspected. When one of its lobes, or a part only of one of its lobes, participates in the inflammation, the enlargement will be irregular; sometimes the inflammation only passes along the prostate to attack the vesiculæ seminales; in these cases the enlargement is further separated from the median line, the generative functions take on increased activity, and the patients complain of very painful nocturnal emissions. It is important to be acquainted with these distinctions; for, when inflamed, the vesiculæ seminales present a feeling of distension, which might easily be mistaken for fluctuation. The surgeon can easily conceive the danger that would result, should an incision be made into these organs. The inflammation of the prostate and vesiculæ is followed by very severe local symptoms, but is not always attended with general reaction; sometimes vomiting, constipation, a tympanitic state, together with nervous symptoms, may arise, accompanied with fever. In some instances, I have seen the inflammation extend to the subperitonæal cellular tissue, and attack the peritoneum itself. Abscess in the prostate may open into the rectum, the pus generally escaping with the motion. In the majority of cases, the pus points in the direction of the urethra or bladder, in front or behind the neck of that organ. If into the bladder, pus can only be detected when the patients make water. If, on the contrary, the abscess empties itself into the urethra, the discharge takes place suddenly, at the moment the spontaneous bursting into the canal occurs, and at intervals between the times at which the patients pass their urine. Both these modes of opening of prostatic abscesses may be attended with urinary fistulæ; but should the abscess empty itself into the rectum, a fistulous opening is not to be dreaded. We shall see, in speaking of treatment, that it is best to give issue to the matter as soon after its formation as possible." [*Gazette des Hôpitaux*, 1847, p. 512.]

The diagnosis between this form of disease and inflammation of the neck

of the bladder, is assisted by remembrance of the fact, that the pain in the perinæum is increased on making water, lasting some minutes after the urine has passed ; but the calls to relieve the bladder are not frequent. In inflammation of the neck of the bladder, on the contrary, there is constant desire to micturate, small quantities only passing at a time, but with great relief to the patient.

In this treatment, leeches in large numbers should be applied to the perinæum, or cupping-glasses, warm baths and opiate enemata, with gentle purgatives. But if by these means, the patient is not so far relieved, as to be able to pass his urine freely, Mr. Acton advises immediate recourse to catheterism ; and for this purpose he prefers a silver catheter, having failed in the introduction of elastic instruments, from which the stilet has been withdrawn, according to Sir B. Brodie's plan.

Chronic inflammation and enlargement of the prostate are familiar to all, and need not delay us.

Epididymitis. This is a not uncommon complication of gonorrhœa. The pain commences in the perineum, extends along the course of the cord, and becomes fixed in the back of the scrotum. The discharge somewhat diminishes ; but beyond swelling confined to the epididymis, there are no marked local appearances ; and, by proper treatment and rest, the patient will rapidly recover. If, however, the patient neglects himself and takes exercise, " the consequences soon become apparent ; the swelling in the scrotum increases, great pain is experienced on making the slightest movement, and the patient supports the testicles with his hand, so great is his fear of motion, which aggravates the pain in the course of the cord. At this stage, he is often awoke by great augmentation of pain from nocturnal emissions, and he is surprised at seeing his linen stained with semen mixed with blood. There is, however, occasionally some alleviation of the suffering after an emission.

" M. Ricord states that he has seen pus intimately mixed with the seminal fluid. I have witnessed considerable augmentation of suffering to the dull aching pain in the perinæum when the patient goes to stool. A careful examination of the scrotum at this stage of the affection will show that there is not only redness of the skin, with great augmentation of heat, but that effusion has taken place into the tunica vaginalis. If the surgeon, with the left hand, embrace firmly the affected half of the scrotum, so as to render tense the testicle covered by its envelopes, and with the fore-finger of the right hand gently but suddenly press on the centre, a distinct feeling of fluid will be experienced, and the elastic body of the testicle will be felt below it. Should a lancet be thrust into the point where fluctuation exists, a clear or slightly turbid serum, varying in quantity, will often escape, and the size of the tumour will sensibly diminish. When the fluid thus contained in the tunica vaginalis has escaped, the greater portion of the remaining swelling is found to depend on the epididymis, which is hard and painful, and can be felt distinct from the testicle ; this appears to constitute the disease, at least in the majority of the cases. Effusion may not be confined to the tunica vaginalis ; we often see the subcutaneous cellular tissue infiltrated with serum, and become œdematous or phlegmonous : inflammation may result, and distinct abscesses form. However, when intense suffering has preceded, shooting upward to the loins, when much fever is present, accompanied with hiccup, a tendency to syncope, nausea, vomiting, together with excessive sensibility of the apex of the swelling, we may affirm that the testis itself is the principal seat of the affection ; and if the fluid in the tunica vaginalis has been allowed to escape, the testicle may be found hard, having lost its proper elastic feel, and seems to form a nodulated body which we are unable to distinguish from the epididymis."

The predisposing causes of the disease are fatigue, violent exercise, repeated sexual intercourse, and any circumstance producing excitement of

the organs. Mr. Acton relates a striking case, illustrative of the influence of excited passions (p. 197). Injections he does not believe ever produce it, unless they be used injudiciously. The *direct* cause is inflammation of the urethra ; and it is a significant fact, very suggestive of reasons for speedy cure of the original affection, that epididymitis rarely comes on during the first week, when the gonorrhœal inflammation is most acute. From some statistical tables drawn up by Mr. Gaussaile, it appears that the first week presented 3 cases, the second 4, the third 5, the fourth 16, the fifth and sixth 39, two months 2, and three months 1.

Terminations. The organ may recover itself completely. There may be hydrocele, or rarely effusion of pus or coagulable lymph. Abscess of the scrotum may occur, or it may become chronically thickened. The testicle may become hard and irregular, and suppuration occur ; when the slough separates, the seminiferous vessels become unravelled, and appear as so many shreds at the opening, and not unfrequently a fungous growth sprouts out.

The *Treatment* at first must be strictly antiphlogistic, and absolute rest be enjoined. If these means fail, M. Ricord recommends a somewhat bold practice :

"In some instances, if in spite of our treatment the disease increases, we should treat it still more actively ; if the symptoms become again aggravated, and suppuration occurs, free incisions should be at once made. One of my colleagues, M. Vidal, has very properly recommended that the old plan of Jean Louis Petit should be put in force. This consists in dividing the tunica albuginea, so as to overcome the state of strangulation produced by the inflamed seminal tubes. If orchitis exists, this division of the tunica albuginea is an excellent plan, although the operation might alarm many surgeons : still it is a very simple affair, and puncture of the tunic often takes place in tapping hydroceles, without any ill consequences. We can readily imagine that the division, even in cases of a sound testis, where there is only epididymitis, may do much good ; for a swollen epididymis may occasion strangulation of the testicle. The division should be made with a lancet, and extend one or two centimètres in length. Much alarm has been created relative to hernia and protrusion of the tubuli seminiferi, but experience does not bear out such a supposition." Mr. Acton also recommends strapping with mercurial, belladonna, and ammoniacum plaister, in cases of irritable testis.

Acute and Chronic Inflammation of the Bladder. Mr. Acton's descriptions and opinions precisely coincide with, indeed are largely taken from, those of the most established writers, and therefore we need not particularise them.

In obstinate cases of chronic cystitis, he, however, adopts a method of cure which is certainly not common. "Provided these means fail, and unfortunately failures are not uncommon, we must have recourse to the following plan of injecting the bladder with nitrate of silver. To effect this, I pass a gum elastic catheter into the bladder, and draw off the urine, and then, with a glass syringe, which fits accurately to the instrument, I inject the whole of the following solution into viscus : ℞ Argent. nitrat. ʒij ; aque destill. ʒiv ; M. ft. inject. The immediate consequences are, increased pain, which for the moment is very severe, the urine that is first passed is bloody, and some tenesmus is experienced. In a short time, however, these symptoms abate on the patient keeping his bed, and paying great attention to his diet ; at first no liquids should be taken, nor for the first few hours preceding the operation ; subsequently the usual quantity of tea or barley-water may be indulged in, and the various balsams, particularly turpentine or spruce, should be prescribed. In a very few days the urine will contain less of this ropy mucus, and ultimately none will be noticed ; in other cases, the injection may again be resorted to at the end of four or five days, and repeated until a complete cure is effected. We rarely or ever observe any of the ill consequences which probably might be expected to arise when injections are thrown into this important organ."

In the two next sections, we are presented with a full and very sensible discussion of those quack-patronized subjects, *Spermatorrhœa* and *Impotence*. We entirely commend the spirit in which they are written; and rejoice to find that Mr. Acton is not among the number of those who see the evidences of seminal weakness in every cachectic, low-spirited man who consults them. In the treatment of severe cases of spermatorrhœa, he has found injections of nitrate of silver more successful than the solid caustic, applied after the method advised by Lallemand.

BLENNORRHAGIA IN THE FEMALE.

Blennorrhagia of the Vulva closely resembles balanitis in the male, is produced frequently by the same causes, and cured by the same treatment. "It may affect the epithelium of the mucous membrane only, or, gaining the deeper parts, may occupy the glands or follicles, or even the vulvar glands, which we have compared to Cowper's glands, and which, according to M. Moulinier, ought to be regarded as the organs secreting the venereal virus. In the first stage, before the eye can detect any local change, the patient complains of an unusual sensation in the genital organs, and sexual intercourse is desired; there is itching, redness, heat, and swelling. The secretion now becomes greater; at first it is but the augmented flow of the normal moisture, but soon it becomes irritating, and adds to the inflammatory state. The discharge, however, soon takes on a muco-purulent character, and this is more apparent in proportion as the follicles become the seat of the disease. If the inflammation gains the deeper portions, considerable swelling occurs, which may assume an œdematous character, or become phlegmonous; when the nymphæ, naturally large, become inflamed, their size may increase to such an extent, that they may be protruded beyond the larger labia, and constriction of them take place, resembling what happens in paraphimosis. Not unfrequently, abscess follows these œdematous swellings. In stout women, the complaint may extend laterally to the groins, producing a most offensive discharge, attended with an eczematous state of the skin. The inflammation may likewise gain the apertures of the vulvar glands, which M. Huguier has so well described, and may reach the parenchymatous structure of these glands; and they may be felt through the thickness of the labia, as little abscesses, or they may gradually disappear, or may form cysts, which are not unfrequently found in this situation.

"A very frequent symptom of vulvitis is the exaggerated sensibility of the vulva, which is principally confined to young women. In long-standing cases of vulvitis, the passage may become narrowed so much as to produce a sort of stricture of the entire canal. This blennorrhagic affection of the vulva produces great sexual desire, attended with secretions and lascivious dreams, which, if occurring frequently, appear to weaken the patient considerably.

"*Treatment.* Among prophylactic means, cleanliness stands first. Vulvitis, like balanitis in the male, may come on in consequence of inattention to washing the parts. In the commencement a soothing plan should be employed, and separation of the surfaces attempted, followed by the use of lotions of nitrate of silver, in the proportion of ʒj to ʒij of distilled water, with the addition of warm baths. Under these means a rapid cure results. If the inflammation has gained the deeper structures, the soothing plan is the best, or leeches may be applied to the groins; nitrate of silver lotions may be employed; if a phlegmonous condition of parts occurs, it may be better to rely only on depletion. The moment an abscess is formed, it should be opened; for pus has a great tendency to burrow in the loose cellular tissue, and make its way to the rectum, perinæum, or vulva, and recto-vulvar fistula may result. If the abscess is seated in the vulvar gland, it should be opened early. There is only one circumstance which should cause us to pause; namely, when inflammation occurs around an already formed cyst.

It would be out of place to give a detailed description of recto-vulvar fistulæ; but I may mention that great good will result from compression in the course of the fistula, together with injections of strong solution of nitrate of silver, or cauterising the surface with the solid caustic. This cauterisation should be rapidly executed, if you wish the parts not to retract; sometimes scarification of the edges will do good.

"As a consequence of chronic vulvitis, partial morbid secretion may be observed in the folds of the passage, particularly between the nymphæ and carunculæ. These secretions, which only become apparent when the surfaces are pressed, are very difficult to be got rid of by means of astringent injections or even caustic. They arise from the follicles which are hypertrophied, and being seated at a great depth, can only be reached by a narrow neck. To destroy these diseased parts, a narrow bistoury should be passed into the canals leading to them; a free opening having been made, the surfaces should be freely cauterised, or filled with lint." [*Gazette des Hôpitaux*, 1848, p. 212.]

Blennorrhagia of the Urethra. This is much rarer than the other forms, and is almost always a consequence of sexual intercourse, whereas the other may arise spontaneously. The symptoms resemble those observed in the male, but are usually less severe. The abortive treatment may be successfully tried, the solid nitrate of silver being used, if the case be seen early enough. In the acute stage, antiphlogistic and demulcents are indicated, and subsequently copaiba and cubebs.

Blennorrhagia of the Vagina. Mr. Acton here quotes largely from a paper by M. Boys de Loury, surgeon to the Hospital in Paris, where the registered prostitutes are treated. He finds it to exist most frequently among young girls from fourteen to twenty years of age. The symptoms are itching and heat of the parts, and afterwards pain. On examining the interior of the vagina, we first remark pus lying between the folds, so that the canal presents two colours very distinctly, the furrows being of a yellow or greenish puriform shade, the rugæ of a vivid red. If the pus be removed, the membrane underneath is found of a still brighter red. Sometimes erosions are seen on the surface, in the form of red lenticular spots. In some cases, the disease occupies the entire vagina; in other instances, the two inferior thirds, or even the upper half. In this latter case the os participates in the condition of the vagina, and assumes a brownish red colour, attended with augmented sensibility. A very obstinate form, which may be denominated *papular vaginitis*, is sometimes met with in women in advanced stages of pregnancy.

Vaginitis has by no means always a venereal origin. It is far from uncommon in unhealthy, scrofulous, ill-fed children: and Dr. Cormack and Dr. Barnes have recently described a form of it, which occurs in scarlatina. [London Journal of Medicine for 1850, pp. 869-72.]

Vaginitis is sometimes complicated with urethritis, and with inflammation of the entire pudendum. Abscesses also may form in the labia,—in some cases resulting in phagedæna. The os uteri may also become affected, and even ulcerated. According to M. Boys de Loury's statistics, the average duration of vaginitis, in the acute stage, is thirty-three days; when complicated with urethritis, ulcerations, chancres, etc., it varies from six weeks to two months. Chronic vaginitis lasts from thirty to forty days.

In the acute stage, tepid baths and injections, leeches to the groins, and aperients, should be employed. In the chronic stage, astringent injections, and nitrate of silver are to be used. Mr. Acton applies the latter in the solid form, by means of the speculum. We have seen much good result from a strong solution applied by means of a sponge.

4. Blennorrhagia of the Uterus. This section is scarcely as full and precise as might have been expected. Mr. Acton recognises the frequent existence of non-specific ulceration of the cervix uteri, as, we believe, every man must do, who will take the pains to look for himself, and not suffer his

eyes to be blinded by prejudice. According to his experience, true chancres are exceedingly rare in this situation. But it must not be forgotten, that a woman suffering under discharge from an ulcerated os or cervix uteri, may communicate blennorrhagia to her husband, especially if, from any circumstances, the discharge be rendered of a more puriform character than ordinary.

Blennorrhagia of the Ovary. Mr. Acton believes that, as, in the male, epididymitis frequently results from gonorrhœa, so the female who is affected with blennorrhagia, may have ovaritis. He is inclined to think that the disease recently described by Dr. Hassing, of Copenhagen, as the colic of prostitutes, was of this nature. The same opinion was previously expressed by Dr. Tyler Smith. [London Journal of Medicine for 1850, pp. 756, and 922.]

BLENNORRHAGIA COMMON TO BOTH SEXES.

Blennorrhagic Ophthalmia. Of this very serious disease, Mr. Acton admits two varieties,—one arising from absolute contact of gonorrhœal matter with the eye ; the other, of a rheumatic, or catarrhal nature. We must refer our readers to the work for what is said upon both these forms.

Gonorrhœal Rheumatism. Our author fully bears out the general opinion of the extreme intractability of this affection. In many cases, he believes a residence in a warm climate to be the only cure. Several of his patients made full trial of the water system, but without deriving any benefit from it.

Blennorrhagia of the Anus. This is a very rare affection. Mr. Acton has only seen it in cases where unnatural crimes had been committed. Local treatment by nitrate of silver, is the proper method of cure.

NON-SPECIFIC AFFECTIONS FOLLOWING SEXUAL INTERCOURSE.

Warts, vegetations, herpes preputialis, eczema, and excoriations are treated of. We extract Mr. Paget's description of the microscopic character of warts : "The warts examined were specimens of ordinary appearance from the glans penis and the lining of the prepuce. They were narrow-stemmed, and on their broad and flat expanded parts bore a crowd of small and often flattened conical processes. In all cases they were of recent growth, and appeared very vascular. They consisted of two principal substances, namely, an outer epithelial covering, and an inner vascular tissue, like certain forms of rudimental cellular tissue. The epithelial covering was composed of numerous layers of tessellated, scale-like cells, resembling, both in structure and arrangement, the epithelial cells covering the glans and inner surface of the prepuce. The epithelium thus extended over the whole wart formed fully half its substance. The vascular substance of the warts was continuous with that of the thin dermal tissue of the glans or prepuce, and was connected with the subjacent looser cellular tissue. It consisted of a pale and obscurely filamentous blastema, in which were imbedded very numerous bodies, like nuclei, oval, shining, dark edged, well defined, made more distinct by acetic acid, and having no nucleoli. It had all the characters of such nucleated blastema as is found in the rudimental state of many normal examples of fibro-cellular tissue."

In the treatment, Mr. Acton makes no mention of strong acetic acid, which we have found very useful. He recommends powder of oxide of zinc in simple cases ; and in more obstinate forms, a powder composed of equal parts of ærugo and pulvis sabinæ.

The section on *eczema* is worthy of attention ; for this complaint is often mistaken for syphilis.

In our next number we propose to consider the Second Part of Mr. Acton's volume, which is devoted to Syphilis.

(To be continued.)

THE TEETH AND THEIR PRESERVATION, IN INFANCY AND MANHOOD, TO OLD AGE. By ALFRED CANTON, M.R.C.S.L. pp. 297. London: 1851.

This small volume will repay perusal: it is written by an author evidently as fully acquainted with the scientific as with the practical department of his profession. Not the least useful part is the appendix of prescriptions, which makes the reader independent of the trash so often vended as "dentifrices"; compounds which, in eight cases out of ten, are as valueless as they are dear. The absence of an index, or table of contents, is a fault which ought to be rectified, if a second edition be called for; which, from the character of the book, may be anticipated.

OUTLINES OF PHYSIOLOGY, ANATOMY, AND SURGERY. By WILLIAM WILKINSON, Surgeon, Private Lecturer on Medicine. 12mo. pp. 412. Edinburgh: 1851.

MR. WILKINSON has here condensed within very narrow limits a great amount of correct information, and has also clothed it in very simple language. To the embryo student at the threshold of his career, works of this kind are decidedly useful as pioneers,—as preparers of the mind for the perusal of more serious and more ample treatises; but so meagre a book of outlines can be of no value to the properly educated practitioner. *Mary's Grammar* is a capital book for the nursery; but when English grammar has to be learnt in good earnest, the child's decoy must be thrown aside for Murray or Latham. In the same way, the youth who has fairly entered upon his career of medical study ought to be above caring for Mr. Wilkinson's *Physiology, Anatomy, and Surgery.* As a book, then, we have no objections to the work before us; but we demur to the author's estimate of its proper and probable destiny. It is far more likely, we fear, to be used in the grinder's laboratory, than in the harmless way to which we have adverted; and assuredly it is not suited to educated practitioners or *bonâ fide* students of medicine.

CATALOGUE OF MEDICAL AND SCIENTIFIC WORKS: TO WHICH IS ADDED A CLASSIFIED INDEX OF SUBJECTS, INCLUDING THE NAMES OF THOSE AUTHORS WHO HAVE TREATED UPON THEM. pp. 83. London: 1851.

This is not a mere bookseller's list, but is a really valuable work. It "is intended to comprise books published within the last five and twenty years, excepting pamphlets and other publications of less than half-a-crown in price." The merit of authorship seems to belong to Messrs. Highley and Son, of Fleet Street.

PRACTICAL REMARKS ON SOME EXHAUSTING DISEASES. By SIR JAMES EYRE, M.D. *Second Edition.* pp. 100. London: 1851.

The object of this small book is to illustrate and enforce the excellence of oxide of silver as a remedy in Epistaxis, Hæmoptysis, Hæmatemesis, Menorrhagia, Hæmaturia, Dysentery, Leucorrhœa, Epilepsy, and Chorea. When a practitioner is engaged in testing the powers of a pet remedy, he is very apt to adopt more favourable conclusions as to its therapeutic value than others are able to justify; and we ought therefore, perhaps, to receive the glowing testimony of SIR JAMES EYRE, as to the efficacy of oxide of silver in the above-named diseases, with a certain amount of caution. Still, from our own experience, we can testify that the medicine is a good one; and undoubtedly the author deserves a considerable part of the merit of bringing its uses and mode of administration prominently before the profession, by the first edition of this work, which appeared in 1845, as well as by papers in the periodicals. It would be unfair in us to give an absolute verdict as to the greater value of gallic acid in most of the affections for which Sir James Eyre prescribes the oxide of silver, as we have not made extensive

comparative trials with the two medicines, and are not aware of any adequate experiments of this kind having been instituted. This much we can aver, however, that we could, *primâ facie*, make out as strong a case for gallic acid, as Sir James Eyre has made out for oxide of silver, though perhaps we could not clothe our monograph in such pleasing language, or conclude it with a peroration at once so plaintive and so powerful as that which we now transcribe.

"The grateful thanks of the author must now, in conclusion, be rendered, not only to those numerous friends (carefully selected, and anxiously retained during a stirring professional life of nine-tenths of half a century), for the help which they have given to him, both literally and orally, in this their united search after truth; the press, too, and the profession very generally, have assisted: one by generous commendation, the other by manfully working with him, trusting to the honest guidance of a stranger; each and all seeking the only reward worthy of the name, the pure and unsordid delight of doing good! Only four individuals were unable, they said, to discover any virtue in the medicine. These gentlemen must either have gone to the wrong laboratory: or there might have been a resisting idiosyncrasy in these medical men—who can tell? However it may have been, all that now remains is, for it to be *distinctly understood*, that the time for suing for information upon our subject, *in formâ pauperis*, is past; the writer declares, *suo periculo*, that there is no medicine so powerful, not only in the diseases already touched upon, but in some others yet to be set forth, as the oxide of silver in small doses." (pp. 109, 110.)

The author generally prescribes the oxide of silver in half-grain doses; but he also frequently gives it in smaller quantities. In cases of violent menorrhagia, he advises the doses to be repeated every five hours.

Nice et son Climat, avec des Notices sur le Littoral de la Méditerranée de Marseille à Genes. Par Edwin Lee. pp. 132. Paris et Londres: 1851.

This is a reprint of a portion of the author's *Manuel du Voyageur Valetudinaire*, the second edition of which, we are informed, is out of print. We do not know why this work by an Englishman, and evidently chiefly intended for the English, should have been written in French. It is, however, pleasantly composed, and contains the necessary information.

Mr. Lee is evidently partial to Nice; but in his details is, upon the whole, discriminating. Gouty, rheumatic, and paralytic patients seem to derive benefit from a sojourn at Nice. As for Genoa, we are told—and not untruly—that it is the worst climate in Italy. The beauty of the ladies is the only thing it appears which can be admired in that city: but even with the fair sex Mr. Lee is not quite pleased. They have abandoned as a head-dress the graceful veil (borrowed centuries ago from Spain), and now they are generally wearing in its place—like the foolish ladies of Madrid—fashionable French bonnets! Having been in Genoa, and having paid some attention to this matter ourselves, we can say with the author, "*le mantilla leur convenait mieux que les modes Françaises.*"

Prevention and Cure of Spinal Curvatures and Deformities of the Chest and Limbs; being the result of many years' experience. By Mrs. Godfrey, Renshaw Street, Liverpool. London: 1851.

Old women have in all ages been famous as quacks, and there is nothing very remarkable in a lady taking up the Spine; except that it had already been pretty well secured by charlatanic and, perhaps, also by other members of our profession. It is a new feature, however, in medical literature for a medical advertisement-book by a female to have the same publisher as the Pharmacopœia, and the sterling volumes of Williams, Robert Lee, Prout, Liston, and others.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

DELIOUX ON THE PHYSIOLOGICAL AND THERAPEUTIC ACTION OF THE VEGETABLE ACIDS.

Dr. Joseph Delioux, Professor of Materia Medica, in the School of Naval Medicine at Rochefort, has published in the *Gazette Médicale* for May 31, 1851, a valuable paper on the Physiological and Therapeutic Action of the Vegetable Acids. This article we now translate, with merely verbal curtailments.

The therapeutic effects of the vegetable acids are entirely distinct from those of the inorganic or mineral acids. The chemical differences between them are shewn up to a certain point in their pharmacodynamic actions, and hence an identity in their effects as medicinal agents ought not to be expected. The chemico-physiological actions of these two kinds of substances are distinguished chiefly by the following characters:

1. Most—it is incorrect to say all—the mineral acids coagulate albumen powerfully, and are thus plastic caustics (*caustiques plastifiants*) when pure, and more or less powerful astringents when diluted. Such are the sulphuric, hydrochloric, and nitric acids. Phosphoric acid, which has often been incorrectly classed with those which have no power of coagulating albumen, has an entirely distinct action, and is ranged among fluidifying caustics. The vegetable acids, on the contrary, like all organic acids, do not coagulate albumen; hence the strongest of them, employed pure, act as fluidifying caustics, and when diluted, they have no astringent action on the tissues. Tannic acid and its congeners coagulate albumen, but much less than the mineral acids; and the coagulum can be redissolved in an excess of the albuminous fluid. Tannin also acts strongly on gelatine; hence, when it is applied to animal tissues, which consist both of albumen and gelatine, it produces effects in which it is surpassed by no other astringent, and which it has moreover, the advantage of producing without irritation or pain.

2. Mineral acids, when introduced into the blood, do not undergo decomposition; they remain either free or combined, or are sooner or later eliminated. The organic acids, and especially the vegetable acids, when introduced into the blood, always, at least in part, undergo decomposition. The former may impede the circulation, by coagulating the albumen of the blood, and so diminishing its fluidity; the latter, having no coagulating power on the albumen, but often fluidifying it, retard the circulation in an entirely different manner, which will be presently described.

Those vegetable acids which have a strong affinity for bases, which strongly redden litmus paper, and possess a decided taste, have when concentrated, an energetic caustic action: in a lower degree of concentration, they are slightly caustic (*cathérétiques*); when very much diluted, or naturally weak, they have only a slight irritant action, or none whatever. Yet they must not be classed as astringents, if this term be restricted to those substances which condense the albuminous tissues. Viewed in this light, tannic acid and its congeners alone, among vegetable acids, should be considered as astringents. If, however, it be borne in mind that some of the acids, such as the acetic, are volatile, and that volatilisation always involves a certain lowering of temperature, it may be admitted that their application to the surface of tissues has a secondary refrigerating effect, which produces a constriction of the fibres analogous to that which results from pure astringents. It may even be supposed that, by irritating the nervous radicles, they call

into action organic contractility. But they will not be found to be such efficacious astringents as the mineral acids.

The vegetable acids, when absorbed, do not coagulate the albumen of the blood, but rather increase its fluidity. With the exception of tannic acid, they all combine with the alkaline bases in the blood; but the new salts are soon transformed into carbonates, their organic acid being destroyed and burnt up by the oxygen introduced into the system during respiration. To effect this, the acids being composed of carbon, hydrogen, and oxygen, absorb oxygen to form water and carbonic acid, which are expired, while a portion of the carbon is converted into carbonic acid, which combines with an alkali. But the oxygen thus consumed is borrowed from that intended for the arterialisation of the blood. And as the rapidity of the circulation is in a direct ratio to the oxygenation of the blood, the retardation of this movement will be the immediate consequence of the combustion of vegetable acids. This is the true explanation of the temperating action *(action tempérante)* of these acids. It is not based on speculative theories, but on the most positive results of chemical analysis. The fact of the destruction of the vegetable acids, established especially by the labours of Wöhler and Liebig, is well calculated to fix our attention on the power of chemical forces, which the organism holds in reserve; for we find them produce, at a temperature of 38° cent., a degree of reaction which can only be produced artificially at a red heat.

It is not, however, to be supposed that the whole of a vegetable acid, especially when taken in large quantity, is converted into carbonic acid and carbonates. The skin and the kidneys eliminate acids. The sweat is acid, and acetic acid is distinctly found in it; it might therefore be admitted that a certain quantity of this acid, when admitted by the primæ viæ, is rejected by the sudoriparous glands. The urine is normally acid, and owes this character chiefly to uric acid; it only becomes alkaline when, after some time, the urinous products have undergone ammoniacal fermentation. But moreover, in patients under treatment by vegetable acids, these have been detected in more or less considerable quantities in the urine. It has been said, that the organic acids alone can be eliminated in this way: M. Mialhe believes that, as they do not coagulate the albumen of the serum, they easily pass uncombined through the kidneys, while the mineral acids, detained both by their bases and by the albumen which they have coagulated, cannot enter into the urine.[1] But, although it be admitted to a certain extent, that the passage of mineral acids into the urine, is not so easy as that of vegetable acids, yet this power ought not to be altogether denied to the former. The experiments of M. Orfila show that in cases of poisoning with concentrated acids, not only the acetic, tartaric, and oxalic acids can be discovered in the urine, but that the sulphuric, nitric, and hydrochloric can likewise be detected.[2]

It remains to be explained how the mineral acids escape complete neutralisation by the alkalies in the blood, and how the organic acids can in part escape the combustion which commonly takes place in the lungs. The explanation of these phenomena is, I think, furnished by a peculiar anatomical arrangement in the abdominal venous system. M. Claude Bernard has discovered direct communications of pretty considerable size between the vena porta and vena cava, which turn the blood directly from the former into the latter. He also observed that the vena cava possesses: 1, Muscular fibres below the hepatic vein, tending to produce a reflux of the blood. 2, Valves at the level of the renal veins, so that the blood cannot flow farther down, but is obliged to enter the renal veins, which thus act as arteries. This arrange-

[2] Orfila. Traité de Toxicologie. 4me Ed. Tome i, p. 86.

ment explains the rapid passage of certain substances into the urine: it also shews how, when fluids have been absorbed in quantities capable of disturbing the hepatic and the cardiac circulation, nature has provided a diverticulum which ensures, in all circumstances, the maintenance of the regular course of the blood. But as this phenomenon occurs when large quantities of aqueous drinks have been taken in, and as the acids are generally administered in a large proportion of water, it seems beyond a doubt, that a portion of the acids may pass, with the excess of their vehicle, through this diverticulum, escaping both the neutralisation by alkaline bases and the combustion in the lungs; and that it is in this way that the acids appear in the urine, in the same state as when absorbed.

This anatomical arrangement will also explain the rapid appearance of many other substances in the urine, and the innocuity or diminished noxiousness of certain poisons, as well as the varying action of different medicines, in proportion to the quantity of the vehicle in which they are administered; or the amount of solid and liquid matter with which they meet in the alimentary canal.

There is another class of physiological considerations which are important in the administration of acids.

In the animal economy, the great majority of the fluids possess the alkaline character: acidity is only manifested rarely, and as if in exception. In the vegetable economy, the contrary is observed: the acid has the precedence of the alkali.

The three principal humours of the human body—blood, lymph, and serum—are strongly alkaline; and so are most of the fluids which emanate from the blood. All the recrementitious fluids are thus alkaline; while an acid character is shewn only in the excrementitious fluids, several at least of which, as urine and perspiration, seem principally intended for the elimination of acids. It may be objected, that secretion of acid takes place on extensive surfaces, both on the skin and on the tegumentary mucous membranes. But the quantity is small, in proportion to the mass of alkaline fluids enclosed in the body or effused on its surfaces. Besides, an acid secretion is almost everywhere accompanied by an alkaline: thus, in company with the sweat, we find the alkaline sebaceous secretion, which completely effaces the acidity of the transpired fluid in certain cutaneous folds: in the vicinity of the acid fluid which exudes from the muciparous follicles, the glands and glandules discharge on the mucous membranes the saliva, pancreatic juice, etc., all of which are alkaline. The antagonism between the acid secretions of the external integument and the alkaline secretions of the internal integument has been too absolutely expressed. The antagonism does exist, but it is on the spot, and not at a distance. All the humours whose office it is to digest alimentary or medicinal substances, owe their efficacy to an albuminoid matter which only acts in the presence of alkalies, not merely in the digestive canal, but also in the blood. In the latter, M. Cl. Bernard has ascertained that sugar is transformed, not only under the influence of alkalies, as had been said before him, but also, as in other parts, of an albuminoid matter. The only exception to this great law is the gastric juice, the pepsin of which acts in the presence of acids.

The moderate use of acid drinks produces a state of calm and comfort in certain febrile and inflammatory conditions; but they may produce evil and even disastrous results, where wrongly or inconsiderately administered. The abuse of the vegetable acids produces anorexia, dyspepsia, mucous and serous fluxes, atony, paleness, œdema of the tissues, slowness of the circulation with smallness and weakness of the pulse,—the debilitation, in fact, of all the assimilative functions. And the result cannot be otherwise: for they tend to alter the constitutional crasis of all the fluids of the living body, and especially to deprive the digestive fluids of the properties indispensable to the

performance of their elaborative functions, without which nutrition cannot be normally performed. And, if this abuse be pushed so far as to produce acidification of the blood, diabetes might be the fatal consequence, if the ideas of some modern authors on the pathogeny of that affection be correct.

Some good advice may be given to those persons who, while in perfect health, make an immoderate use of acid drinks. These may produce less inconvenient effects during the summer and during hard exercise, than in the winter and when the corporeal forces are inactive; because, under the first named circumstances, the sweat removes from the system those principles whose excess might be hurtful. But they have not the advantages which the seductive attraction of a transient coolness seem to promise; for, after appeasing the thirst, they leave the individual in a state of atony, while a slightly spirituous or cordial drink stimulates and re-animates. An intelligent reform has been effected in this sense in the navy, by the substitution of brandy for vinegar in the drink of sailors in hot seasons or in intertropical countries. Nothing can more clearly shew the pernicious action which is exercised on the economy by the obstinate use of acid drinks, than the experiments made by the coquette threatened with obesity. Vinegar, the common weapon against this enemy of beauty, will at the end of a certain time cause the disappearance of the adipose secretion, and also of the health. She will indeed grow thin; but she will at the same time poison herself.

Physiologists, toxicologists, and therapeutists have ascribed a more powerful effect than I am disposed to allow, to the local effects of vegetable acids. For example, all the modifications which absorption and nutrition undergo in consequence of their abuse, have been ascribed to the astriction produced by their contact. But this hypothesis is contradicted by carefully observed chemical, physiological, and pathological facts. The non-coagulating vegetable acids cannot tan the tissues, nor, consequently, close their absorbent pores; on the contrary, they pass easily into the circulation, and it is in the blood that their action is developed.

Intestinal fluxes may sometimes indeed be restrained by vegetable acids: but this is not to be ascribed to their pretended astringency. Cases of this kind have probably been ill interpreted; and we are the more warranted in believing this, as it is now known that diarrhœa is sometimes kept up by the super-alkalisation of the intestinal juices. The employment of acids would correct this by an entirely chemical action. Some persons consider the digestive canal as a mere tube, through which the matters taken in pass from one end to the other; and that, when the medicinal effect of any substance is required, it is arrested at that part of the canal where we wish it to act. But such persons should remember, that medicines soluble in the stomach, and liquids, when not in great quantity, are absorbed without passing beyond the pylorus; that it is only insoluble medicines, or an excess of fluids, that reach the intestines; that these liquids are readily absorbed by the veins; and that aqueous drinks only descend into the lower part of the small intestine when they have not been absorbed higher up, which is an exceptional case. It is, then, impossible to admit that acids, especially those which do not coagulate, act locally on those parts of the alimentary canal which are the source of the diarrhœa.

In the time of iatro-chemistry, when all pathogeny was founded on the acidity or the alkalescence of the humours, the acids formed the half of therapeutics. Again, in the reign of Broussaism, when irritation was everything in pathology, and gastritis was at the bottom of every irritation, then lemonade shared with diet and bleeding the honour of uniformly and easily curing all diseases. At the present day, acids are found to be far from being so useful as alkaline medicines. The use of the vegetable acids only depends on a small number of indications, which are, however, distinct enough to

warrant their rational employment; but their unseasonable use, or their abuse soon destroys their merit. Alkalies, on the contrary, enter largely into rational treatment: there is less danger in super-alkalising the organic fluids, than in introducing an element incompatible with the regular exercise of the functions which these fluids are intended to fulfil.

The vegetable acids may be divided into THREE GROUPS, each of which is characterised by distinct properties, and capable of special application. This division is also equally rational in a chemical point of view.

I. PURE ACIDS. These shew most distinctly the physiological and therapeutic characters of the vegetable acids. All that has been already said is immediately applicable to them, and it only remains to give a summary of their qualities.

When concentrated, they act as caustics, corroding and often perforating the tissues. When administered internally in that state, they produce all the symptoms of irritant poisoning: their antidotes will then be those of all acids, as magnesia, chalk, soap and water, alkaline solutions, or any substances which, by saturating them, form salts incapable of doing harm. In proportion as they are diluted with water, they lose their irritant properties. They may then, when applied to the surface of wounds, produce a cleansing rather than an astringent effect. They may, through the refrigeration caused by their evaporation, and the irritation which they excite in the organic contractility, give rise to a certain degree of fibrillar astriction, at the same time that they moderate the peripheric heat of the body. Administered internally, in medicinal doses, dissolved in large quantities of water, they refresh, especially if their vehicle be of a low temperature. They are promptly absorbed, and as promptly eliminated by the kidneys and skin, or transformed in the blood into water and carbonic acid; the latter being in part eliminated by the lungs and skin, in part saturated by the alkaline bases in the blood. The result of this combustion is to diminish the arterialisation of the blood: it would seem to keep the arterial blood in a state more or less like venous, as at least M. Orfila has seen in his experiments on acetic acid. It is thus that the cooling effects of vegetable acids can be explained. Giacomini, when he called them *venous hyposthenics*, was wrong in restricting to a portion of the circulation a sedative effect which is exercised over the whole of that system. This hyposthenic effect is aided by a diuresis, which renders still more active the simultaneous ingestion of a large quantity of drink; and it is often increased by secondary diaphoretic effects, connected with the depurative function of the skin in regard to acids. These effects are produced especially when the acidulated drinks are hot, or when, though cool, they are taken by persons under the influence of a high external temperature. In the latter case, the result is exactly the opposite of what is desired; for, by provoking profuse perspiration, the previously existing weakness of the individual must be increased. Finally, if vegetable acids are sometimes useful in modifying a too highly alkaline state of the fluids, they should be used cautiously, and not persisted in; and the nature of the normal crasis of the fluids, adapted to the conditions of animal life, should be always borne in mind.

II. ACID FRUITS. These contain one or more organic acids, especially the tartaric, malic, and citric, to which they owe a part of, but not all, their therapeutic properties. The alkaline bases, here present, act also as efficaciously, and less hurtfully, as temperants, sedatives, and diuretics. Acid fruits are far from producing the same inconveniences as free acids: they present to the assimilative powers a combination of acids with soda, lime, and chiefly potassa, and rendered still more mild by pectin and sugar, so that the oxidation in the blood acts chiefly on a salt formed by a vegetable acid, and the result of the transformation is an alkaline carbonate. Unripe fruits, in which the acids predominate over the sugars and the alkaline bases, produce

well known inconveniences to digestion and nutrition, by super-acidifying the fluids: but ripe fruits act by their alkaline bases as much as, and more than, by their acids. Grapes, for instance, which are rich in bitartrate of potash, render the urine alkaline, and may be employed with manifest advantage in diseases where mineral alkaline drinks are indicated.

III. Tannin and Tanniferous Substances. This group is well characterised. Tannin is met with, more or less modified, in a great number of medicinal substances, which owe to it their peculiar astringent properties. Tannic acid, the only coagulating organic acid among those which are used in medicine, may act in this way much more efficaciously than all the vegetable acids. To it alone may be granted the property of modifying the absorbent power of the tissues by tanning them; and there is no doubt, that, if immoderately persisted in, it will produce great alterations in absorption and exhalation. But its coagulating power is not so great as its property of being absorbed: for, when either dissolved in an abundant vehicle when taken in, or, if it is administered solid, dissolved at a later period by the gastric or intestinal fluids, its plastifying power is diminished as it is diluted, and the coagula formed are susceptible of being redissolved by the alkaline salts in the digestive fluids. When introduced into the blood, its action is less understood than that of other organic acids. It must undergo combustion like them, and a certain degree of excitement of the circulation must result: but the therapeutic effects obtained by its use, and characterised by a general state of astringence and tonicity in the organism, agree better with the hypothesis of a coercing action on the albuminous elements in the blood.

DR. BURROWS ON DISEASES OF THE ANTERIOR MEDIASTINUM: MEDIASTINAL TUMOURS.

Dr. Burrows, in a clinical lecture on the more important Diseases of the Anterior Mediastinum, published in the *Medical Times* for June 7th, 1851, directs special attention to tumours occupying that region. They may be either tubercular or malignant growths: he believes them to be most commonly carcinomatous.

The development of a tumour in the anterior mediastinum is often slow and insidious, and, from its rarity, is often unsuspected. Its existence is more especially indicated—1. By the usual symptoms of irritation and pressure on some portion of a respiratory tube; 2. By various local symptoms, resulting from pressure and obstruction to the return of blood to the heart through the cava superior or its tributary veins; 3. By physical signs, indicating the presence of a solid in the upper part of the thorax, capable of transmitting the heart's sounds far beyond their proper limits, and modifying the respiratory murmur in the upper lobe of one or perhaps both lungs.

In the earliest periods, there are repeated and distressing attacks of urgent dyspnœa, coming on in the night, and resembling spasmodic asthma. During the paroxysm, and even at other times, there is uneasiness immediately above the sternum, in the lower part of the windpipe, and an inclination to cough up something which causes constant discomfort. The dyspnœa may subside after the patient is roused from sleep, and has preserved the erect posture for a short time, or after the expectoration of some viscid mucus. Auscultation and percussion seldom yet give any precise information. If an examination be made during the paroxysm of dyspnœa—which is, however, scarcely practicable—there will probably be heard loud tracheal sounds, masking all other respiratory sounds; or tubular breathing, with rhonchus, will be heard over a considerable portion of the chest. When the asthmatic seizure has declined, the tracheal sounds will subside; some rhonchus or large crepitus may be still heard through a portion of one lung; and sometimes the vesicular murmur is weakened in some portion, while the resonance on percussion is healthy.

The suspicion of some cause of pressure on the respiratory tubes near the bifurcation of the trachea, to which the continuance or frequent recurrence of the above symptoms might give rise, is strengthened by various local signs of pressure and obstruction to the return of venous blood to the heart through the vena cava and its tributary veins. The cutaneous veins about the upper sternum and one clavicle—generally the right—become more conspicuous than natural. The external jugular, the thyroideal, the mammary, and thoracic veins, become permanently enlarged and tortuous ; and the current will probably be ascertained, by making pressure at various points, to be moving in a direction the opposite to that which is natural. After a while, the superficial veins of one upper extremity become enlarged and conspicuous. Œdematous swelling is now observed on one side of the throat, about the upper portion of one side of the chest and in the upper extremity, and, in adult females, in the corresponding breast. This œdema will at last extend to the face, especially the eyelids, which become puffy. The eyes have a glassy, watery look, with rather dilated pupils ; this state of the eyes is not unfrequently observed where there is an obstruction to the passage of blood through the right cavities of the heart.

Careful and repeated auscultation and percussion will now indicate the presence of some solid beneath the sternum, which transmits the heart's sounds far beyond their proper limits, and which seriously impairs and modifies the healthy respiratory murmur in the upper lobe of one lung, and perhaps afterwards in a greater extent. The heart's sounds will be heard distinctly to the summit of the sternum, and to a varying extent, beneath the right clavicle; but without the peculiar blowing sound which generally attends aneurisms. The pulsation of an aneurism is also absent. The lower portion of the trachea is more or less forced out of its normal situation. The respiratory murmur will be impaired or inaudible over certain portions of the upper part of one lung; and if any breath-sound be heard, it will be tubular or bronchial. As the case advances, the respiratory murmur is much impaired in the lower part of the affected side. The stroke-sound is dull all over the sternum, over the greater part of the front of the affected side, and posteriorly over the scapula, towards the root and base of the same lung ; while it is resonant in the axilla of the affected side. The dyspnœa, the orthopnœa, and ineffectual cough, together with the above-named physical signs, may lead pleuritic effusion to be suspected. Some may indeed exist; but it will be quite inadequate to explain all the distressing symptoms of asthma which have been observed. Moreover, the most resonant parts of the affected side are in the axilla and hypochondrium, while the greatest dulness is detected in the subclavian region and towards the root of the lung—phenomena the reverse of those of advancing pleuritic effusion.

The dyspnœa is now urgent and constant, occasionally threatening immediate suffocation. The patient remains in a state of orthopnœa, probably unable to speak or swallow, without bringing on a dreadful increase of suffering. The progress of the disease is well illustrated in the following cases.

Case I. J. L., aged 15, was admitted into St. Bartholomew's Hospital, on March 7, 1850. He was thin, pallid, and delicate looking; the eyes were slightly suffused; the lips dry and parched; skin warm; pulse 132, very small and soft; tongue red, with elevated papillæ; bowels open; urine abundant. He complained of dyspnœa, and of a peculiar croupy tracheal cough, with copious thin frothy expectoration, and of some pain in the chest, chiefly between the scapulæ. He was supposed to have caught cold about two months ago, since which he had complained of pain in the chest, a bad cough, failing strength, and loss of flesh.

On auscultation, there was prolonged, loud, coarse, tubular breathing all over the right side in front and behind, and less intense tubular breathing in the left subclavian region ; also behind over the upper part of the left

side, while vesicular breath-sound was heard in the left infra-scapular and axillary regions. The stroke-sound was completely dull all over the right side, across the sternum, and over the upper part of the left side before and behind: the resonance was good in the left axilla, and impaired in the lower half of the left side behind.

The dyspnœa, cough, and difficulty of expectoration went on increasing; and the right external jugular, and some other veins of the neck, were found distended, and the trachea was thrust towards the left side. On March 26, there was increasing congestion of the veins of the neck and shoulder, œdema of the right arm, and the trachea passed to the acromial side of the sterno-mastoid muscle. He died on March 29, more from asthenia than apnœa.

Post-mortem Examination, made on the following day by Dr. Kirkes. The lower portion of the trachea was pushed beyond the left sterno-clavicular articulation. On removing the sternum, there appeared a large mass occupying nearly the whole right side of the chest, extending forwards rather beyond the middle line, and passing upwards under the trachea, towards the left sterno-clavicular articulation. In front, the mass was adherent to the sternum; laterally and above, it adhered to the costal pleura, and had caused slight erosion of the upper ribs; below, it extended beneath the level of the fifth rib. The mass appeared to have originated in the tissue of the mediastinum, and to have encroached upon the substance of the upper lobe of the right lung, which was greatly compressed, devoid of air, of a pale leaden colour, and apparently quite free in structure from any portion of the foreign growth. The middle and lower lobes of the lungs were also much compressed, and almost empty of air. This compression, however, seemed to be partly due to a little fluid which occupied the lower part of the pleural cavity. By means of the growth, the heart was pushed unusually to the left side; the large vessels in the mediastinum were elongated and distorted, but apparently not sufficiently compressed to materially interfere with the transit of blood; the œsophagus and trachea were displaced and compressed. The right bronchus passed through the middle of the mass, and appeared very narrow.

The malignant growth was uneven and nodular on its surface; it was covered by a smooth membrane, evidently formed of the pleura. The superficial portions consisted of masses of white, soft, medullary carcinoma. The great bulk, however, was made up of a soft, friable, pale-yellowish material, abundantly infiltrated with dark extravasated blood. This effused blood constituted a large part of the whole mass, and was in many places disposed in large masses, though usually it was scattered in points and streaks in the midst of the reticular yellowish material. Interspersed within this peculiar material were several masses of ordinary soft cancer, reduced to the state of pulp. The left lung and heart were healthy. No other part was particularly examined.

Case ii. Miss — aged 26, a patient of Mr. Stewart of Aldersgate Street, was seen by Dr. Burrows on April 6, 1850. She was suffering from severe orthopnœa, and congestion and œdema of the upper part of the body, principally on the right side. No careful or prolonged physical examination could be attempted; but over the greater part of the right lung there were dulness, rhonchus, large crepitation, and transmitted tracheal sounds.

The patient had been in apparent health a month previously; but had been attacked with cough and other symptoms, which had led pleuritic effusion to be suspected. Dr. Burrows suggested occasional doses of chloric ether, and mustard poultices to the chest.

April 8. The chloric ether had afforded some relief, but there were still orthopnœa, œdema, and difficulty of deglutition. Auscultation detected loud tubular breathing, with bronchophony all over the upper part of the right lung before and behind; and there was great dulness on percussion. The breathing was less tubular, and the percussion rather less dull, in the axilla and over the lower part of the same side. The heart's sounds were trans-

mitted to the right side, while the impulse was felt more in the left axilla than normal. The breath and stroke-sounds were nearly normal on the left side. From these symptoms and physical signs, Dr. Burrows diagnosed the existence of a mediastinal tumour, and advised, as palliatives, the continued use of chloric ether and counter-irritants, and iodide of potassium internally and externally. The patient died early in May.

Post-mortem Examination. On removing the sternum, the upper and middle part of the right pleural cavity was found occupied by a large lobulated mass of brain-like cancer, continuous with similar masses in the mediastina, and adherent to the costal pleura, especially in the mammary and axillary regions. Several various sized independent masses of medullary cancer, in different states of softening, and of various shades of colour, from milk-white to dark chocolate, were scattered through the substance of the lung. The lower half of the pleural cavity, and the various spaces between the projections of the malignant growth, contained about a pint and an half of turbid serum. The right bronchus, in its course to the lung, passed through the midst of the mass, and, immediately after entering the root of the lung became very narrow; then it, and nearly all the various branches to their termination, suddenly opened out into wide pouch-like dilatations, interrupted here and there by constricted portions. Many of these dilatations appeared like large cysts, filled with thick, tenacious, puriform mucus. The mucous lining was red, rather coarse, but moderately smooth. The large masses situated in the mediastina, and lying along the bodies of the dorsal vertebræ, had displaced and compressed the roots of the great vessels at the base of the heart; while the superior cava, which was quite encircled by one of the masses, was so extremely reduced in size at its entrance into the auricle, as scarcely to admit of the passage of a narrow probe along its canal. Above this point, the vessel gradually assumed more of its ordinary diameter; its interior was smooth, and it contained no coagula. The inferior cava was rather above its ordinary size. The pericardium contained some turbid serum, in which a few flakes of recent lymph were suspended. Its surface presented numerous patches of vascularity, especially where spread over the roots of the great vessels, and over the nodules of the cancerous masses which projected into the cavity at the base of the heart. The heart and left lung were healthy. No deposits were found in the kidneys, liver, spleen, or other parts examined.

PURULENT PYELITIS: CALCULI IN PELVES OF KIDNEYS.

The following case was related by M. Charcot.

Case. A young girl, aged 18 years, was admitted into the Charity Hospital, under M. Briquet, on March 10; she died on the 20th of the same month. She had had sharp pains in the kidneys at various times for three or four months. There were, however, no symptoms of true nephritic colic; and she stated that she had never passed gravel or calculi with the urine. On admission, there was slight fever, with evening exacerbations; she had some erratic rigors; and there was pain in the loins, increased by pressure, and more severe in the right lumbar region. Percussion shewed that both kidneys were increased in size, but the right more than the left. Five or six days before entering the hospital, she had been attacked with hæmaturia for the first time. After this, the urine, which was in almost normal quantity, became thick and very fetid, and exhaled a gangrenous odour, especially towards the end of her life. When left to stand, it deposited a purulent sediment: the supernatant portion, however, did not become clear, and gave a copious precipitate with nitric acid. On the last two days of life, the patient presented the symptoms of a pretty severe typhoid state. She had no vomiting. The treatment principally consisted in the application of cauteries, by Mayer's process, to the region of the right kidney.

Dissection. Both kidneys were enlarged to almost double their natural size. This was due to a dilatation of the pelvis with fetid pus; its walls

were covered with a green false membrane, and presented in some points ulcerations of a gangrenous aspect and odour. The substance of the kidneys was thinned and flattened, but not otherwise altered. A calculus of the size of a haricot bean was found in the pelvis of each kidney; and the pus in the pelvis of the left kidney also contained one of the size of a large pea. The ureters were double their normal size, and the walls were thickened; they also here and there presented dilatations. The mucous membrane of the bladder was thickened and brown. [*Gazette Médicale de Paris*, May 31, 1851.]

CASE OF HÆMOPTYSIS (?) NEONATORUM.

The history which we are about to quote is published by Dr. Charles G. Adams, in the *American Journal of the Medical Sciences* for April 1851, p. 364 This case was probably one of *congenital purpura*, or what the French writers call *hémorrhagie constitutionelle;* and therefore, as the history given by Dr. Adams does not fully justify the title which he has prefixed to it, we have added a note of interrogation. The nasal and buccal mucous membranes seem as likely as the pulmonary to have been the source of the hæmorrhage. The case, in fact, was an extreme one of the familiar affection termed (so improperly) *icterus neonatorum*, in which, as also in certain congestive fevers, the skin, after purpling, becomes yellow, not from the colouring matter of the bile, but from effusion of blood into the cellular tissue under the skin, the result of hyperæmia, associated with a morbid condition of the blood and the capillaries. The change of colour is identical with what takes place in a bruise. We have compared the report of the *post-mortem* appearances in Dr. Adams's case, with some of those recorded by Dr. Cormack as characterising "the yellow and highly congestive cases" of the fever which prevailed in Edinburgh in 1843-44, and have been much struck with the similarity. In the infant whose case is now to be described, as much as in the cases of fever, the disease was clearly constitutional, involving a morbid condition of the blood.

History. The infant—a female—was born after seven and a half months' gestation. The labour was natural; but the funis was round the neck, and respiration was established artificially. During the first twelve hours, the respirations were feeble, and there was no pulse at the wrist. The infant, afterwards nursed, and cried well, had natural evacuations from the bowels and the bladder, a pulse at the wrist, warmer extremities, and freer respiration. But, about an hour before death, it had a sudden discharge of bright arterial (?) blood from the mouth and nose, with symptoms of suffocation, which led the nurse to think it was dying. It rallied, however, and respiration again became comparatively easy. In thirty or forty minutes, it suffered another similar attack of hæmorrhage, under which it sunk, twenty-four hours after birth. The quantity of blood lost might have been five or six drachms.[1]

Necropsy thirty hours after death. *Exterior.* The skin had universally a uniform yellow tint. Upon the neck and upper extremities were seen numerous petechiæ, or circular livid spots of extravasated blood, varying in size from a diameter of half a line to three or four lines. [These were observed before death.] There was no *rigor mortis.* The *encephalon* was not inspected. *Thorax.* The thymus gland was healthy. The lungs were of a very dark livid colour; and solid, except a small portion on their lower anterior edge (perhaps one or two cubic inches), which was of a more healthy hue, crepitated under pressure, and alone had a specific gravity lighter than water. Upon incision, the solid portion presented a surface almost black, glistening like the cut surface of a coagulum, though less smooth and uni-

---

[1] The mother's first labour, which had occurred ten months previously, was also premature. The child was born in a putrid state at the commencement of the ninth month. The father is a slender man, and has had two attacks of hæmoptysis.

form. The bronchia, where they could be traced, were filled with a bloody frothy mucus. No tubercles could anywhere be discerned. In the pleural cavities there was a small quantity of straw-coloured serum. The heart contained dark fluid blood: its parietes were tolerably firm. The foramen ovale was closed by its diaphanous valvular membrane. The ductus arteriosus remained pervious. *Abdomen.* Upon laying back its parietes, the liver and spleen concealed from view every other viscus, filling almost the entire abdominal cavity. The peritoneum was natural. The stomach was considerably distended with gas: its peritoneal surface presented numerous lengthened livid spots of extravasated blood, from one to three or four lines in width, partially encircling the viscus, and more abundant and larger towards the cardiac extremity. The intestines—particularly the small intestines (which throughout were of a pink hue)—presented externally dark spots of extravasated blood. The stomach contained three or four ounces of dark-coloured sanguineous fluid, with one or two black coagula floating in it. Its mucous coat was sufficiently firm: it was of a bright rose-colour, from the evident engorgement of minute capillaries, and was quite dark in some places. The ecchymosed spots existed in its thickness, and beneath it. The small intestines contained a considerable quantity of thick bloody mucus, having a slimy aspect and feel. The mucous membrane of the small intestines was considerably softened in some places. The mesenteric glands were enlarged and of a rose-colour. In colour and consistence the liver was natural, though somewhat congested. The gall-bladder was of a very light colour, and comparatively empty. The spleen was natural in colour and consistence; but *somewhat exceeded the average size* and weight of the adult organ.

PATHOLOGY OF DIABETES.

We reprint the following from the 2nd vol. of the *Transactions of the American Medical Association,* pp. 89. "For all practical purposes, in the present state of our knowledge, we may, in the opinion of Dr. Todd, adopt with advantage the following view of the pathology of Diabetes. 'That it is primarily a disease of the mucous membrane of the stomach, whereby an abnormal diastase is formed, which readily converts into sugar such aliments as admit of that conversion; the mucous membrane probably likewise secretes sugar; the sugar thus formed, passes into the blood, and is rapidly eliminated by the kidneys, causing, at the same time, the attraction to those organs of the elements of a large quantity of water.'"

"Very much to the same point are some interesting remarks of Professor Flint, in a late number of his journal *(Prov. Med. and Surg. J.),* on the pathology and treatment of this affection. 'The presence of sugar in the blood and various secretions other than the urine,' he remarks, 'renders it inappropriate longer to rank diabetes among renal diseases. It is a disease affecting the assimilatory process, in consequence of which, sugar ingested passes unchanged into the blood-vessels, and alimentary principles capable of being converted into sugar undergo that chemical change. The kidneys are involved only as one of the excretory outlets by which this useless saccharine material is eliminated from the system. The hyper-secretory action of the kidneys, (which is probably due to the presence of sugar acting as an excitement,) constitutes an important element of the disease. This will serve to explain, in part, the dryness of the surface, the costiveness, the thirst, &c. The loss of those alimentary principles which contain sugar, or are capable of conversion into sugar, for all purposes of healthy assimilation, will explain the debility, the wasting, and the great gravity of the disease. We have thus advanced a considerable way in our knowledge of this disease; but we are still at a distance from knowledge of the nature of the perversion which the processes of assimilation undergo, and of the ulterior morbid condition upon which the perversion depends. In other words, its true pathology and etiology are still unknown. The knowledge, however, which has been acquired, is not without its practical value.

It prevents, in the first place, treatment based upon the idea of its being essentially a urinary disorder, and other false pathological views, and in this way saves the patient from measures which might prove not only useless, but injurious. This, although negative, is nevertheless not the least important of the advantages which attend an improved knowledge of diseases generally. . . . . Our rational course, in the present state of knowledge, is to endeavour to restore the proper action of all the functions; and especially to modify and improve the processes of assimilation."

M. Mialhe believes that diabetes "depends upon a want of sufficient alkalinity in the fluids of the body; that the transformation of amyloid substances into sugar, is not peculiar to diabetic patients; it is not an accidental phenomenon, but a necessary part of the digestion and assimilation of food; that this is brought about by an animal *diastase* in the saliva, which he has discovered; that amyloid substances must in all animals, without exception, be converted into sugar under the influence of this diastase. *But what becomes of this sugar?* It must participate in nutrition, and, in order to do this, it undergoes certain transformations; for in the normal state, it is not detected in any of the secretions. Its passage through the kidneys is pathological, and depends upon a disturbance which has its origin in a want of alkalinity in the blood. The alkalies in the blood, M. Mialhe contends, are the principal agents in the digestion and assimilation of saccharine and amyloid substances. The saccharine principle must undergo farther transformations to be assimilable. In the healthy subject, the alkalinity of the blood is sufficient for this decomposition; but if this be deficient, the transformation fails to take place; the sugar becomes a foreign body, and is cast off, not only by the kidneys, but by all secreting surfaces, and *we have diabetes.* The cause of this affection may therefore be traced to a defective assimilation of the sugar, through a want of alkalinity in the animal economy. Human blood is naturally alkaline, but would eventually become acid, through the ingesta, but for the counterbalancing effects of especial secretions—the urine and the perspiration, which when normal, are always acid. The saliva and the tears are uniformly alkaline."

PLANTAIN AS A REMEDY IN INTERMITTENT FEVERS.

Dr. Chevreuse, of Charmes-sur-Moselle, relates the following case:

A lady, aged 56, had for some time had attacks of tertian ague, coming on about ten o'clock in the morning, and not leaving her till the night or the next morning. The sweats were very profuse. When Dr. Chevreuse first saw her, which was not until she had been treated without effect by leeches and cupping, he ordered an enema of sulphate of quinine to be given five or six hours before the first stage of the fever. Thirty-five *centigrammes* (about 5½ grains) were given, but they only produced pains in the intestines, and dryness in the throat. The dose was afterwards raised to sixty and then to seventy *centigrammes*, without producing any change. Fifty *centigrammes* were then given by mouth; and subsequently inunction of quinine as well as other means were tried, but all without success. After the patient had suffered for four months, and was growing thin and losing strength, some of the juice of plantain leaves *(plantago major)* was administered to her. She took about a quarter of a wine glassful before the rigor. The first dose purged her, and increased the fever, which continued this time longer than usual; but after the second dose, which was given in the same manner, the fever did not reappear, and there merely remained some weakness, which gradually disappeared.

Dr. Chevreuse states that, in many cases, plantain-juice had cut short paroxysms of fever, which had resisted sulphate of quinine. [*Revue Médico-Chirurgicale*, as quoted in *Journal des Connaissances Médico-Chirurgicales*, March 1, 1851.

TREATMENT OF ERYSIPELAS BY THE TINCTURE OF THE MURIATE OF IRON.

Drs. Hamilton Bell and Charles Bell have (in the *Edinburgh Monthly Journal* for June 1851) directed attention to their successful treatment of erysipelas by this preparation of iron.[1] The first object is to have the bowels freely opened. If the erysipelas be mild, fifteen minims of the tincture are administered in water every two hours, till the disease is completely removed. When the attack threatens to be more severe, the dose is increased to twenty-five minims every two hours, and persevered in night and day, however high the fever and delirium. The only local applications ever found necessary, are hair-powder and cotton-wadding. While the chalybeate is trusted to for the removal of the disease, it is necessary that the bowels should be attended to. In podagral erysipelas, the tincture of the muriate of iron has been found equally valuable as in other cases.

Dr. Hamilton Bell thus explains the rationale of the treatment :—"In inflammation, the capillary vessels having apparently lost the power of separating or electing the component parts of the blood which are necessary for functional purposes, and having become, to a certain extent, inert tubes, a stream of blood is admitted, for the circulation of which they are not calculated. In other words, I consider, that in erysipelas, the capillary vessels are in an atonic state."

This hypothesis appears to Dr. H. Bell to be supported by the effect of the treatment which he has adopted in erysipelas,—the cases, he thinks, demonstrating that when an extensive portion of the surface of the body is violently inflamed, producing a high degree of fever and cerebral excitement, the symptoms subside, when the system "is rapidly surcharged with, or brought under the influence of the muriated tincture of iron."

SURGERY.

ESCAPE OF PUS FROM THE PUNCTA LACHRYMALIA: NO LACHRYMAL TUMOUR.

M. Béraud exhibited to the Society of Biology, in Paris, in March 29, a specimen taken from a male subject, about 50 years old. The puncta lachrymalia and ducts were perfectly healthy. There was no valve at their common orifice in the lachrymal sac, such as are present in two-thirds of the cases which he had examined. The lachrymal sac contained a small quantity of puriform matter; it was narrowed in every direction, especially on the left side, where it was reduced to one-half its size. The surface was covered with small openings, the orifices of the glands contained in the sac. There was no valve at the lower orifice of the sac, either on the right side or on the left; according to M. Béraud, it should be present in about half the cases. The nasal canal on both sides was completely obliterated by the mucous membrane of the duct. The lower orifice of the meatus could not be seen. There was no lachrymal tumour or fistula, in spite of the complete obliteration, and of the absence of valves, to which structures M. Béraud attributes a considerable part in the formation of these affections of the lachrymal passages. [*Gazette Médicale de Paris*, May 31, 1851.]

---

[1] Ferri Muriatis Tinctura. *Edin. Pharm.* 1841, p. 104. "Take of red oxide of iron, six ounces; muriatic acid (commercial), one pint; rectified spirit, three pints. Add the oxide to the acid in a glass vessel: digest with a gentle heat, and occasional agitation for a day, or till most of the oxide be dissolved: then add the spirit, and filter."

TREATMENT OF INCURVATION OF THE NAILS.

Mr. H. E. Davidson, in the Boston (U.S.) *Medical and Surgical Journal*, says :—The mode that I have employed, and with the most complete success, for the relief of this difficulty, is the following. A piece of a very light watch spring, of sufficient length to extend across the nail from one edge to the other, is turned into short hooks at the extremities. Two plates of silver, sufficiently thin to be easily pliable in the fingers, are to be cut of an oblong shape, say from one quarter to one-sixth of an inch in width by one-third to two-thirds of an inch in length, with rounded corners, and one end punched with a hole of sufficient size to admit the hooked extremity of the steel spring. The nail should be permitted to attain sufficient length to allow the hooks (which are to be made of the above-described strips of silver) to be insinuated under its edges ; the hooked extremities of the spring are then to be passed into the eyes of the hooks, its centre resting upon the centre of the nail. The spring should not be too stiff, or it will elevate the edges of the nail with too much force, and occasion a painful tension of the soft parts attached to it. The more rapid expansion of the nail will be promoted by enveloping the parts in a wet roller. Where the matrix of the nail, and the nail itself, are sound and healthy, I believe that this method will never fail speedily to restore the nail to its normal condition.

A METHOD OF VACCINATING.

Mr. Edward Crosse makes the following suggestion in the *Lancet*. "I know not whether the following mode of vaccination has been before practised ; if not, perhaps you will favour me by its insertion. It consists in forming a blister, by means of a piece of emplastrum lyttæ, the size of a small pin's head, retained on the arm by adhesive plaster sufficiently long to raise the blister, detaching the cuticle with a lancet, and applying the vaccine virus to the raw surface."

"The struggles of a strong child having prevented inoculation by the ordinary methods, I adopted this plan with success. It was rapidly performed while the child slept. A fairer surface for absorption is presented. And this little operation, insignificant in its execution, though important in its results, is much facilitated, and rendered more certain of success."

CICATRISATION PROMOTED BY OAK BARK.

M. Grusell has lately intimated to the French Academy of Sciences, that charpie suspended in a decoction of oak bark for some days and then dried, forms an admirable dressing after the excision of cancerous tumours, as it preserves the simple condition of the wound, and obtains rapid cicatrisation.

GONORRHŒA IN THE FEMALE TREATED BY INJECTIONS OF URINE CHARGED WITH CUBEBS.

M. Hardy, in a paper recently communicated to the Hospital Medical Society of Paris, announces that he has treated with success a great number of cases of gonorrhœa in the female, by administering cubebs internally, and then employing, as a vaginal injection, the patient's urine. He begins with four grammes daily, and increases the quantity by two grammes daily, till he reaches ten grammes. The urine is injected as soon as it is passed. In three or four days, the mucous membrane assumes its natural appearance, and the discharge ceases ; but it reappears if the injections be discontinued. To confirm the cure, it is necessary to cauterise the mucous membrane of the vagina in eight days with a solution of nitrate of silver. In general, three cauterisations complete the cure. [We cannot help suspecting that the use of the caustic lotion is the best part of the treatment ; and that it might be made to supersede the preliminary proceeding in the majority of cases.]

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

Tuesday, April 22, 1851.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

Application of the Heat of Electricity in Practical Surgery. By John Marshall, Esq., F.R.C.S. Eng. The author narrated a case of fistulous perforation of the right cheek, in a strumous man, twenty-five years old. A fine platinum wire, 1-50th of an inch thick, was passed through the fistula, so that its ends could be connected with the poles of a Groves' battery, consisting of four cells, each having a platinum surface of thirty-two square inches, and a zinc surface of thirty-eight square inches. The galvanic current was kept up for nine seconds; but little pain was felt from the action of the heated wire; sloughs appeared at both orifices of the fistula; that on the inner orifice came away on the fifth day after the operation; the outer one was separated on the sixth day. On the eighth day, the inner opening was closed; on the eleventh, the outer opening was also closed. A smaller sinus was discovered some days afterwards on the inner surface of the cheek; and by a repetition of the operation, was also cured within a fortnight. Mr. Marshall had employed the *electric cautery* in rectal fistulæ and in internal and external hæmorrhoids, with success. He anticipated that its employment will occasionally be found more advantageous than the knife, scissors, or ligature.

Benefit derived from the Inhalation of Chloroform in a case of Pulmonary Consumption. By T. Spencer Wells, F.R.C.S. Great alleviation of the cough and sufferings were obtained, without any ill effects.

Inhalation of Chloroform; its Anæsthetic Effects, and Practical Cases. By Robert Dunn, Esq., M.R.C.S. After stating the generally admitted threefold division of the nervous system into—*first*, the physical, or excito-motory and reflex; *second*, the nutritive and secretory, or ganglionic; and *third*, the sentient, psychical, and voluntary, or cerebro-spinal system, Mr. Dunn maintained that there is no point in physiology more clearly made out, than that the great hemispherical ganglia are exclusively the seat of perception and its associate, memory—the centre of intellectual action, and of all the operations of thought—"the sole receptacle", in the language of Cuvier, where sensations become perceived and consummated", formed into ideas by their ganglionic action, and where the will exerts its power; but that they are neither the seat of sensation nor of motion. Sensation has its seat in the sensorium commune, or collection of sensory ganglia; and the motor power, in the corpore striata and anterior segmental ganglia of the spinal cord. Sensation and perception ought not to be confounded; they are perfectly distinct, and have their seats in different nervous centres. The former is effected through the direct agency of the sensory ganglia; the latter is mental, and exclusively cerebral. The mechanism (so to speak) of their action is different. While, in sensation, it is direct and single, each sensory ganglion responding directly to the stimulus received, or impression made on its ganglionic centre; in perception, a double ganglionic action is involved. The various sensations or impressions of the sensory ganglia, as the first step in the process, are transmitted through commissural connexions to the hemispherical ganglia; and there, as the second step, become converted, by the ganglionic action of the cerebrum, into ideas, which furnish incentives to intellectual action, and materials for thought. The corpora striata, thalami optici, and corpora quadrigemina, are distinct cephalic ganglia, each exercising a different function; and they, with the nervous centres of the

special senses and the cranio-spinal axis, constitute the nervous apparatus of automatic life. The thalami optici and posterior segmental ganglia of the spinal cord are the great centres of tactile and common sensation; the corpora quadrigemina are not simply the ganglionic centres of vision, but also of simple emotional impulses, readily excited into action by sight, and independently of the cerebrum. The sensory ganglia are the seat of the emotional feelings, or, in other words, of the feelings of pleasure and pain associated with the emotional states; but, with Dr. Carpenter, Mr. Dunn thought that the true emotions, like the moral feelings and the animal propensities, are of a composite nature, involving an intellectual element, in all of which, the feelings are of sensorial, and the ideas of cerebral, origin.

What are the feelings experienced, and the phenomena observed, during the slow and gradual inhalation of the vapour of chloroform? After giving the different degrees of narcotism noted by Dr. Snow, and the quantities of chloroform required to induce them, Mr. Dunn traced the order and sequence of the effects of the inhalation upon the different nervous centres. The sensory and motor ganglia are the first to come under its influence. Sensation is suspended, and immunity from pain secured, while some degree of intellectual consciousness is still persistent. The function of the cerebrum, in the centre of intellectual action, is the next arrested, and coma supervenes—a total abolition of consciousness, reducing life to a series of automatic movements; after this, the medulla oblongata and true spinal centres become involved. The ganglionic system is the last to be implicated; but, with the arrest of the peristaltic action of the heart, life ceases.

What conditions are necessary to secure uniformity of effect, and safety to the patient? These are, that the chloroform be pure, and that the mode of inhalation be slow and regular, with a proper dilution of atmospheric air. There is not a single fatal case upon record, where these conditions have been rigidly observed. The eye of the administrator ought never to be off the face of the patient. Chloroform destroys life as certainly as carbonic acid, if respired until the excito-motory and ganglionic systems come fully under its dominion. In the succession of effects, during its slow and gradual inhalation, the ganglionic system is the last to become involved, and the contractions of the heart the last of the vital actions to be arrested; but the order is reversed when the lungs have been suddenly overcharged with the undiluted vapour, and the patient may die from the direct effects of the chloroform upon the heart, before insensibility has been produced, and the nervous centres of the encephalon affected. As the inhaled chloroform is again eliminated from the blood, and passes off unchanged by the lungs from the body, it may be fairly inferred, that it acts in its integrity, and not by its separate elements, upon the vesicular matter of the nervous centres; and that beyond the direct and immediate effects produced by its presence in the blood upon these centres, no lasting ulterior or injurious effects can reasonably be expected to result from its use.

Its range as a therapeutical agent is in consequence limited, and its effects often transient; but present relief from pain is a boon to the sufferer, and its modus operandi in regard to the different nervous centres points plainly to the class of medical cases in which it has been found to afford relief; viz. neuralgia, spasmodic asthma, delirium tremens, hysteria, hysterical and puerperal, and some other forms of mania,—certain convulsive and spasmodic affections,—puerperal convulsions, chorea, epilepsy, and tetanus. Still, it is chiefly, if not entirely, in the great majority of cases, as an ancillary to the adoption of more efficient curative measures, that we can view it in the light of a therapeutical remedy.

The use of chloroform in midwifery has given rise to much discussion. Its effects must be studied in their relation to the physiology of parturition. In the sequence of effects from the inhalation of chloroform, as the spinal and ganglionic systems, on which the parturient act essentially depends, are the

last to come under its dominion, we run no risk of seriously interfering with or of arresting their action, if we use common prudence in its administration. In cases of excessive motor action, with a rigid and unyielding condition of the os uteri, passages, and outlet, the advantages of anæsthesia are great. In instrumental midwifery, and in cases of turning, when the patient is nervous, restless, or unmanageable, it presents a valuable auxiliary. The fact, that immunity from pain may be secured without the suspension of intellectual consciousness, ought never to be forgotten in obstetric practice.

Dr. Sutherland mentioned that he had advantageously employed chloroform in two cases of epilepsy, in which the "aura epileptica" was present. In one, the fits were suspended for two years; in the other, for not quite so long a period. He had employed it also in some cases of insanity in St. Luke's Hospital, in which it acted as a temporary sedative, but not as a curative agent. He had, however, seen three cases of puerperal mania resulting from the use of chloroform administered during pregnancy. One of these cases occurred in a lady whose epileptic fits had been suspended by chloroform; in the absence of the nurse she had inhaled a great quantity of the agent, and mania was the result. In another case, he had himself administered the agent; and in the third instance, he had received a letter from the gentleman who had attended the case, in which it was stated that the mania came on after the use of the chloroform.

Dr. Copland, after speaking of the great interest of the paper, said, that we should not employ chloroform in organic diseases of the heart, nor in cases of neuralgia, where there was any reason to suspect that there was disease of the nervous centres. He was surprised that no notice had been taken of the effects of chloroform on the lungs themselves. The gist of the first paper was to show the usefulness of this agent in some spasmodic affections of the air-passages. In some cases, however, it might be injurious. In some cases in which chloroform had been used and the patients had died, symptoms of congestive pneumonia had presented themselves, which were regarded as the effects of chloroform, rather than of the operation to which the patients had been subjected. In some cases in which he had been consulted respecting the inhalation of chloroform in operations upon the teeth, he had generally objected to it; for he had seen two cases of congestive pneumonia from that cause, in one of which cases the patient did not fully recover from the disease under six months. It was most desirable not to use chloroform in cases where there was a tendency to lung disease; and this caution held especially good in early phthisis, in which there was usually a tendency to congestive inflammation.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

Fatty Degeneration of the Placenta, and its influence as a cause of Abortion, Death of the Fœtus, Hæmorrhage, and Premature Labour. By Robert Barnes, M.D. Lond. The author related two cases of delivery at the seventh month. In the first, flooding occurred twice without obvious cause, and unaccompanied by pain, at the third month; and again at the seventh month, when labour followed. In the second case, there was no hæmorrhage previous to delivery. In both cases, death of the child occurred some time previous to delivery. In both cases, the placenta was studded with fatty masses, apparently isolated from the surrounding structure. These masses were firm, yellowish-white, and bloodless. The diseased and apparently healthy portions of the placenta were continuous; and the fatty masses were the result of fatty deposit or degeneration in the proper placental structure. In one case, branches of the umbilical vessels, in an atrophied condition, were traced through several of the fatty masses. In the examination of the minute structure of the altered parts, the author had availed himself of the assistance of Dr. Hassall.

The following conclusions have been arrived at:—The placental villi were thickly studded with innumerable minute spherules of oil. The chorion was much altered; thickened, destitute of nuclei, of a yellow colour, and more or less broken and detached from the vessels. The umbilical capillaries no longer presented nuclei in their walls, these being replaced by spherules of oil. The spherules of oil were contained, some in the chorion, others in the walls of the blood-vessels, many in the intervals or spaces between these. The cavities of the vessels were almost exclusively free from fatty deposition. The vessels were destitute of blood. In some parts, the process had extended to complete disintegration of the original structure. In parts which, to the naked eye, appeared healthy, evidences of fatty deposit and degeneration were observed. A number of specimens of sound placentæ had been examined, and the occurrence of a certain proportion of oil as a normal constituent had been determined. With the exception of a case of fatty degeneration of the placenta, recorded by Professor Kilian, and of which an abstract appeared in the *British and Foreign Medico-Chirurgical Review*, for January, 1851, p. 272, no distinct recognition of the nature of the affection is to be met with. The author thinks that this change of structure promises to throw light on the disputed question of hereditary transmission of predisposition to fatty degeneration. It shows also how rapidly such a change of living structures may take place. The conversion of portions of placenta into solid unyielding structure, and the consequent imperfect attachment of these portions, and of the surrounding healthy structure, to the womb, giving rise to hæmorrhage, and premature labour, may occur possibly during the life of the child. A more frequent occurrence probably is the destruction of the fœtus, in consequence of imperfect nutrition, and by a process of slow asphyxia. Fatty degeneration may also cause abortion in the early periods. With reference to treatment, it was suggested, whether the disposition to this destructive change, if known and established by the observation of preceding pregnancies, might not warrant the induction of premature labour, with the view of anticipating the period at which the fœtus would almost certainly be destroyed if left in the womb. Some suggestions were also offered with reference to the general treatment to be adopted with a view of counteracting the disposition to fatty degeneration before and during pregnancy.

Dr. R. Quain said that fatty *deposition* and fatty *degeneration* were processes entirely distinct in their nature and their effects. The deposition of fat from the blood led to the formation of adipose tissue; fatty degeneration, on the other hand, was a result of the disintegration of albumen and fibrin, and of the tissues into the formation of which they entered. There was here no adipose tissue, but a mere aggregation of granular particles. This disintegration may be witnessed in the formation of adipocire, or it may be made to occur experimentally in dead flesh, and the changes could be then followed by the microscope. It may be observed in various albuminous, fibrinous, and other products in the living body, but beyond the sphere of vascular action, and also in various tissues, the nutrition of which had been modified by inflammation, or obstruction to the blood-vessels. The disease of the placenta under discussion was due to some analogous condition, to inflammatory action, or to some modification of the circulating and nutritive apparatus of the organ, by which the albuminous or fibrinous elements of the blood were retained in the blood-vessels, or extravasated, and then subjected to the process referred to. We were acquainted with a tough, leathery state of the placenta, with calcification of the organ; and the origin of these conditions was to be explained in the same way. It was only by tracing these morbid conditions to the primary lesion which produced them, that we could hope to discover the means by which their recurrence could be prevented.

Dr. C. J. B. Williams said that the whole topic of fatty degeneration

was one of growing importance, not only as constituting a serious lesion in itself, but also as forming a remarkable element, of very common occurrence, in several other morbid processes, in cachectic states. He thought that Dr. Barnes had clearly established the existence of fatty degeneration of the placenta in the cases narrated; but he could not admit it to be probable that this was the primary lesion, or one against which practical measures, to prevent abortion, could be profitably directed. The author had too much regarded fatty degeneration as an independent and original vital process, like that causing hypertrophy, or malignant disease, instead of being, as it truly is, a chemical transmutation of fibrinous or albuminous deposits or textures, consequent on a failure of that degree of the nutritive process necessary to maintain a higher order of structure. One of the earliest observers who had set this matter in its true light was Mr. Gulliver, who, in his paper on the "Atheroma of Arteries", published in the Society's *Transactions*, and subsequently in his editions of Gerber and Hewson, had made known many examples of fatty degeneration of deposits and textures, and had suggested the probability that the change is chiefly chemical. About the same time, he (Dr. Williams) had compared this fatty transmutation in the living body to the conversion of dead flesh into adipocire; and had cited numerous instances, in which the products of inflammation and obstructed natural tissues undergo more or less of a similar change during life. The later researches of his friend Dr. R. Quain seemed to him (Dr. Williams) to have completely established this view, and to have further traced many of the modes in which impeded nutrition promoted the degradation of the natural tissues into molecular fat.[1] It seemed to him (Dr. Williams), that it might now be received as a general law, that whenever tissues or deposits are imperfectly supplied with blood, yet are sufficiently nourished to keep them from becoming dry or decomposed, there will be found the process of fatty transformation, more or less resembling the same change which takes place out of the body. Thus, imperfectly-organized lymph in the pleura, pericardium, or peritonæum; lymph in the texture of the lung or of cellular membrane; fibrinous clots in vessels; blood-clots in the brain; soft, recent enlargements of complex organs, as of the liver, kidneys, testicle; crude tuberculous masses, and torpid growths, non-malignant and malignant, had been repeatedly found by him (Dr. Williams) to afford, under the miscroscope, the clearest evidence of falling under this law. This law is, in fact, a most satisfactory clue to much that has been hitherto obscure in pathology, and unravels much of the mystery of the processes of softening of tissues, maturation of abscesses and tubercles, the breaking down of consolidated masses in spongy organs, and the weakening and wasting of muscular and glandular structures. But this view would teach us to look beyond the mere fatty degeneration itself to the impaired or obstructed circulation, and sometimes altered condition, of blood, which was its cause; and, as in the case of the fatty portions of the placenta, of which they had been hearing, it must often remain a question whether the degeneration was not *rather the consequence, than the cause.*

Mr. Streeter hoped the monograph just read would be published in the *Transactions*, where no disease of the placenta, except Dr. R. Lee's case of adhesion to the scalp, had as yet been recorded.

Dr. Robert Lee endeavoured to throw doubt upon the existence of fatty degeneration of the placenta.

Dr. Barnes had not been convinced of the necessity of the distinction Dr. R. Quain had drawn between fatty deposition and degeneration. He felt great diffidence in dissenting from the explanation of these cases given by Dr. Williams; but he could not admit that the fatty degeneration was the result of the death of the fœtus, or of previous disease in the placenta.

[1] London Journal of Medicine, July 1850, p. 705.

The history of the cases, and the development which the fœtus had in both instances attained, convinced him that the fatty degeneration was the cause of the death of the fœtus; and no evidence of any other disease or morbid deposit was detected in the placentæ. The affection had been traced in the apparently healthy portions as well as in those more obviously altered, through every stage, from simple deposition on the walls of the umbilical vessels, their investing chorion, and the other normal tissues of the placenta, to actual degeneration and disintegration. Dr. Barnes referred to a specimen which had come into his possession, in which the affection presented itself under a different phase; and in which undoubtedly fatty metamorphosis of the placenta had taken place after the death of the fœtus. He should lay an account of this specimen, which still existed, before the Society on a future occasion.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

Cases of Unusual Difficulty in the Diagnosis of Pleuritic Effusions. By T. A. Barker, M.D. In the first case, there was extensive emphysema of the left lung, which had encroached greatly on the right side of the chest, pushing the heart and mediastinum beyond the mesial line. The right lung adhered closely to the costal pleura, and was reduced to about a fourth of its usual size: it was exsanguine, and contained no air, resembling a lung compressed by effusion in the pleura. In consequence of these changes, no respiration could be heard in the right lung during life: the right side of the chest was universally dull on percussion, and the patient could only lie on the right side, or sit erect. There were other symptoms closely resembling those of hydrothorax; and the dyspnœa, and symptoms of approaching apnœa, being very urgent, a very fine trocar was introduced into the chest, to ascertain whether there was fluid. No inconvenience resulted; and the symptoms were explained, on *post-mortem* examination, by the state of parts above described. The next case was one in which, without any of the general symptoms of pleuritic effusion, it was discovered that there was no respiration going on in the posterior third of the left lung. In four days the person died; the lungs were healthy, but there was extensive effusion, confined to the back part of the chest by a very narrow line of adhesion, extending from the upper and back part of the chest to the diaphragm, half way between the ribs and the sternum. Three other cases were referred to, in which pleuritic effusion had been limited by adhesions in the same position. Two other cases were shortly alluded to, in which there was considerable emphysema, but respiratory sounds could be heard in every part of the affected side, in consequence of the lung being kept partially in contact with the ribs by numerous adhesions, forming several separate cavities in which the purulent matter was contained.

Case in which a Fibro-Cellular Tumour was removed from the Hand. By S. Solly, Esq., F.R.S. A married woman, aged 49, was admitted under Mr. Solly's care into St. Thomas's Hospital, on February 22, 1851, with a tumour on the palm of the left hand, resembling in shape and appearance a large oblong potatoe, the diameter varying from three to five inches, and attached by a broad pedicle. Some patches of ulceration existed, two or three lines deep, having none of the characters of malignant disease. The surfaces bled easily, and were surrounded by a limited blush of redness. The tumour was elsewhere of a pale colour, with small tortuous veins ramifying on it. It had an elastic feel, much like that of encephaloid disease: in some parts giving the idea of fluid, in others being firmer. There had lately been some increase of pain, but it was not constant, and depended much on position. The health had been but little affected. The tumour encroached on all the fingers, but did not prevent flexion and extension, and a considerable proportion of the skin of the palm remained intact. Much difference of

opinion existed as to whether the disease was or was not malignant. Mr. Solly was inclined to consider it as a species of enchondroma. By a grooved needle, some jelly-like stuff was obtained, containing much granular matter, with many exudation corpuscles, and some few spindle-shaped cells, with here and there a common epithelial cell. Mr. Solly removed the tumour on March 1st, 1851. When examined, it had the appearance of an enchondroma of a soft kind. There was a firm, white, dense matrix, enclosing glairy fluid. No true cartilage could be found. Portions of the tumour were sent to Mr. Quekett and also to Mr. Birkett. Communications from these gentlemen show that they agree as to the non-malignant character of the disease. A careful report of the actual condition of the tumour after removal, drawn up by Dr. J. L. Bristowe also tends to the same conclusion. The wound was of a healthy character, and, on the 19th of March, it is reported to have been only one-fourth of its original size. The swelling and tenderness of the fingers diminished, and the back of the hand regained its natural appearance.

Aneurismal Dilatation of the Posterior Tibial Vein, communicating indirectly with the Popliteal Artery. By Edward Cock, Esq. G. M., aged 28, a tide waiter, was admitted into Guy's Hospital, October 30th, 1850, for a large swelling on the back of his leg, which had come on after a long and severe attack of fever. This swelling had all the indications of being a deep-seated abscess under the gastrocnemii muscles. Eleven years previously, his femoral artery had been tied for secondary hæmorrhage following a wound in the popliteal space. He had perfectly recovered from the accident and the operation, and the only inconvenience he ever experienced was a swelling of the superficial veins of the leg, which took place about two years afterwards, and became permanent. On October 3rd, a puncture was made in the swelling, which gave exit to nearly three ounces of dark, grumous, pitchy blood, which did not coagulate, and had evidently been extravasated for a considerable period. Two days after the puncture had been made, nearly a pint of pus escaped from the wound, to the great relief of the patient, and the abscess continued to discharge and diminish in size during a period of twelve days, the man's health and strength daily improving. On November 14, sudden and alarming hæmorrhage took place, to the extent of nearly three pints. The cavity of the original abscess became distended with blood, and infiltration was rapidly taking place into the tissues of the leg, and through the popliteal space towards the thigh. It was judged expedient to amputate the leg above the knee, after which the man got perfectly well.

Examination of the Amputated Limb. In the popliteal space, corresponding with the original seat of injury eleven years previously, there existed a small sac, into which opened the popliteal artery, and to the walls of which were attached the termination of a fibrous cord, which represented the popliteal vein, obliterated up to the line of amputation. Proceeding from the interior surface of the sac were two vessels; the one being the continuation of the popliteal artery, reduced in size, and passing down to be distributed normally to the leg, and the other, the popliteal vein, permeable, dilated, thickened, pouched, and puckered, which passed down, and divided as usual into the anterior and posterior tibial veins. The former was completely obliterated; the latter immediately terminated in an aneurismal dilatation, about as large as a hen's egg, and was situated under the soleus muscle. An irregular opening in the sac communicated directly with the cavity which had constituted the abscess when the patient first came under observation, and which subsequently, (at the time when the hæmorrhage took place), had become distended with blood, derived from the popliteal artery by means of its communication with the vein. All the deep-seated veins of the leg had evidently been long obliterated, and were occupied by solid coagulum, the blood having been returned through the agency of the superficial veins.

MEDICAL SOCIETY OF LONDON.

SATURDAY, APRIL 26, 1851.

EDWARD W. MURPHY, M.D., PRESIDENT, IN THE CHAIR.

EXHIBITION OF A MAN WHO HAD HIS ABDOMEN LAID OPEN THIRTY YEARS AGO. By THOMAS WAKLEY, ESQ. MR. WAKLEY exhibited the man, W. W., who, he said, had been for more than thirty years an object of interest to surgeons. A few days ago, he applied at the Royal Free Hospital in consequence of hernia on both sides. He was now about 58 years old. About the year 1823, he was a seaman on board the *Minerva*. The crew had captured three whales, and all hands were employed in "fleuching the blubber", with knives used expressly for that purpose. The fleuching-knives are straight, as long as a scythe, and as sharp as a razor. He had turned from his companions to micturate, and when again returning to his work, the deck being slippery, he fell forwards, with the edge of his fleuching-knife turned upwards. The lower part of the abdomen was completely opened from the anterior inferior spinous process of one side, to that of the opposite side. The intestines protruded on the thighs, and the penis was severed from the trunk. Several bleeding arteries were tied; the intestines were carefully replaced within the abdomen; the edges of the wound were brought together, and retained in juxta-position by numerous sutures: a catheter was passed through the incised urethra into the bladder, and kept there for two months. The bowel was not opened at any part, although the peritonæal covering of the intestine is reported to have been grazed. The bladder was not wounded, owing, of course, to its collapsed condition, as the man had just emptied it of its contents. In less than four months, the parts had quite healed, and the man was able to employ himself in the easy work of the service. Mr. Wakley said, that the case was a very instructive one, showing, under favourable circumstances, what nature (assisted by the surgeon) could accomplish. It was also associated with the names of celebrated surgeons deceased. Sir Astley Cooper, Sir Charles Bell, and others, had considered the recovery so remarkable, that they had lectured to their respective surgical classes upon the case. Sir Charles Bell stated that the man must inevitably become ruptured; and his words have now become verified after more than a quarter of a century. He had only become ruptured within the last two months. Mr. Wakley thought the case unique, as one of a recovery and long life after so severe and extensive an injury of the abdomen.

ON VENOUS MURMURS. BY DR. OGIER WARD. The author began by mentioning the discovery of the sound by Laennec, who, though he had a suspicion that one kind of murmur resided in the jugular vein, yet he was more disposed to attribute the various murmurs heard in the neck to the arteries, and to the bruit musculaire in the platysma and mastoid muscles. M. Bouillaud, who next took up the subject, having attributed the murmurs solely to the arteries, Dr. Ogier Ward was induced to investigate the subject in 1836; and he established it as an indisputable fact, that the sounds in question were produced by the veins alone, though they were modified by the vicinity of the carotid arteries, as regards the internal jugular veins. These conclusions of the author were afterwards confirmed and extended by Dr. Hope and the Committee of the British Association, with a few unimportant exceptions; and were generally admitted by British physiologists, though the French pathologists still adhered to their former opinion. However, in 1843, M. Aran published an elaborate paper on the subject, and induced his countrymen to yield to him an assent which they had hitherto denied to foreigners. From that time the venous origin of the murmurs has been gradually acknowledged in France, and on the Continent generally. The author described the cause of the sound as being the quicker flow

through the veins of blood of abnormal tenuity ; and the difference in the tone of the murmurs produced by pressure of the vessel, to the formation and acceleration of currents in different directions in the vein below the point of pressure. The difference in the sounds produced by shaking oil or water in a bottle is a familiar illustration of this fact, which has been also established by numerous experiments, from which the following law has been deduced—viz., That the increase in the sound is directly as the velocity, and inversely as the density of the fluid. Whenever, therefore, the density of the blood is reduced below a certain standard,—which, however, varies with the individual,—venous murmur is the consequence. Venous murmurs are of two kinds, continuous and remittent ; the former is heard in solitary veins, as the external jugulars ; the remittent murmur is heard in the venæ comitantes, in which the sound is augmented and remits synchronously with the beat of the artery, which modifies it by its pressure on the vein. The external and internal jugular veins afford the best and readiest examples of the sound, from the current of blood being quicker through them in consequence of their ordinary perpendicular position ; but the sound ceases in the horizontal posture, or if the head be lower than the body. On the other hand, the sound is increased, and its tone rises to what is called the "musical hum", by slight pressure of the stethoscope, by which the rapidity of the venous current is augmented ; and also during inspiration from the influence of the same cause. In examining the murmurs, care must be taken to avoid confounding the remittent venous sound with the intermittent bellows murmur that is often heard in the carotids. All observers, both in this country and on the Continent, except the British Association Committee, concur in confining the existence of venous murmurs to persons of weak constitutions, or suffering from disease or loss of blood. Hence it is met with universally in chlorotic and anæmic subjects, whose blood is deficient in several of its constituents, but especially in red globules.

Dr. Ogier Ward having remarked the frequency of the venous murmur in children, whether anæmic or florid, was induced to make a number of observations upon them, and the result he has obtained is, that *all children, male or female, under seven years of age, exhibit the venous murmur.* In girls it generally continues till after puberty and the establishment of menstruation, whether the person be pale or florid. The author has not been able yet to establish the average period of its cessation, either in boys or girls, but from the frequency of its occurrence in adult young women, he believes that a very slight derangement of the general health is sufficient to produce it in them. The greater proportion of water in the blood both of children and females, is a satisfactory explanation of these facts. There is, however, so great a discrepancy in the analyses of the blood taken from such patients, that no exact limits can be assigned to the variations consistent with the health of the individual, as determined by the presence or absence of the venous murmur. With the exception of children, the existence of venous murmurs offers a pretty sure guide to the diagnosis and treatment of various diseases attended with a change in the condition of the blood. In the adult, the author has never met with a case in which tonic remedies were not useful, especially iron, unless the patient laboured under some form of disease that counteracted its influence. The selection of the preparation of iron best adapted to the case, must be guided by the symptoms.

Saturday, May 3, 1851.

Edward W. Murphy, M.D., President, in the Chair.

On some Fallacies in the Modern Practice of Medicine, more especially Homœopathy, and in estimating the Results of Practice by Imperfect Statistical Inquiry. By Dr. Routh. He would not enter on the subject of the theory of homœopathy, but simply on that of the practice—*i.e.*, the argument of experience. To prove this, homœopaths first dis-

figured the allopathic practice, and then advanced on their side statistical tables well calculated to deceive. In defence of rational practice, Dr. Routh adduced chlorosis as an example, in which the blood-globules and the iron contained in them were deficient. In a healthy person the iron varied from thirty-three to forty-five grains—an appreciable quantity, which infinitesimal doses would not congregate in centuries. In the collection of these data, homœopaths overlooked three considerations: 1st. Differences of locality, whereby type, variety, and amenableness to treatment, were greatly affected, illustrating this point by his experience on visiting the continental hospitals. 2ndly. The constitutional or prevailing diathesis of diseases in the same places might vary. The present type of British disease was adynamic; twenty years ago it was dynamic; hence many cases of homœopathic success now. 3rdly. There existed at present a peculiar mental epidemic, as it were, which often tended to effect cures; a tendency to perversion so powerful as, by its influence on the mind, to assist recovery materially. To this cause he ascribed several instances of cures, and astounding results which he had obtained by coloured water. Here was one secret in homœopathic cures. That such was really the case was proved by the failure of homœopathy in the treatment of animals. The real cases of cure were only those in which, if left to themselves, the animal would have recovered, or where a most severe dietetic regimen was also conjoined. These alleged cures also were anonymous, or came second-hand, reported by non-medical persons. The alleged cures of farcy and glanders in horses, extending, as they did, over two to twenty-eight months' treatment, he believed were either not genuine, or chronic cases, where the disease had worn itself out. The argument from children was only negative. This class of patients was most of all susceptible to dietetic regimen.

Dr. Routh then entered largely on the subject of the general mortality in hospitals. The homœopaths gave a result of 4 to 6 per cent. The allopaths, sometimes as low as 2 per cent., gave a result usually of 7 to 9 per cent. This he illustrated by results from the different hospitals in Europe. Amongst the causes of this disparity he had traced the following:—

1st. Homœopaths excluded in their results the cases brought in moribund. Allopaths did not. He showed, however, a table of the mortality from fever in Belfast, from Dr. Mateer. This exclusion, in an average of eighteen years, diminished the mortality 22 per cent., and in 1821, 127 per cent. If it were so for one disease, what would it be for all?

2. Were the cases admitted as severe? Owing to the natural distrust in homœopathy, few severe cases came to them. They went to the allopathic hospitals. He had seen one patient admitted for very slight headache; cases of intoxication, and vast numbers of hysterical cases, were included. This, by increasing the number of non-fatal diseases, necessarily diminished the per centage of mortality.

3. The numbers used were small; and he (Dr. R.) showed, from the Irish tables of hospital mortality, that no returns could be depended upon unless above 10,000. It was said 100 well-selected cases gave good results. He believed, however, from experience, that they were only in the direction of truth. Another 100 cases equally well selected might give a direct negative.

4. Another source of fallacy was the different amount of comfort enjoyed by hospital patients. From personal observation he could state, that Fleichmann's Hospital was unsurpassed in this respect by any other hospital he had seen. The students were either none or few in number, and the patients were not tormented by repeated manipulations.

5. The patients were both younger and of a better class. Out of 320 patients seen in that hospital by Dr. Balfour, 280 were under 40, only 22 above. In the published account for Linz, in 1844, out of 555 patients, 478 were under 40. They were of a better class, not the very poor and weakliest. This he had personally remarked, as had also another Fellow of this Society, Dr. Glück.

The effect of youth in arresting the mortality of disease generally was well-exemplified in the army returns, where, out of some 400,000 admissions, the mortality was only in 1 in 56. In the navy, out of 300,000, 1 in 101.

Dr. Routh alluded to the homœopathic returns from *pneumonia*. Homœopaths were fond of quoting Grisolle's 304 cases, with a mortality of 13 per cent. Dr. Sampson had collected 909 from Briquet, Grisolle, the Edinburgh Infirmary, and Skoda, giving a mortality of 23 per cent. In opposition, Fleischmann's cases were quoted—300, with a mortality of 6 per cent; or from a larger collection, including the results of three other hospitals, 970 cases, with a mortality of 43 or 4 per cent. Many of the reasons above given would explain this; some require, however, particular mention,

1st. Pneumonia in Austria is seldom complicated—usually simple idiopathic. This he attributed to the extreme rarity of Bright's disease of the kidney in that country; and in many returns the complicated were usually classed under the head of the fatal complications, and thus escaped notice. The complicated were only distinguished from the idiopathic in the Linz returns. From 1843-6 there were 93 cases of idiopathic; only eight of complicated: proportion, 8 per cent. In Dr. Tessier's 41 cases, the proportion was 14·6 per cent. In 140 he had collected, occurring in the practice of Drs. Taylor, Walshe, and Peacock, 55 per cent. were complicated. This would explain the difference of mortality. The cases of the Glasgow Infirmary, so often quoted by homœopaths, from 1843-45, were mostly all complicated, chiefly typhoid, and many brought in moribund.

2nd. Age was most important in pneumonia. The mortality was high above 40; low below it, excluding children. The army returns gave the mortality out of 12,000 cases as 1 in 29, sometimes as low as 1 in 45; the navy, 1 in 26, sometimes as low as 1 in 59, out of some 3,000 cases. The best homœopathic return was one in 22; Fleischmann's, 1 in 16; and these were simple cases; the others mixed.

3rd. Sex was another most important feature. The distinction was not made by homœopaths. There were 75 males usually seized by pneumonia to 25 females; but the per centage of mortality among females was more than double. Indeed, by comparison in the Registrar-General's Returns for 1843 and 1844, calculating from 8,000 fatal cases, the different numbers of persons living at each age, the per centage mortality to seizure from pneumonia, excluding children, was 100 males to 211 females. In Dr. Tessier's 41 cases, 3 only were females; and if we took Fleischmann's 19 cases, recorded by Dr. Balfour, as a sample of all, the results from the preponderance of males would be 4 per cent.; too favourable.

Dr. Routh then gave an analysis of Tessier's 41 cases. There were 3 deaths; the cases were, 4 only of double pneumonia, 1 fatal; 30 of simple idiopathic single, 1 fatal; 1 secondary and fatal; 5 complicated. Of these 38 successful, 1 died, before leaving the hospital, of phthisis; another, of erysipelas: giving thus a mortality of 1 in 8. In the 38 besides, 6 had been treated also allopathically, and should be excluded; leaving 35 cases, 5 deaths, or 1 in 7. The cases treated allopathically had a shorter duration of treatment, and left the hospital sooner after convalescence. For so many cases of idiopathic, and with so many males, this was high. On the other hand, the analysis of 141 cases in the practice of Drs. Taylor, Walshe, and Peacock, gave 43 deaths: mortality, 1 in 3; but in this number (141) there were 33 cases of idiopathic single pneumonia, 14 idiopathic double, 2 deaths, among males: mortality, 1 in 23; among the females, 5 of idiopathic single, none of double pneumonia: general mortality for idiopathic, 1 in 25. There were 9 cases of simple pleuro-pneumonia among males, and no deaths; giving a mortality of 4 per cent. only. The remaining were complicated: 52 cases, 30 deaths among males, or 1 in 1·7; 26 cases, 12 deaths, among females; mortality, 1 in 2: total, 78 cases, 42 deaths, or 1 in 1·8. In 127 cases the

age was stated; 61 males under 30, 35 above; 17 females under 30, 14 above; or 78 under 30, 49 above.

After some remarks on the inert treatment observed in such cases by the Viennese allopaths, Dr. Routh concluded by giving examples where under divers treatment, the mortality with Laennec, Wolf, Bouillaud, Louis, etc., had been occasionally very low; adducing also the eleven of Grisolle, cured by emollients only. Declining, however, to deduce conclusions from small numbers, he finished by stating, that idiopathic simple pneumonia under 40 was a very benignant disease; instancing the cures effected by drinking cold water only in many of these cases, as recorded by the Belgian Commission, Drs. Moreta and Compagnani, in Italy. The best treatment in these cases appeared from the researches of Dr. Dietl, of Vienna, the allopathic physician to the Wieden hospital, to be simply the dietetic. Dr. Dietl had treated 85 cases of pneumonia by bloodletting, with a mortality of 20·4 per cent.; 106 by tartar-emetic, mortality 20·7 per cent.; and 189 by simple and strict dietetic regimen, mortality only 4·12 per cent. The bleeding often made the pneumonia complicated. The homœopathic returns should be more carefully analysed before credit was given them; he attributed success to the powers of Nature, and the selection of cases; and, perhaps, even amongst rational practitioners, good might result by trusting more to Nature and diet.

Saturday, May 31, 1851,

Edward W. Murphy, M.D., President, in the Chair.

Galvanic Cataplasms of M. Recamier, by E. J. Tilt, M.D. The cataplasms consisted of galvanic piles, each composed of twelve couples. The couple was formed by a riband of zinc and copper; and each couple was separated by a piece of flannel. On the coloured side was cotton wool; on the other, a piece of gutta percha tissue, to insulate the apparatus. The electrical force generated in the apparatus found vent through the copper rings, to which the insulated copper wire could be attached when the energy was required. In some people, the acrid perspiration was sufficient to increase the intensity of the electric action, but more active effects were produced by wetting the flannels with dilute vinegar, or a weak solution of common salt. An unusual sensation of warmth was felt when one of these cataplasms was tightly bound to the skin; a pricking sensation was felt, and the skin becomes red, when two were placed at a distance from each other, but connected by the wire; and a stronger effect was produced when one was placed over the seat of pain and another on the spine. The apparatus might be worn without inconvenience night and day. It had been successfully used by Professor Recamier in cases of chlorosis and amenorrhœa; and he was trying its effect in sterility probably connected with ovarian disease. He has also employed the galvanic cataplasm with success in the treatment of rheumatic and nervous pains, in a case of obstinate constipation, and in asthma; and a patient with angina pectoris was benefited, but not cured.

Treatment of Febrile and other Diseases through the Medium of the Cutaneous Surface. By William Taylor, Esq. The author expounded his views on the treatment of fever, scarlatina, measles, and by lardaceous inunction. Notice has already been drawn to this subject in the London Journal of Medicine, vol. for 1850, pp. 865 and 970.

This being the last night of the Session, the President delivered a suitable valedictory address, in which he urged Fellows to forward their papers early to the Council, as in future suitable papers only are to be brought forward.

MISCELLANEOUS INTELLIGENCE.

THE JENNER MONUMENT COMMITTEE.

In our last number (p. 587) we alluded to the means which were being taken to erect in bronze, in a suitable situation in London, Mr. Calder Marshall's statue of Jenner, the model of which has been placed in the Great Exhibition. We had hinted that the Committee were backward in coming before the public, and that precious time was being lost. We have since received a most satisfactory communication from the Honorary Secretary. We now find that the delay has been unavoidable, and has arisen from a most praiseworthy resolution of the Preliminary Committee, that the benefits of vaccination not having been confined to Great Britain, but having extended to the whole world, the monument of its illustrious discoverer ought not to be a merely national testimonial, but a tribute to his memory *from all nations*. In consequence of this, applications were sent to many eminent men in foreign parts, asking them to be members of committee and receivers of subscriptions in their respective countries; and sufficient time has not yet elapsed to allow of replies being received to all these communications. These answers, however—all of the most gratifying description—are now rapidly coming in, and the names of the Committee, and the methods and plans for receiving contributions will, we understand, be immediately made public.

The total expense of erecting the statue, with its pedestal and *basso relievos*, is estimated at something under £4,000. When we consider the hearty zeal which the very mention of the scheme has already called forth, we are convinced that the amount of subscription will far exceed this sum; indeed, we do not anticipate that less than £20,000 or £30,000 will be collected; and we should certainly have wished that the Committee had announced the object to which the subscriptions are to go, after the £4,000 has been expended on the specific object of the statue. We find, however, that the Committee are by no means so sanguine as ourselves, and that they think it most prudent to confine their exertions for the present to the one definite object of the statue. At the same time, they wish it to be understood that, in the event of our anticipations appearing correct, they will be prepared to take immediate steps to ascertain the opinion of the Subscribers on any plan for the disposal of the surplus which may be suggested. On the whole, we are not disposed to complain of this determination; more especially when, in the event of the subscription list verifying our prediction, it guarantees the very publication we contended for, which, moreover, would certainly be unnecessary, unless the amount collected exceeds the £4000 required for the statue.

We have been gratified with the perusal of many cordial letters of adhesion received from eminent foreigners; and we regret that our limited space will, in this number, enable us to print but a very few of them: but on a future occasion, we propose to lay before the profession more of these interesting documents, including some of the most gratifying character, just received from the United States.

1. *From the* Chevalier John de Carro, M.D., *of Carlsbad, the friend and first disciple of Jenner.*

My dear Sir,—I am highly flattered by your letter of the 19th instant, about Jenner's Monument. You can place my name on any paper by which subscriptions may be raised. I give you here for that purpose my various titles, of which you can insert what you please.

Chevalier John de Carro, *M.D. of the Faculties of Edinburgh, Vienna, and Prague; Physician at Carlsbad, Honorary Citizen of the same town;*

decorated with the Imperial Austrian Golden Cross with the Crown for Civil Merit; Corresponding Member of the Imperial Society of Physicians at Vienna; Actual Member of the Society of the National Museum of Bohemia.

I take the liberty of sending to you the list of the various proofs of what I have done as *friend and first disciple of Jenner*.

Being perfectly sure that the present generation knows but very little of what I did for India half a century ago, you will oblige me very much, in my old days, in submitting these indisputable facts to those who must feel its advantages there, and to whom their author may not have had the good fortune to make himself known. I shall always be happy to hear from you regarding the progress of your grand enterprise; for though an old man, my activity knows no bounds. Dispose of me and of my good will. So busy as I am as a Spa-physician, I shall always find time for answering your letters, and for doing everything in my power.

Believe me, my dear Sir, with the highest regard, your most obedient humble servant,

J. DE CARRO, M.D.

Carlsbad, at Sir Walter Scott's, 1st of May, 1851.

To George Vere Irving, Esq., Hon. Sec. pro temp.,
10, *Ampthill Square, London.*

FACTS.

1. I was born at Geneva in the year 1770, and graduated at Edinburgh, on the 24th June, 1793. I began vaccination on the Continent of Europe on the 10th May, 1799, at Vienna, on my two sons, Charles and Peter, both still alive.
2. In the year 1800, I sent, by Lord Minto (formerly Sir Gilbert Elliot), British Envoy at Vienna, whose physician I was, to the Earl of Elgin, British Ambassador at Constantinople, vaccine matter, which succeeded perfectly on his children.
3. This success having caused a great sensation in some parts of the East, I was desired to send vaccine matter to the British Resident at Bagdad. It arrived fluid, and succeeded. A vaccinated child was sent, immediately after the insertion, to Bassora, where the same thing was done, and a vaccinated child sent on to Bombay; from Bombay all over India, to Ceylon, Persia, etc. etc.
4. Jenner, in his *Continuation of Facts and Observations on the Variolæ Vaccinæ*, 1800, p. 5, attests my priority on the Continent of Europe. Drs. Ballhorn and Stromeyer, of Hanover, who followed my example, dedicated *to Dr. Jenner and to me* the account they gave of their first experiments, published at Leipzig, 1801. Friese, of Breslau, and Nowack, of Schmiedeberg, who received from me their vaccine matter and instructions, dedicated *to me alone* the result of their labours, calling me the *first vaccinator on the Continent of Europe*, and the *most active propagator of the vaccine in Germany*. All of them are long ago no more alive.
5. All the attempts made by Dr. Jenner to transplant his preservative to India failed, very likely for want of precaution in keeping it fluid. Every ship sailing to India was supplied with it, but all in vain. In his despair about it, he offered a reward (from his own purse) of £1,000 sterling. I should have been happy to claim it from a sovereign, or from a government, but never from a colleague.
6. Jenner sent me a silver snuff-box, upon which was engraved "*Edward Jenner to Jean de Carro*" for my European and Asiatic propagation; and he did the same honour to Dr. Benjamin Waterhouse, of New Cambridge in America, being the first vaccinator in the New World! When my jubilee for fifty years of doctorate was celebrated here, on the 24th June 1843, my silver snuff-box, containing a lock of Jenner's hair, sent to me by Dr. John Baron, of Gloucester, his friend and biographer, was deposited by me at the National Bohemian Museum of Prague.

7. The diploma of congratulation, sent to me for my jubilee, by the medical faculty of Prague, is addressed to me as : *viro, scientiâ, scriptis æquè ac factis clarissimo ; immortalis Jenneri amico et proto apostolo, cujus de vaccinatione merita vastus resonat orbis ; medicorum Nestori, juvenili solertiâ insigni.*
8. When Sir Arthur Paget, British Envoy at Vienna, who succeeded Lord Minto, and forwarded my correspondence with the East, knew my first success at Bagdad, he announced it to the East India Company in London, a committee of which voted to me, the 20th of March 1804, *two hundred guineas for the purchase of a piece of plate.*
9. Dr. Milne, who had distinguished himself very much at Bushire in Persia, by spreading vaccination, was transferred to Bombay. Having heard from some traveller coming from Vienna, that I was going to be married a second time, he begged leave to offer to my future wife a pair of Cachemere shawls. He desired Mr. Jonathan Duncan, governor of Bombay, to forward them to Vienna ; but His Excellency refused it, saying that he would take the present on himself, adding to the pair of shawls three pieces of beautiful muslin. The present was voted by the *Honourable Governor in Council*, in the most flattering terms.
10. Our late Emperor Francis conferred on me hereditary knighthood, and his diploma confirms all the merits for vaccination.
11. The present Emperor Francis Joseph has conferred lately on me the *golden cross with crown, for civil merit.* The inclosed description, written by one of my colleagues, relates the festivity of my decoration.
12. The Hospodars of Moldavia and Wallachia, Alexander Moronsi and Constantin Ypsilanti, rewarded me, a great many years ago, by valuable presents, for the introduction of vaccination into their principalities.
13. Ludwig I, king of Bavaria, did me the honour to grant to my eldest daughter the honorary canonicate of the Royal Order of Ste. Anna, a decoration only conferred upon regular proofs of nobility.
14. My third son, Edward, had Dr. Edward Jenner as *god-father.*
15. It may here be a matter of interest to know how I sent the vaccine fluid so successfully to Bagdad : I impregnated with it some dry lint (charpie), which I placed between two flat pieces of glass, one of which had a little cavity ; some mucilage joined them hermetically ; they were tied with pack-thread, sealed with red wax, and the whole of it was surrounded with candle-wax, under the form of a middle-sized apple.

N.B. All these notes are completely at the Committee's service, as well as any further correspondence. LE CHEVR. J. DE CARRO, M.D.

Carlsbad, 1 May, 1851.

P.S. I have published : *Histoire de la Vaccination en Turquie, en Grèce et aux Indes orientales.* Vienne, 1804. Dédié à S. E. M. Arthur Paget, Envoyé Brittanique à la Cour de Vienne. Translated into German by F. G. Friese, M.D. Breslaw, 1804 ; with important additions of the author and notes of the translator.

THE JUBILEE[1] of the fiftieth year of the doctorate, celebrated here on 24th June 1843, in honour of the Chevalier John de Carro, the friend and first apostle of the immortal Edward Jenner, occupies the most honourable place in the annals of the Baths of Carlsbad. Yesterday (19th December 1850), the Order of the Golden Cross, with the Crown for Civil Merit, were conferred, most justly, by His Majesty, our august emperor, on the Nestor of the physicians of Bohemia, or rather of the whole empire, and whom we are proud to reckon among our fellow-citizens. This *fête* has caused true joy to

[1] We give above a translation of this inclosed paper, referred to in paragraph 11. In our Number for February 1851, p. 191, we briefly mentioned the honours which had been conferred on Dr. de Carro.

all our good inhabitants, who know all that he has done to add to the celebrity of Carlsbad, and to make it better known in the five parts of the civilised world.

All his colleagues came to conduct him to the place chosen for the decoration, the *Cabinet des Gazettes* in the house of Mühlbad. This solemn march was accompanied by a most brilliant flourish of trumpets. There the ceremony of decoration took place, in the presence of all the authorities of the town and numerous spectators, in the above-named hall, which was decorated with a portrait of our august sovereign, surrounded with garlands.

When the ceremony was ended, our Nestor, who acknowledged that he owed his perfect health to our Naiads, to whom he had devoted his labours for a quarter of a century, was conducted solemnly, and accompanied by all the witnesses of the ceremony of installation to the Golden Fleece (*Maison de l'Etoile d'Or*), where a large banquet was given in his honour by M. J. P. Knoll, burgomaster of Carlsbad. During the dinner, the band of the regiment of Welden, composed of seventy instruments, executed the most brilliant pieces. The guests warmly responded to the toasts, which were most honourable and fitting to this occasion, and the first of which was our august and youthful monarch. Another was in honour of the illustrious chief of the Imperial armies, Marshal Radetzky, and was followed by the most animated *vivats*. The Austrian Hymn was magnificently performed ; and numerous toasts were given and harangues delivered in honour of the hero of the feast. A collection was made by our worthy dean, for some poor families of the place.

Thus passed the *fête*, remarkable for its perfect cordiality, and an evidence how true merit can be recognised and appreciated. Dr. Mannl.

II. Professor Otto, *of Copenhagen, to* G. V. Irving, Esq.

Copenhagen, April the 20th, 1851.

Sir,—I hasten to inform you, that I feel much honoured by being chosen a member of the permanent committee about to be formed for raising subscriptions to erect a monument to Jenner, and consequently can have no objection to my name being placed on the list. If I can be of any service in my country as to the procuring of subscribers, I shall certainly do my utmost ; but I fear that the many sacrifices which the late war has required, will shut the pockets of many who else would be well disposed to open them for that purpose. Hoping to call on you in London in June,

I am, Sir, with many compliments to Mr. Spring,

Your obedient servant, C. Otto.

III. Professor Schrœder Van der Kolk *to* G. V. Irving, Esq.

Sir,—I felt highly honoured and obliged by your most gracious offer of permitting my name to be placed amongst the honourable men who intend to form a permanent committee for the erection of a statue to the immortal Dr. Jenner, to whom mankind is so much obliged, and I accept it with the utmost gratitude. But since I am not informed what are the duties implied on the committee in question, I beg you to make me acquainted with them. Is it your meaning that I should try to collect subscriptions in Holland for the erection of the proposed statue, or do you wish me to be useful for it in any other respect ? If these requirements do not exceed my powers and means, I shall feel highly glad to concur in the universal acknowledgement of the great merits of Dr. Jenner. A few lines from you on this subject would therefore afford me a great pleasure, and in the expectation of this, I remain with the utmost respect, Sir, your most obedient servant,

Utrecht, 10th April, 1851. J. L. C. Schrœder Van der Kolk.

iv. *From* Dr. Seoane *of Madrid.*

Madrid, May the 8th, 1851.

To John Conolly, M.D., *Chairman of the Preliminary Committee for raising Subscriptions to erect a Monument to* Jenner.

Sir,—It is with great pleasure I have just received your kind invitation to form part of the permanent committee about to be formed for raising subscriptions to erect a statue to Jenner. I hold in the greatest veneration the memory of this great benefactor of mankind, and I believe with the Committee, that it is the duty of all the nations of the earth to contribute for raising a monument worthy of such a man. I shall have, in consequence, much pleasure in doing everything in my power to promote this idea.

I will receive and put willingly in execution the instructions of the Committee ; and I pray you to send me the letters with the directions you will find below, in order that they may reach me without the retard with which I have received your letter ; and if you have to send me any printed papers, I hope you will be kind enough to send them, with my direction, to the Spanish ambassador, to whom I write to-day with this object.

I am, Sir, your most obedient servant, Mateo Seoane.

P.S. A Don Mateo Seoane, Presidente de la primera Seccion del Consejo de Sanidad. Calle del horno de la mata, Madrid.

v. *Translation of a letter from* Dr. J. Müller *to* Dr. J. Conolly.

Honoured Sir,—I have just returned from a journey to Triest, where I have been staying some weeks this spring, in order to continue some observations which I made there last autumn. My answer to your letter, which arrived here while I was absent, is therefore rather late. I can quite understand the feelings which prompt the English physicians to erect a Memorial to *Jenner*. There is no medical service which can be compared to that which he has rendered, with regard to *universality*. And as its effects spread over the whole human race, it deserves our acknowledgment, that the Committee for the erection of the *Jenner Monument* do not confine the subscriptions to the countrymen of *Jenner*, but rather, that individuals of other nations should assist. With regard to your proposal to add my name to the permanent committee, I can assure you that I with pleasure acquiesce in it, and that I feel myself honoured by that participation. Accept, at the same time, the assurance of my exceeding respect for you. J. Müller.

vi. *Translation of a letter from* Dr. de Lima Leitao, *of Lisbon, to* John Conolly, M.D., *and* George Vere Irving, Esq., *London.*

Gentlemen,—I have had the honour to receive the letter which you have written to me, dated the 11th of this month, by order of the preliminary committee, of which you are the President and Secretary, intended to raise subscriptions for the erection, in a public place in London, of the statue in bronze of Dr. Jenner, after the design of Mr. W. Calder Marshall. You invite me to take part in the permanent committee, which is about to be formed for this object. I am deeply sensible of the honour which the respectable committee has thus shewn me. Persuaded that the great discovery of Dr. Jenner, most glorious for England, has been also extremely beneficial, and will always be so, to the whole civilised world, I think that the Committee is performing an act of universal justice, in permitting the whole civilised world to subscribe to a monument worthy of the man who has bestowed on all the same memorable service, by the discovery of vaccination. You may therefore place my name on the list of the permanent committee ; and I beg you to assure them that I will, according to your desire, do all in my power. Believe me, Gentlemen, with respectful esteem, your very devoted servant,

A. J. de Lima Leitao, M.D.,
Professor of Clinical Medicine in the Medico-Chirurgical School of Lisbon.

Lisbon, April 30, 1851.

VII. *From* DR. MARX *of Goettingen.*

Goettingen, 27 April, 1851.

HONOURED SIR,—The honourable invitation to promote the raising a memorial to Jenner, I accept with thanks.

I have seized every opportunity which has on former occasions offered itself, of manifesting the most perfect esteem for the memory of that noble man, and distinguished physician; as well as for his insufficiently recognized services to suffering humanity. The last opportunity I had of doing this was when his biography by John Baron appeared. I noticed this in our literary pages, and made some additions, which may not be uninteresting to the author, if they should come under his notice. My review is contained in the *Göttingischen Gelehrten Anzeigen*, 1839, pp. 92-115.

The political commotions in my country have of late years almost exclusively occupied time, strength, and resources. It is to be hoped that another lively fellow-feeling will soon be roused.

With the assurance of deep respect, Yours humbly, MARX.

THE HOMŒOPATHIC FELLOWS OF THE EDINBURGH COLLEGE OF PHYSICIANS. The Edinburgh College of Physicians consists of Fellows of two classes; the RESIDENT and the NON-RESIDENT. The former pay a larger fee on admission, and have a seat in the College; the latter have no participation in the government or advantages of the institution, excepting the right to call themselves Fellows; but if they subsequently go to reside in Edinburgh, they must, if called on, pay the difference of fee, and *de facto* join the College. It is rumoured that three gentlemen in the Resident List (though two of them only are actually living in Edinburgh) practise homœopathy, and are cut off from professional intercourse with their brethren, by the Resolutions which we reprinted at p. 588 of last number.

1. DR. WILLIAM HENDERSON, Professor in the University of Edinburgh.
2. DR. WILLIAM MACDONALD, Professor in the University of St. Andrews.
3. DR. RANSFORD, once in practice in Edinburgh; then in Alnwick; and now (since his adopting homœopathy), in York.

Dr. Henderson, early in his career, exhibited some talent, and might eventually have taken a good position in the profession; Dr. Macdonald is better known as a transcendental anatomist, than as a practical physician; Dr. Ransford, though not of note or notoriety in any branch of medical science, was well known to the medical profession in Edinburgh, as the bustling and efficient Treasurer of the College of Physicians.

COLLEGE OF SURGEONS OF EDINBURGH AND HOMŒOPATHY. At a Meeting of this College, held on the 16th of May, the following Resolutions were moved by the President, and unanimously carried. In Scotland, therefore, the homœopathic quacks are now fairly expelled from the ranks of the profession.

1. The College having considered a series of Resolutions, transmitted by the Royal College of Physicians [of Edinburgh] in regard to homœopathy,[1] feel called upon to express their opinion that the system so designated, being entirely inconsistent with the principles professed by candidates for the diploma of the College of Surgeons, any Fellow or Licentiate who practises it, or countenances others in doing so, by meeting them in consultation, will justly incur the disapprobation of the College.

2. That a copy of the above Resolution be transmitted to the Royal College of Physicians.

Signed in name and by authority of the College,

JAMES SYME, *President.*

[1] LONDON JOURNAL OF MEDICINE for 1851, p. 588.

The New Hospital for Consumption. The foundation stone of the City of London Hospital in the Victoria Park, was laid on Wednesday the 25th June, by His Royal Highness Prince Albert, under the most auspicious circumstances. After the ceremony, a large and distinguished company partook of a splendid déjeuner. The Earl of Carlisle, the Chevalier Bunsen, and the Bishop of Oxford, greatly enlivened the proceedings, by eloquent and interesting speeches. A blessing on the work was invoked by the Bishop of London. On the 11th of June, 1844, His Royal Highness Prince Albert laid the foundation stone of the sister institution at Brompton.

Brompton Hospital for Consumption and Diseases of the Chest. The authorities of this Institution are at present actively engaged in collecting contributions, for the purpose of completing this edifice. A grand military concert and fancy fair, held on the 18th and 19th June, in the gardens of the Royal Hospital, Chelsea, have, after paying all expenses, cleared we believe, about £1,000. It is proposed to have, this season, another fête, with the view of raising a further sum of money for the building fund.

Mesmerism numbers among its votaries, two illustrious northern Professors, viz:—Dr. Gregory, of Edinburgh, and Dr. Macdonald, of St Andrews. Dr. Macdonald has recently been delivering familiar lectures on the nervous system, at the house of Mrs. Holmes, a fashionable mesmerist, residing at 4, Cork Street, Burlington Gardens.

APPOINTMENTS.

Lane, James, Esq., elected Assistant Surgeon to the Lock Hospital, *vice* Henry Lee, Esq.

Lee, Henry, Esq. (formerly Assistant Surgeon), elected Surgeon to the Lock Hospital.

OBITUARY.

Miller, Dr., F.R.C.S.Edin., late of 32, Buccleuch Place, at 11, Arniston Place, Edinburgh, on the 8th June.

Phillips, Thomas, Esq., late member of the Medical Board, Bengal, founder of the Llandovery School, and of several scholarships in St. David's College, Lampeter, to which College he had for many years been a munificent benefactor; at his residence, Brunswick Square, London, in his 91st year.

Rogers, William, Esq., F.R.C.S.Eng., at his residence, on the 6th June, aged 54. He practised at Great Stanmore, and in its vicinity, for the last thirty years. He was much esteemed.

Rowland, Samuel Baker, Esq., poisoned by hydrocyanic acid, aged 33, at his residence, Walham Green, Fulham. Mr. Rowland was the assistant and successor of the late Mr. Rouse, who perished by the same poison. On two occasions, Mr. Rowland was shipwrecked, and made wonderful escapes.

ORIGINAL COMMUNICATIONS.

ON THE MUSCLES OF THE EYEBALL, AND THE NERVOUS INFLUENCES WHICH REGULATE THEIR ACTIONS.

By HENRY LEE, Esq., F.R.C.S.Eng., Assistant-Surgeon to King's College Hospital, and Surgeon to the Lock Hospital.

Most of the voluntary actions of our bodies are performed by us with reference only to the end which we have in view, while we generally remain unmindful of the mechanism by means of which they are produced; and with respect to the involuntary motions, which are the most important of all, provision is made for their continuance day after day, quite independently of our will, or even of our consciousness. Each muscular fibre employed in the former set of movements is under the influence of, and guided by, common sensation, or what may be termed the muscular sense. This may be appreciated by, and may act in concert with, the will. Thus we are quite conscious of the amount of effort made in endeavouring to raise a weight, although we do not move it. This sense it is which gives us the knowledge of the exact amount of force required in different muscles, in order that they may concur in producing any movement of the body. If this sense is impaired, or ceases to act in conjunction with the will, the muscles act irregularly, imperfectly, or not at all. When, for instance, the nerve of sensation has been paralysed in the head of a horse, the lower lip will hang, and the animal will be unable to eat its food, because it does not *feel* the amount of *effort* required in the several muscles to produce a combined action. Or, again, when a person loses sensation in his lower extremities, although the power of motion is unimpaired, yet will he be unable to walk, because he has no means of knowing or of indicating to each muscle the exact share which it should take in balancing his body. This sense may, however, be supplied by another under certain circumstances. Thus, well-known cases have occurred, in which the power of sensation was lost in the hand or arm, and in which anything placed in the hand would drop, the muscles receiving no intimation of the amount of action required of them. But, in such instances, if the eye were kept fixed on the object, it could be retained

perfectly well in the hand. Hence, the sense of sight supplies the deficiency of the muscular sense. This observation tends to illustrate the way in which the muscles of the eye are regulated in their actions. Unlike other muscles, they have not, or possess in a very imperfect degree, a muscular sense in conjunction with the will; and in this respect their physiological relations are in some degree analogous to those of the involuntary muscles of the body. When the eyes are closed, for instance, we should not know in which direction they looked, were it not that the eyelids occasionally feel the prominent cornea beneath them; or, again, we should in vain require a blind man to fix his eyes upon any given spot; and the evident cause that he cannot do so, is that the sense which governs the muscles of the eye is absent.

The peculiar use of the muscles of the eye in directing it and adapting it to vision, in fact, requires that their actions should be regulated, not by common sensation, but by the sense of sight; and it appears that under these circumstances we remain unconscious of the amount of effort required in any particular action. A local plan of governing the movements of the eye is adopted, which does not depend upon, or communicate with, the general sensorium.

If the finger be placed on the eyelid, so as to feel the convex cornea, we shall become aware of the sudden and rapid motions of the eyeball which are habitually taking place, although generally we have no intimation of them when the eye is closed. In every act of winking, the eye is thrown up to the roof of the orbit, which we should never have known from common sensation, had it not been discovered by other means. In these instances, again, it becomes apparent that the muscles of the eye are not regulated by common sensation; but as the eye is nevertheless guided with the greatest precision in every act of vision, we cannot but ascribe the power which controls their actions to the sense of sight: a point in physiology which has not hitherto been duly acknowledged.

It is probably owing to the absence of the muscular sense in this region, that the means employed for the adaptation of the eye to vision at different distances have so long been made the subject of dispute. Could we be conscious of the effort made in altering the focus of the eye, we should probably be at no loss to ascertain the means by which it is effected; but as the adjustment of the eye takes place under the government of its own nervous influence, and is produced by its own construction, we can only reason upon it, without being able to test our conclusions by our sensations.

The muscles attached to the eyeball are of two kinds, the recti and the obliqui. The *recti* muscles arise from the bottom of the orbit, and run in a straight course over the sides, the upper, and the under surface of the eye. The *obliqui*, in man, have a direction backward and outward as they pass to their insertion; but in many animals, whose eyes are situated laterally, they are nearer the front part of the eye at their insertion than elsewhere; so that although in all animals they have a transverse direction (one passing above, and the other below the globe), yet in some they pass from behind forwards, and in others from before backwards,[1] in reference to the eyeball.

[1] As the position of the eye varies in different animals, the terms anterior and posterior, internal and external, are used in reference to the eye, the cornea being considered the anterior part.

The *recti* perform the office of directing the axis of the eye, turning it to every point in the sphere of vision, and are, as we have seen, under the control of the sense of sight. It frequently happens that one retina is much more sensitive than the other; and under such circumstances, the more feeble impression may be habitually disregarded. The controlling power may then likewise be deficient, and the two eyes may not usually be directed to the same object. A person thus affected will in vain endeavour, by any effort of the will, to direct the wandering eye to any object, as long as the impression of that object remains distinct on the stronger eye, but does so immediately that the more vivid impression is lost. Some individuals become practically aware of the fact, and close the stronger eye in addressing a person situated on the opposite side.

It is necessary for distinct vision, that the impressions on the retina should remain a certain time. If this condition is not complied with, confused images are produced. It is therefore necessary, not only that the eye should be moved from object to object, but that it should be capable of being fixed upon any point upon which the mind is intent. This is equally true, whether the object seen be at rest or in motion, and whether the eye itself be stationary or not. The straight muscles obeying the visual sense are sufficient to direct the eye to any point in the sphere of vision, and to keep it fixed upon such point during the time that the retina is duly impressed; and when the object seen is in motion, the recti muscles are all that is required to make the eye follow it as long as it moves in straight lines. But should it revolve upon its axis, it is obvious that the straight muscles could produce no corresponding motion of the eye. Or, again, if the head is moved in any other but a straight line, the recti muscles have no power of keeping the eye fixed upon an object during the time. In motions of this kind, therefore, in which the relation of the eye to external objects is changed, or when the external object moves in a circle, an apparatus is required by means of which the eye may revolve upon its axis, and so remain fixed with regard to the object seen during the time required for the due impression of the retina. A provision is made for this object in the oblique muscles, which, from their position in different classes of animals, should rather have been denominated "transverse". These embrace the globe of the eye, rotating it on its axis. The action of these muscles cannot be better illustrated than in looking at a carriage wheel in motion. If the eye is allowed passively to rest on the wheel, a confused image is produced, and no part is distinctly seen. But as soon as the separate spokes are observed, the eye is thrown into a series of slight rotatory motions, during each one of which it follows the wheel a sufficient time to see it distinctly. After each such motion, the eye regains its former position, and is again ready to follow the wheel to the same extent as before. Or when we look at an object, and move the head from shoulder to shoulder, the eye is moved in the arc of a circle whose centre is the neck, and the image of the object would be in constant motion upon the retina, were there not a provision for rolling the eye as well as directing its axis. It was formerly supposed, indeed, that the motion of images upon the retina gave the idea of the motion of the objects which produced them. Thus, Keill, in his *Introduction to Natural Philosophy*, p. 79, says:

"Those objects will seem to be moved, whose images are moved upon the retina." More accurate observation, however, shows us, that unless the eye is fixed for a certain, although it may be a very short period, upon an object, there can be no distinct perception of it. The point of sensation, the axis of the eye, and the thing seen, must be maintained, not only in the same straight line, but in their respective relations with regard to position, for a certain time, before a distinct impression can be produced.

The object, as has been observed by Hunter, becomes the fixed point, the centre of motion commanding the direction of the axis of the eye, as the north demands the direction of the magnetic needle; and this relation is maintained during each act of vision, whatever be the motions of the head or of the object at the time. If the head is moved towards the right shoulder, the superior oblique muscle of the right side acts sufficiently to counteract the effect upon the eye until a distinct perception has taken place. The muscle is then relaxed, and again brought into action, so as to allow a succession of distinct visual impressions, as has been illustrated in the example of the carriage wheel. When such a motion, or series of motions, is produced in one eye by the superior oblique, exactly corresponding results take place in the other eye by the action of the inferior oblique. These two muscles consent in their actions as if they were one, and yet we find that they derive their nervous influence from separate sources. Now, as we find every part of the living body fitted by its structure to the exact functions which it has to perform, we cannot doubt that a meaning is contained in this peculiar adaptation, which obtains throughout the whole class of animals that have moveable eyes. What the true interpretation of this particular disposition may be, I will not at present undertake to determine. But I may remark, that as the oblique muscles (taken together) have a double supply of nervous influence, so have they a two-fold office.[1] In all eyes that I have had an opportunity of examining, the oblique muscles embrace the eye, and have evidently the power of compressing it. In the cod and jack and other fish, the oblique muscles have a somewhat different relation to the eye to that which obtains in the human subject. They arise from the anterior and inner part of the orbit, and passing backward and outward, nearly in the transverse diameter of the eye, are inserted with the superior and inferior rectus into the upper and under part of the globe. The recti muscles arise very far back in the orbit, and proceed forward as well as outward to their connexion with the eye. They therefore meet the oblique muscles above described nearly at right angles. In birds, the superior oblique muscle arises from the anterior and inner part of the orbit, passes backward and outward, and expands into a flat triangular muscle, being inserted into the most projecting part of the upper surface of the eyeball. The inferior oblique is smaller, but takes the same direction as the superior oblique, and is inserted in a similar manner into the lower part of the eye. In quad-

[1] Sir C. Bell has with much justice insisted on the consent which obtains between antagonistic muscles, and has shown by direct experiment, that if a muscle contracts its opponent will relax, and *vice versâ*. Two muscles, supplied by different nerves, may thus have a mutual influence upon each other, and concur in performing a double function.

rupeds, the oblique muscles have the same origin and disposition as in man, but, owing to the eyes being situated at the side instead of the front of the head, their mutual relations are somewhat altered. In nearly all animals, they proceed more directly across the globe of the eye than in man.

It may be stated generally, that in those animals in which the socket of the eye is large, as compared with the head, and the eye directed laterally, the superior oblique muscle arises from the margin of the orbit, and proceeds backward and outward, or, in many instances, directly outward to its insertion; whereas in those where the socket is comparatively small, it arises with the recti from the bottom of the orbit, and after passing forward, is reflected through a pulley to its insertion. Whatever diversity there may be in the attachment and disposition of this muscle, it has a distinct nerve appropriated to its sole use in all classes of animals. Had its action been exactly similar to that of the inferior oblique, a branch of the same nerve might have supplied both. The superadded nervous influence implies a superadded function. Now the only action that the oblique muscles can have in all animals, besides that of rolling the eye in its socket, is to compress the eyeball. For although in some animals, from their oblique direction, they might be supposed to influence the direction of the eye, this would not be the case in others. In the swan, for instance, the so-called oblique muscle runs directly across the eye in its transverse diameter. From the observation of the actions of this muscle in man, its use has been assigned, by no ordinary authority, to be that of raising and dragging the eye, in conjunction with the changes to which the other features are subjected "in bodily pain, in agony of mind, and in all this class of passions." But not to mention that there are whole classes of animals in whose features no such expressions ever are recognised, the disposition of this muscle in fishes and birds entirely forbids the idea of any such office being assigned to it.

Although we cannot therefore determine satisfactorily the exact relations of this muscle, yet we infer from what has been said, that it has a twofold action: first, that of rolling the eye; secondly, that of compressing it so as to alter its focal length. But as other explanations equally ingenious have been maintained with reference to the mode in which the eye adapts itself to vision at different distances, we would not here enter upon the discussion, as to whether this effect may not also be produced by other means, but simply observe that the oblique muscles, taken together, have a double function, and a double supply of nervous power. Dr. Hosack, in a paper published in the *Philosophical Transactions* in 1794 (part II, page 222), observed, that external pressure was capable of altering the focal length of the eye, so as to adapt it to vision at different distances. "With a speculum," he says, "I made pressure upon my eye while directing attention to an object twenty yards distant, and saw it distinctly; but endeavouring to look beyond it, everything appeared confused. I then increased the pressure considerably, in consequence of which I was enabled to see objects distinctly at a much nearer than the natural focal distance; for example, I held a book before my eye at the distance of two inches. In the natural state of the eye I could neither distinguish lines nor letters,

but on making pressure with the speculum, I was enabled to distinguish both with ease."

Dr. Porterfield[1] objects to this explanation, that in the jack the oblique muscles "are both situated on the under side of the eye, where they decussate each other in the form a cross", and he therefore argues that the disposition of these muscles is not such as to allow them to compress the globe of the eye. "Had they been so disposed as to embrace the globe in the form of a ring, their contraction might then have squeezed the eye into an oblong form." Having repeatedly dissected the eye of the jack, I am enabled to say positively that the oblique muscles have the very disposition which Dr. Porterfield is here contemplating. His assertion respecting their decussation below the eye, has evidently arisen from mistaking the inferior rectus for one of the oblique muscles.

In all birds, the eye is embraced in like manner, in its transverse diameter, by the two oblique muscles; and when the eye is directed towards the beak, it comes more fully within the grasp of these muscles than at any other time. It is obvious, that in the act of feeding, and using their beaks for other purposes, birds require distinct vision of objects situated very near the eye; and it is equally obvious that rays of light, proceeding from a point near the extremity of the beak, would diverge before they entered the pupil, and would consequently form an image, or come to a focus, at a greater distance behind the lens, than if they had been parallel before they entered the eye. The range of vision in birds, both with regard to near and distant objects, is probably greater than in any other class of animals, and in them, as in fish, the oblique muscles are always well developed. These considerations lead us towards the solution of the question which has been asked for some hundred years past, namely, why the superior oblique muscle has one nerve distributed exclusively to it; and why that nerve, having a separate origin, and giving off no twig or branch, is sent into the orbit where there are already so many nerves? There may be, and probably are, some finer means of adjustment of the eye to vision at different distances within the organ itself, but we cannot but associate the function of this nerve, which is found in all animals that have moveable eyes, with the means by which such adaptation is produced.

Another adjustment of the eyes, which takes place as rapidly as does that of its focal length, occurs in the adaptation of the axis of the eyes to meet upon any object to which attention is directed. Here, again, we have a special action to be provided for, and a special nerve distributed to one of the muscles concerned. It is worthy of remark, that in this case, as in that of the oblique muscles, one muscle only is supplied by the special nerve, although two muscles (the internal and external recti) are equally concerned in the action. As we have a twofold motion to be provided for, (namely, that of the two eyes together, while their axes remain in the same relation to each other, and also that whereby the relation of the axes is altered, as in looking from a distant to a near object), so we have a twofold supply of motive nervous power.

The external rectus is supplied by the sixth nerve, which is almost

[1] PORTERFIELD on the Eye, vol. i, p. 424, *et sequent.*

exclusively distributed to it; and the internal rectus is supplied by the third nerve, which also supplies the other muscles of the eye. We therefore regard the ordinary motions of the eyes, while they act in concert, as under the influence of the third nerve, and their different degrees of divergence and convergence we regard as controlled by the sixth nerve. In every act of vision, therefore, there are no less than three distinct motor nerves employed, each of which conveys its mandate with a rapidity and precision of which we have not the means of forming even an accurate conception.

The muscles connected with the eye are peculiar in having the nerves which supply them with motive energy entirely distinct in their origin and course from those which supply them with sensation; and are also peculiar, as we have seen, in having their actions controlled and regulated rather by the sense of sight, than by the sensation which usually presides over muscular action. This peculiarity of disposition displays to us in a wonderful manner the care that is taken to supply every muscle (and every fibre of a muscle) with nervous influence adapted to its peculiar office. In ordinary muscles, the motive power and sentient or regulating influence are communicated through one nerve; and it is not so easy to trace their mutual relations and dependencies, as when these functions reside in different nerves. And although the mode in which the nervous energy is developed is quite as wonderful in the former case, it is more readily appreciated by us in the latter.

We have seen that in every distinct act of vision, the eyes have not only to be directed to their object, but their focal length has to be precisely adjusted; and that the sensations of the retina are the means by which these actions are governed. The rapidity with which they take place is such, that no one probably, unless directing especial attention to the point, would appreciate the interval which elapses between two distinct impressions as the eye runs over the surface of any object, and receives in succession the reflection of its different parts; and yet, for each such impression the sensation of the precise adaptation required has to be received by the retina, transmitted through the optic nerves, and, reflected again through the nerves of motion distributed to the muscles of the eye. The rapidity of such communications is truly electrical. One of the most striking instances of the rapidity of such communication of sensation, and consequent action of the muscles, is afforded in those instances where gunpowder accidentally explodes in a person's face. The eye takes cognizance of the flash, the information is transmitted to the brain, thence along the facial nerve through a circuitous route in the petrous portion of the temporal bone, to the outside of the face; and the circuit is completed, and the eyelids closed, before a single particle of the powder reaches the surface of the eye.

13, Dover Street, Piccadilly, July 1851.

ON CATAMENIAL DIARRHŒA.

By E. J. TILT, M.D., Senior Physician to the Farringdon General Dispensary and Lying-in Charity, and to the Paddington Free Dispensary for the Diseases of Women and Children.

Our information respecting diarrhœa as connected with the functions of the female generative organs may be expressed in the three following Propositions.

1. The induction of diarrhœa by purgatives often brings on menstruation when it has been temporarily arrested, or when it has been continuously checked, as in chlorosis; and likewise, the induction of diarrhœa by purgatives, whether given intentionally or not, has often determined abortion, or hastened delivery.

2. It is known that severe uterine diseases are often accompanied by constipation, and even more frequently by diarrhœa.

3. We know that in some cases, the cessation of the menstrual function at the change of life, is followed by diarrhœa; and that, guided by this fact, as well as by the experience of former times, one of the illustrious founders of the London Medical Society, Fothergill, justly recommended the use of purgatives to prevent the occurrence, or at least, to diminish the danger of the vexatious diseases to which women are liable at that time of life.

Not finding any mention of catamenial diarrhœa in the writings of Friend, our countryman (the best old writer on menstruation), nor in those of Brierre de Boismont (the best modern author), I concluded that I might be the first to draw the attention of the profession to the frequency of its occurrence; but I now find that some time since Dr. Butler Lane[1] had taken considerable pains to ascertain by a statistical inquiry, the state of the intestinal secretions during the menstrual period, and had arrived at conclusions partly at variance with, and partly confirmatory of my own. The result of his inquiry seems to have passed unnoticed; for in the discussion, which arose out of the paper I had the honour to read before the London Medical Society, it was stated by Dr. Murphy and Dr. H. Bennet, that they were not aware of menstruation being so frequently accompanied by diarrhœa as it was proved by Dr. Lane's researches and my own, while some of the fellows could not admit the truth of such assertions, because they either deemed them unphysiological, or because, according to them, if true, they would have been noticed before. This, therefore, is the state of our information relative to diarrhœa in connection with menstruation: I shall attempt, from this starting point, to attain a more definite knowledge of the subject.

Facts. Having been long engaged in a statistical inquiry into the phenomena of menstruation, I had collected several hundred histories of the menstrual function, when I learnt from a lady, that her bowels were always deranged two or three days before each monthly epoch.

---

[1] Lane, Butler, M.D. On Functional Diseases of the Liver associated with Uterine Derangement. London: 1848.

On questioning others in regard to this symptom, I was surprised at finding the first ten make the same statement; however, on continuing my investigation, it appeared that in a great many other women, diarrhœa was not a precursory symptom of menstruation. To prevent any erroneous impression relative to the value of the phenomenon, I shall premise that I have principally derived my information from patients who apply to the public institutions with which I am connected; and that the information obtained does not represent the state of the menstrual function when the patients are attacked by disease, but as it generally occurs at each period of menstruation during health. I have therefore carefully omitted all patients suffering from uterine disease as well as the chlorotic, for reasons which will soon be obvious.

The first object of inquiry is, whether healthy menstruation is accompanied by any intestinal derangement? Doubtless this is often the case, for on adding 100 cases given by Dr. Butler Lane, to 349 collected by myself, making a total of 449, the intestinal functions were deranged in 239, and not deranged in 104 cases. This frequency of intestinal derangement is confirmed likewise by some statistical inquiries made by Dr. Ogier Ward.

Admitting that intestinal derangement frequently coincides with menstruation, it remains for us to ascertain the nature of this disturbance. Judging from his 100 cases, Dr. Butler Lane was led to believe that the normal exercise of menstruation generally induced constipation; but this is not confirmed by more numerous inquiries, and as I infer, that the information was not all collected by Dr. B. Lane, it may be admitted, that if some of the women reported to be habitually costive during menstruation, had been asked whether they were likewise so a day or two before that period, they would have answered, as has frequently occurred in my practice, "No, the bowels were more open just before, and by that I knew that the courses were coming."

A general view of a phenomenon can alone give its true value. I shall therefore inquire into the frequency of that catamenial diarrhœa, whether it occur—

I. At the prodroma of menstruation.

II. During its regular establishment, or

III. At its cessation.

I. As a symptom of the prodroma of menstruation, diarrhœa scarcely ever occurs. I have noted it but three times in 349 cases.

II. As a symptom of regularly established menstruation, it occurred in 168 instances out of 349 women carefully interrogated relative to this point. It did not occur in 155 cases.

In those cases in which it did occur, it preceded the menstrual flow in 67 cases, and accompanied it in 75. It both preceded and accompanied it in 21 women, and in three cases it neither preceded nor accompanied it, but on the contrary, for two days habitually followed the menstrual flow. In the cases of precursory diarrhœa, the action of the bowels was generally suspended during menstruation until the cessation of the catamenial period.

The following table will permit the reader to understand the nature of the catamenial disturbance of the intestinal surface.

STATE OF THE BOWELS DURING HEALTHY MENSTRUATION.

Dr. Butler Lane's List.	No. of obsv.	Author's 1st List.	No. of observations.	Author's 2nd List.	No. of observations.
		RELAXED.		RELAXED.	
		Before the time ..	45	Before the time ..	22
Bowels		At the time	31	At the time	44
relaxed	33	Before and after ..	10	Before and after ..	11
		After	2	After	1
			88		78
				CONFINED.	
Bowels				Before the time ..	4
confined ..	45	Bowels confined ..	73	At the time	23
				After	1
					28
State of					
bowels				UNALTERED.	
unaltered ..	22			Regular as usual ..	77
				Confined as usual	2
				Relaxed as usual ..	3
					82
	100		161		188

On adding the totals of my two lists to that of Dr. Butler Lane, 449 observations are obtained, out of which it would at first appear that some kind of intestinal disturbance during menstruation was only absent in 104 instances; but I consider this proportion to be smaller than what is really the case, from the fact of my not having been sufficiently minute in my inquiries of the 73 women referred to in my first list, as having their bowels confined. If I had asked them whether the bowels were in their usual state, or more confined than usual, I should probably have elicited results similar to those set forth in the second list. It would appear then, that some kind of intestinal derangement may be expected during menstruation in about 75 per cent. of cases. Diarrhœa occurred at some time or other in 199 instances out of the 449 cases, so that this symptom may be expected in about 50 per cent. The frequency of constipation, for reasons already given, cannot be inferred from my first list, nor from Dr. Butler Lane's, which is even less explicit, and further inquiry is necessary before I can venture to assert that my second list is a faithful representation of physiological facts.

III. As a symptom of menstruation at the period of cessation, it occurred in twelve per cent., irregularly in eight, and regularly in four per cent., being vicarious to menstruation every month, in the same manner as is more frequently the case with leucorrhœa.

With respect to the nature of the diarrhœa, it is generally unattended by pain or any other circumstance, and merely consists in a greater relaxation of the bowels, which are moved two or three times a day instead of once. Sometimes however, for two or three days it is preceded by nausea, slight colics, and wind. This last symptom was noticed by Friend, as occurring just before menstruation, and by him erroneously referred to plethora. I have known these symptoms to last habitually eight days before the appearance of the diarrhœa.

With respect to the nature of the evacuations, they are, generally speaking, healthy; sometimes of the usual consistence, or rendered

more liquid by an increased quantity of mucus, while after cessation they are more frequently of a serous or watery nature, like soap-suds.

Pinel mentions (Med. Clin.) the case of a woman who had ceased menstruating for a year, but who suffered every month from violent abdominal pains followed by diarrhœa.

Thus as a prodromic symptom, diarrhœa scarcely ever occurs; it is found in 12 per cent. of cessation cases; and it is a very frequent precursory or attendant symptom of fully established menstruation. Such are the facts from which I now propose to deduce a physiological meaning.

Physiological Inference. Generation, so simple in animals of a simple structure, becomes more complicated as we ascend the scale of created beings; and in the most perfect of all animal forms it attains to so high a pitch of dignity, that for the mere elaboration of a germ, which is only just capable of perhaps becoming a man by conception, the ovaries often call into consentaneous action most of the organs, which, being subsidiary to nutrition, are animated by the ganglionic nervous system. Menstruation then, far from being a passive discharge, to be accounted for by mechanical causes, must be more than ever considered as a critical termination, often preceded by mucous discharges from the generative and intestinal canals, as well as by the complicated nervous phenomena which most frequently precede both the uterine and intestinal discharges. A neural current impels the blood outwardly from the womb; but before this current effectually succeeds in doing so, the same, or at least a parallel nervous current has determined a similar outward flow of mucous secretions from the intestines, in more than 50 per cent. of the women I have questioned; and as no doubt occurs to every one in practice, we often imitate nature with great advantage, and hasten the uterine by accelerating the intestinal discharge.

When once a fact is established on respectable testimony, it is useful to seek to account for it by our knowledge of the laws by which it may be governed. Formerly, it would have been deemed a sufficient explanation to say, that it was the result of sympathy, or that it was caused by the transmission of irritation from the generative to the intestinal apparatus; but the light which Dr. Marshall Hall has thrown on the physiology of the nervous system, permits us to account for the phenomena by reflex action; for if the abdominal and not the respiratory organs are frequently implicated by uterine disturbance, it may depend, as Dr. Snow Beck has justly stated, on the fact that the nerves which surround the womb and the intestinal organs, arise from the same part of the spinal cord, while those going to the respiratory and circulating system, arising from a much higher portion of the spinal marrow, are not implicated in uterine disturbance. Dr. B. Lane in his interesting pamphlet, has sought to explain the intestinal disturbance during menstruation, by admitting a certain balance to exist between the biliary and the uterine secretions, and he says—

"I am therefore inclined to believe that constipation, to a greater or less extent, most commonly coincides with menstruation when the uterus is in a healthy condition, its function exerting a derivative influence in reference to the liver. On the other hand, if congestion of the liver be consentaneous with the period of uterine congestion, spon-

taneous biliary secretion, simultaneous with the menstrual flow, may afford relief; but if there be a still higher degree of hepatic congestion, it may occasion mucous diarrhœa, as it is known to do on other occasions, and that more especially if the irritative influence of dysmenorrhœa be present. Such I believe to be causes of the occurrence of diarrhœa during menstruation, and as a general rule, I consider it indicative of a morbid tendency."

In confirmation of his views, Dr. Lane adduces the fact of menstruation being sometimes preceded by a decided bilious state and that of bilious diarrhœa, sometimes preventing the appearance of menstruation or checking the flow; and lastly he argues, from the utility of mercury in setting right the menstrual function, when it is given to modify the state of the liver.

With deference to so excellent an observer, I cannot help thinking that Dr. Butler Lane has been too forcibly struck with the exceptional cases he has so faithfully represented, and has been led to consider them as more frequent than they are really; for, in taking into consideration the condition of the tongue, the quality of the stools, and the general appearance of the patients, I have seldom, except at the change of life, found any marked disturbance of the biliary apparatus, either in those who were confined or relaxed at or before menstruation. Being thus on one point at variance with Dr. B. Lane, it is just to say, that some of his views have lately received confirmation from a very distinguished observer, Professor Simpson,[1] who says—

"In very many women, the biliary secretion becomes disordered at the return of each menstruation; in some a state of constipation, in others a state of diarrhœa, recurring during each menstrual period. The biliary and menstrual secretions seem almost vicarious of each other; and as in other cases where such physiological relations exist, the two functions are not unfrequently simultaneously deranged in their pathological actions also, both being occasionally increased or decreased together; or, what oftener happens, one being increased in extent and activity, when the other is diminished. In some cases, the cure of an uterine disease seems also to rectify the coexistent, and perhaps resultant, hepatic derangement; while no doubt also, in other cases, we find ourselves unable to amend and correct uterine diseases and discharges, till we have, in the first instance, used appropriate means to modify and correct the attendant hepatic disorder."

Whether irritation, sympathy, reflex action, or a too great activity of the biliary apparatus, be the cause of this intestinal disturbance during menstruation, it must be considered part and portion of the phenomenon of menstruation; and this is all I wish at present to maintain.

I have already pointed out the similitude that exists between the diarrhœa which precedes the elaboration of the germ by the ovary, and that which precedes the parturition of the perfect fœtus by the uterus; and I have shewn that, in both these natural processes, nervous currents direct at the same time the fluids to the outlets of those duplications of the same skin, the generative and the intestinal tubes, which

---

[1] Sympson, Dr. J. Y. Edinburgh Month. Journ. for February 1851, p. 165.

are placed in such close juxta-position, and so much influence each other, because they are governed by the same nervous force, are relieved by the same system of vessels, and are intended to fulfil the same end. For, while the intestinal surface is made for the preservation of the individual, the generative surface is destined for the preservation of the race, which is but another mode of self-preservation, enabling us to exist in the future, and to extend ourselves into time and space.

Facts, founded on 449 observations, made by two different observers, led me to inquire into the physiological bearing of catamenial diarrhœa, in the hope of being thus conducted to the better understanding of some pathological data.

1. Whenever there is a great increase of uterine activity, a tendency to diarrhœa may be expected. Dr. Lane states, that in about half his cases wherein diarrhœa occurred during menstruation, dysmenorrhœa also existed. Dr. Rigby makes a somewhat similar statement respecting the majority of the cases of dysmenorrhœa he has met with; and I have several times seen diarrhœa occur in cases of menorrhagia, both flows progressing and abating together.

Dr. Henry Bennet has stated that, judging from several remarkable cases, he had concluded that prodromic diarrhœa coexisted with inflammation of the neck of the womb, leading him to expect the one when the other was present. I cannot, however, consider diarrhœa a constant attendant on uterine inflammation; for, as Professor Simpson truly observes, "often in uterine disease there is constipation, and sometimes a want of power to expel the fæculent matter, as if there was a kind of paralysis of the rectum; which not unfrequently occurs in cases of retroversion of the unimpregnated womb." In twenty cases of uterine tumours, Dr. B. Lane found that the bowels were unaffected in four instances; constipated in two; relaxed in fourteen instances.

11. If it be true, to a certain extent, that diarrhœa might be expected in diseases of the uterine organ marked by increased activity, it is still more so that constipation may be looked upon as the rule, in those diseases of the ovario-uterine organs characterised by their deficient action; for, as the presence of the menstrual nisus is as much felt by the intestines in their particular way as by the womb, so, when in suppression the womb is deprived of its critical discharge, the intestines are likewise deprived of theirs; and constipation, as Friend has already correctly stated, is the frequent companion of suppressed menstruation.

The obstinacy of constipation in chlorosis led many a practitioner to confide principally in purgatives, long before Dr. Hamilton, of Edinburgh, made it his sole means of treatment. Those cases are indeed exceptional, wherein serous discharges last long in anæmic women, in whom menstruation has long been suppressed. This circumstance, as well as the state of the skin, lead one to suspect this serous diarrhœa to be caused by enteritis, often depending on a tuberculous diathesis.

But of what use are facts, and our deductions from them, physiological as well as pathological, unless they lead to therapeutics? If I mistake not, the knowledge of the very intimate organic relation

existing between the generative and intestinal mucous surfaces, gives us the key of much empirical practice, and will therefore enable us to act in future with that full confidence only to be obtained from knowledge. It explains to us why daily it is sought to insure the deficient action of the womb, in suppressed menstruation, in chlorosis, in labour, by the administration of purgatives; and why, on the other hand, we daily seek to diminish the too great activity of uterine action by the injection of opiates into the rectum in dysmenorrhœa, in irritable uterus, in diseases of this organ, as well as in those little understood conditions of the womb which so often lead to abortion.

London, July 1851.

OBSERVATIONS ON SOME POINTS IN THE PATHOLOGY AND TREATMENT OF THE DYSENTERY OF INDIA.

By JOHN TAIT, Esq., Assistant-Surgeon Madras Retired List, H.E.I.C.S.

Within the last few years, the profession have been favoured with some important contributions to the pathology and treatment of tropical dysentery. The researches of Professor Parkes have disclosed the fact, that ulceration affects the solitary glands of the large intestine, and that it exists during the early stages of the complaint. The standard works of Annesley, Twining, Johnson, and Martin, make no allusion to these features of the complaint, and the discovery adverted to has consequently disproved the idea formerly entertained, that ulceration was met with only as a sequence of a protracted inflammatory attack of the mucous membrane.

The acute dysentery of India is found associated with three grades of ulceration of the mucous membrane of the colon. In the first, which may be styled simple ulceration, in contradistinction to the others, the ulcers, in the earliest stage of their development, are seen as minute points affecting the solitary glands, and from this, to the size of half-a-crown, they present every intermediate variety in point of extent. They are of circular shape, having a ground of coagulable lymph superimposed upon cellular membrane, which frequently presents a variegated appearance from the presence of minute red points of the subjacent muscular fibres. The circumference is guarded all around by an effusion of lymph under the mucous membrane, which directly limits the spread of the disease. The mucous tissue for the space of an inch, or an inch and a half, in the vicinity of the ulcers, is in an inflamed state.

With reference to the ulceration originating in the glands, I may state, that shortly after Dr. Parkes promulgated his views upon the pathology of this disease, I had an opportunity of verifying the truth of his observations, by examining the intestines of a patient who died from an attack of cholera, after being three days in hospital for acute dysentery. By the aid of the microscope, I discovered the small tumefied glands with an ulcerated depression in the centre; and, with the eye unaided by optical instruments, I was enabled to trace the ulcerated specks, in different stages of advancement, to the size of

a split pea. The appearances now described have been carefully looked for by me in the colon of different subjects, but, except in those who had suffered from dysentery, I have not been able to trace them. The phenomena observed during the exhibition of mercury for the cure of the disease, would seem to argue much in favour of the ulceration being primarily located in the solitary glands. Those who have had frequent opportunities of witnessing the therapeutical effect of the medicine in this complaint, cannot have failed to remark that a perfect resolution of the disease is not effected, until the salivary glands are fully engaged by the mercury. Every one is familiar with the metastasis that takes place between the parotid gland and testes; and it would appear that the salutary operation of mercury in acute dysentery arises from the irritant action set up in the salivary glands, translating, as it were, the disease from the solitary glands to those secreting the saliva. Again, I have examined the bodies of many men who died from dysentery complicated with hepatic abscess. I do not remember a single instance in which I did not find the ulcers of the colon either healed or contracting; and I have repeatedly remarked the great relief that immediately followed, with respect to the dysenteric symptoms, on the supervention of hepatic complication, or, in other words, a rehearsal of the phenomena occasionally observed to take place between the parotid and testes.

The absence of such an affection of the glands in other cases than dysentery, coupled with what has been detailed above, are to my mind conclusive proofs that the ulcers have their origin in the solitary glands. The discovery of the fact of ulceration being present in the early stage of dysentery, has been productive of important consequences in the treatment of the disease. The morbid condition of the membrane alluded to, was supposed to be present only when the disease did not yield, or when the evacuations became watery, and the utility of mercury at this stage was much and justly questioned; but from what will be hereafter detailed, it will be observed that this remedy is one of the most valuable agents in producing cicatrisation of simple ulcers, and that it is only in asthenic forms of the complaint that it is inadmissible. The persistence of the symptoms, with loose evacuations, are indicative of the simple ulceration having passed into a more advanced stage, in which nature opposes no barrier of protective lymph to limit the ulcerative absorption, which consequently extends itself, and destroys the patient. This form of the complaint I shall consider under the head of "spreading ulceration."

The symptoms which constitute an attack of dysentery, and with which the simple ulceration is identified, are usually the following: After a premonitory diarrhœa of one or two days duration, the patient experiences a constant desire to go to stool, preceded and accompanied by severe tormina about the umbilicus. Every effort to evacuate the bowels is attended with urgent tenesmus, and nothing is passed but mucus, mixed with blood; the latter being either incorporated with it, or faint traces being interspersed throughout the secretion. In first attacks of the disease, or in subjects who have recently arrived in India, the symptomatic fever usually runs high, and, along with a small firm pulse, there is the dry strictured skin described by the late Dr. Johnson. Some tenderness may generally be felt over

the cæcum, but there is seldom much exalted sensibility to pressure over the other parts of the abdomen. Where the general fever, tormina, and abdominal tenderness are severe, they afford good guides for the employment of active treatment; but cases are frequently met with where these symptoms either singly, or collectively, afford us little information respecting the treatment to be adopted. We therefore require the presence of a symptom, which will assure the tolerance of active and decided remedies. This symptom, I think, is to be looked for in the evacuations. In the form of disease now under consideration, the mucus, however much it may vary in colour, is either viscid and adherent to the vessel into which it is discharged, or it is voided in masses firmly coherent. Where either of these appearances of the evacuations is observed, full bleeding should be at once employed for reducing the inflamed condition of the mucous membrane before mentioned, for lowering the system, and for paving the way for the salutary reception of mercury, on the action of which the healing of the healthy ulcers depends. As soon as the salivary glands are affected, the lymph which bordered the ulcers is speedily absorbed, and contraction of the various solutions of continuity takes place, leaving a visible puckering where union has been effected. Opium in large doses materially expedites this much desired termination of the disease, by restraining the peristaltic action of the bowels, and by mitigating the harassing irritability which accompanies an attack of dysentery, and which proves so adverse to the reparation of structure. When a case of the kind is seen early and is properly treated, its tendency is to terminate in resolution; and if mercury in large doses is to be approved of in this complaint, the variety under review is one above all others where it is most successful, especially should there be nothing but pure mucus in the evacuations, and if the latter are accompanied with urgent tenesmus. Mercury cannot be depended upon for the cure of dysentery, unless the tension of the blood-vessels is well moderated by appropriate depletion; as, where this practice is unattended to, it is apt to engender an unhealthy action. It should be given with full doses of opium, as their combination lessens the chance of the mineral over-exciting the system, and causing further disintegration of the affected tissues.

Between the first and second varieties of ulceration, there is what may be called the transition stage, or the transformation of the healthy into the unhealthy ulcer. A simple sore, when situated on the extremities of the body, is sometimes suddenly changed into an irritable one. The granulations first become dry and shrink, they then take on a stunted appearance, and finally disappear, leaving a ground, which, either from defective, or perverted action, does not possess sufficient vitality in itself to excite contraction of the sore. The like phenomena are observed to take place when the ulcers are situated in the mucous membrane,—with this difference, that while in those affecting the extremities, the disappearance of the granulations takes place from the border towards the centre, in the mucous tissue of the bowels this is reversed:—and it is not until the ulceration undermines the border of the intestinal ulcer, that the ring of protective lymph breaks down, and permits further extension of the disease, which then constitutes the spreading ulceration. The only symptom which can be

relied upon for giving us information of the transition stages being developed, is the discharge from the bowels, which resembles the washings of raw meat. If, during the exhibition of mercury for the cure of simple ulceration, the gums, instead of swelling, become ulcerated and excessively painful—the presumption is strong in favour of this morbid condition of the ulcers being established.

Such cases almost always prove fatal, either by extension of the disease, or by leading to the formation of hepatic abscess. The treatment which I consider most applicable is, ipecacuanha and opium in full doses, with local bleedings, and counter-irritation. Where the morbid action in this form of the complaint fails to dissipate the lymph on the edges of the ulcers, fresh layers of fibrine are deposited, and sometimes in such quantity, that the sore is prevented from contracting, simply from a redundancy of lymph; in fact, in such a case, we have presented to us, on the mucous membrane, the perfect type of the indolent ulcer on the surface of the body. This pathological state of the mucous membrane is the cause of chronic dysentery. The transition stage is therefore fraught with danger, as it is not much under the influence of any treatment; and its terminations are to be dreaded.

There is, perhaps, no disease (cholera excepted) which perplexes a young medical officer on his arrival in India, more than dysentery. When he first enters the service, he is sent to do duty in the General Hospital, where the generality of patients who are admitted suffering from this complaint, are merchant-seamen, etc., who are temporarily stationed in India. Such subjects, when seen early, usually present the symptoms of simple acute dysentery, and the disease commonly gives way to judicious bleeding, with calomel and opium, etc. In a short time, the Assistant-surgeon is ordered to join a European Regiment, where the men have been some years in the country. Cases of dysentery occur, but the men disregard its earliest symptoms; they have recourse to ardent spirits to allay their uneasy feelings, and it is not unusual to find soldiers presenting themselves at Hospital, ten days (and I have known it a fortnight) after the first symptoms of the disease have set in. On admission, they are found affected with an advanced stage of the disease, in which the time for active depletion and the internal employment of mercury has gone by, and the mucous membrane is in a state of spreading ulceration. From the circumstance of soldiers continuing to do their duty for some time after the first invasion of the disease, it would appear that the inflammatory stage of dysentery, uncomplicated with ulceration, is limited to the first few days of the disease, probably to the initiatory diarrhœa. I cannot imagine that acute inflammation could be present for days together without giving rise to corresponding symptoms; but, as soon as ulceration is established, pain is diminished, because the tension, caused by the infiltrated condition of the affected membrane, is relieved by the outlet which the ulceration affords to pent-up fluid.

I now come to the second division, or spreading ulceration. The ulcers are watery-looking and ill-conditioned; their form is irregular, and the edges are undermined from ulcerative absorption, extending some distance beneath the margin. There is no conservative lymph thrown out round the base; they are usually of much larger size than those

first mentioned, and they very often become confluent; so that, in fatal cases, it is common to find the integrity of the mucous coat of the colon completely destroyed by a continued mass of ulceration. The tormina, tenesmus, and general symptoms, give us no particular indications of the disease having advanced to this stage; but the stools no longer present the tenacity of those accompanying simple ulceration; they are loose, glairy, and gelatinous, and, in extreme cases, they become quite watery and offensive. The blood discharged is no longer intimately blended with the evacuations; it is either in loose streaks, or coagula. The treatment which has been found most efficacious in these cases, has been nitric acid and opium. Ipecacuanha and opium in full doses; and, in the adynamic forms of the complaint, three grains of the nitrate of silver every four hours, with opium, have been employed with much success by Dr. Gamble, of H.M. 4th regiment of foot.

The third and last variety is the most fatal form of the complaint; the local disease sets in with great intensity, and runs its course with fearful rapidity, to the sloughing stage. From the first, there is great depression of the system; and, in lieu of the tormina and abdominal tenderness complained of in other cases, there is often nothing more to be discovered than a sense of morbid heat along the course of the colon; pain is usually absent. In two cases of this description, which occurred in my practice in 1843, and which were published in the *Madras Medical Journal*, there was little or no attendant pain or distress. The stools are grumous and offensive, with shreds and *débris* of the affected mucous membrane. A large portion of the inner lining of the gut, or the tubular incrustation of pseudo-membrane formed by coagulable lymph, is not unfrequently discharged. When the secretions from the bowels assume a chocolate-colour, of the consistence of treacle, and are copious and offensive, it is a most fatal symptom of the disease. Very few recoveries take place from this form of the complaint. On dissection, there is found excessive softening of the gut, which breaks down under the hand, and perforation is generally found to have taken place from sloughing of the whole coats of the intestine. I know of no treatment which is of use in this stage. Everything which I have tried has invariably failed; but there is one remedy which has suggested itself to me, and which I think is deserving of trial, viz., *yeast*.

I have already alluded to the beneficial effect on the dysenteric symptoms, which attends the translation of morbid action from the solitary glands to the liver, and where this translation ends in the formation of hepatic abscess. I have been led to remark the extraordinary healing power which the fermented stools, (characteristic of abscess in the liver), possess over the ulcers of the colon. This is not to be wondered at, when we consider the efficacy of carbonic acid in irritability of the stomach and intestinal canal, and its soothing properties in ulcers generally. I therefore regret that I never gave *yeast* a trial, either by the mouth or by injection.

The various forms of ulceration have one common origin in the solitary glands. The first variety passes into the others by the advancing severity of the disease. The simple and the spreading ulceration affect the cæcum, ascending, transverse, and sigmoid flexures of the

colon. The sloughing form I have found most frequent in the ascending colon and sigmoid flexure.

Complete recovery from simple ulcerative dysentery is very common, in so far as regards the mere union of the abraded surface. In the *post-mortem* examinations of men who have been some time in India, and have suffered from dysentery, extensive cicatrices are always remarked in the colon. They seem, during life, to give rise to irritability of the bowels and general emaciation, from the functions of the glands of the mucous lining not being carried on in these cicatrized spots. They are usually dry, and destitute of the halitus which bedews the intestinal mucous surface. I would here remark, that to bring about the union of the ulcers, the case, if seen early in the simple acute stage, should be very actively treated by full bleeding, followed by a scruple of calomel and two grains of opium; a hot hip-bath, and an enema, containing a scruple of acetate of lead, and a drachm of laudanum; much relief usually follows such treatment. In spreading and sloughing ulceration, mercury is contra-indicated, as it is in all cases where there is either a deficiency of fibrine, or where the system fails to elaborate it. In the stage of convalescence, the flow of healthy bile should be solicited by nitric acid, as this secretion is a grateful stimulating corrective to healing ulcers.

These observations are thrown together for the purpose of drawing attention to the *evacuations*, as indicative of the different stages of dysentery, and as the best guides for the treatment to be adopted. I have scarcely hinted at the colour of the secretions, as it is of secondary importance to their physical properties. It will be observed, that many and valuable subsidiary remedies have been passed over, as the aim of the writer is merely to give a few hints, in the hope that some one more able than himself may be induced to take up the subject, and give it that attention which it seems to merit.

Dunse, N.B., June 1851.

BIBLIOGRAPHICAL RECORD.

PHARMACOPŒIA COLLEGII REGALIS MEDICORUM LONDINENSIS. Londini: 1851.

THE new Pharmacopœia of the Royal College of Physicians claims a more extended notice than we can at present bestow upon it; but in reviewing the translations and commentaries now published or announced for publication, we may be able to return to the work to which they owe their origin.

Some will perhaps think that too many articles have been rejected which found a place in the old pharmacopœia, while others will perhaps think, that the system of eradicating useless incumbrances from the *materia medica* has not yet been carried far enough. But it must, we think, be admitted, that the compilers of the present pharmacopœia have exercised, upon the whole, a judicious discretion in its composition; they have struck out a number of matters which can very well be spared, while they have introduced many valuable additions to our stock of remedies, with which the progress of science has happily made us acquainted. Thus, to take a few instances at random: acetosella, acorus, asarum, aspidium, cardamine, centaurium, contrajerva, malva, marrubium, olibanum, opoponax, origanum, pyrethrum, rumex, testæ (oyster shells), toxicodendrum, tussilago, have, we think, very properly been excluded; while many valuable medicines, such as gallic and tannic acids, atropia, morrhuæ oleum, have been introduced for the first time. Formulæ are given for the preparation of chloroform, of sulphate of atropia, of liquor ammoniæ citratis, liquor morphiæ acetatis, liquor morphiæ hydrochloratis, liquor arsenici chloridi, syrupus ferri iodidi, and several others.

New names of botanical genera and species have in some instances been adopted. Elaterium is said to come from ecbalium officinarum instead of momordica elaterium; jalap from exogonium purga instead of ipomæa jalapa; kino from pterocarpus marsupium instead of pterocarpus erinaceus, buchu from barosma serratifolia instead of diosma crenata; the yellow bark is referred to cinchona calisaya, the pale to C. condaminea, the red to an uncertain species; and gamboge, which was formerly improperly referred to stalagmitis cambogioïdes, is now said to be derived from an uncertain species of garcinia. Senna is still referred to the genus cassia, the Alexandrian to C. officinalis and C. obovata, and the Indian to C. officinalis. The question of the true species yielding rhubarb is disposed of by abandoning rheum palmatum, and referring the drug to an uncertain species. In these alterations, we approve the judgment exercised by the College; and where differences of opinion exist as to the exact plant which yields a drug in common use, we think that the question will be better settled by travellers and by botanists, than by an authoritative dictum expressed in the pharmacopœia.

In the nomenclature of chemical compounds, few alterations have been made; but the sesquisulphuret of antimony is now called, and we think properly, the tersulphuret, and the trisnitrate of bismuth is now called the nitrate. We are glad to perceive that no alteration has been made in the pharmacopœial names of calomel and corrosive sublimate; for, although we are inclined to think, from theoretical considerations, that the first should be regarded as a subchloride, and the second as a chloride, yet we are too sensible of the danger of such a charge in the nomenclature to desire its adoption; and we are glad to notice that, in order to prevent all misunderstanding upon the point, the names *calomelas* and *mercurius corrosivus sublimatus* are underlined respectively to chloride and bichloride of mercury. Only one iodide of mercury is retained, which, from its constitution, is the protiodide; and the bicyanide of mercury, which is not used either in medicine or pharmacy, together with that useless and anomalous compound, the hydrargyri sulphuretum cum sulphure, are omitted altogether.

The alphabetical list of medicinal substances, with a short description of their chemical characters, which stood in the last pharmacopœia, is omitted in the present; and the chemical notes, which are very judiciously and carefully drawn up, are attached to the different articles as they are mentioned in their places in the body of the work. The chemical description of arsenic, which was very defective in the last edition, is full and correct in the present.

The College has purposely omitted the processes for preparing many substances which are manufactured on a large scale; for, to use the words in the Preface, "haud iniquum fore arbitrati sumus, ut si quæ sint apud mercatores chemicos accuratissime et limatissime præparata, ea quidem enumeremus potiùs et describamus, quàm quâ quæque ratione et quibus modis præparanda sint, exponamus: utpote quæ nostris usibus eousque inserviunt, ut eadem a nobismetipsis præparari minime necesse sit." And a little farther on we are told: "Verum enimvero cùm ad hæc et alia quævis rite preparanda summa cura et diligentia pro viribus nostris impensa est, non tamen abnuimus, quin possit fieri, ut aliis fortasse modis minori sumptu vel magis commode aliis in re chemicâ peritis eadem præparare liceat." This modest admission, however, is in very little accordance with the official English announcement with which the book commences, and in which we are told, that "Her Majesty doth strictly require, charge, and command all and singular apothecaries and others, whose business it is to compound medicines, or distil oils or waters, or make other extracts within any part of Her Majesty's kingdom, that they and every of them, immediately after the said Pharmacopœia shall be printed and published, do not compound or make any medicine or medicinal receipt or prescription, or distil any oil or waters, or make other extracts that are or shall be in the said Pharmacopœia mentioned or named, in any other manner or form than is or shall be directed, prescribed, and set down by the said book, etc. . . . And Her Majesty doth hereby declare that the offenders to the contrary, shall not only incur Her Majesty's just displeasure, but be proceeded against for such their contempt and offences, according to the utmost severity of law."

Notwithstanding the inclination manifested by the College to omit the details of the preparation of many of the pharmaceutical compounds, they have still retained formulæ for the preparation of calomel, corrosive sublimate, tartar emetic, and hydrocyanic acid, the mode of preparing which might just as well be left to the discretion of the manufacturer. We cannot help lamenting that, although the College threatens the royal vengeance against "all and singular apothecaries and others," if they venture to deviate from the directions given in that Pharmacopœia, no control whatever is exercised by the legislature over those who take upon themselves the manufacture and sale of medicines. This important branch of therapeutics is, in fact, left to the individual respectability of the wholesale druggist, who, if he act honestly has no reward except that of his own conscience, and, if he act otherwise, has no tribunal to punish his errors or expose his ignorance. But we grieve to add, that the directions of the College cannot always be complied with; and that some of them are so vague as to be useless. The Latin language is ill suited to the simplicity and explicitness which ought to characterise a book written for the use of London tradesmen.

A Practical Treatise on Diseases of the Urinary and Generative Organs in Both Sexes. By W. Acton.

(Concluded from p. 653 of last Number.)

The subject of the *Second Part* of the work before us is Syphilis. We quote Mr. Acton's definition, because, though clumsily worded, it presents, in one view, many circumstances which it is of much advantage to keep continually in mind:

"Syphilis is a virulent and specific affection, the essential character of

which is its dependence upon a *special* cause, or a distinct morbid poison or *virus*, identical, and hitherto thought peculiar to man.

"Never arising *sud sponte*, but always, in the present day, the result of contagion from another person, capable of producing, when coming in contact with the economy, local effects, in which we find the fatal cause which has produced them. These local consequences may react on the system, and develop constitutional symptoms which, under certain circumstances, are readily transmissible from the parent to the child, but which cannot again reproduce the specific cause which gave rise to them. Now, although this specific cause may reproduce its effects several times on the same individual (when placed under the necessary favourable circumstances), the general constitutional symptoms will occur but once in a man's life. Lastly, syphilis may be called a disease which most frequently requires a special treatment."

PRIMARY SYPHILIS.

Chancre. The true characters are best observed in the artificial ulcer produced by inoculation :

"During twenty-four hours succeeding the operation, the inoculated point becomes red ; in the course of the second and third days, the surrounding parts are slightly swollen, and assume a papular appearance, or already traces of a vesicle are seen on the summit ; on the third or fourth day a fluid, which is more or less transparent, is observed beneath the epidermis, and a distinct vesicle becomes apparent, where the papula previously existed, and a dark dot is seen in the centre, owing to the coagulation of the blood which had escaped through the puncture of the lancet ; from the fourth to the fifth day, the vesicle assumes a pustular character, and a distinct depression is seen in the centre, so that it represents very distinctly, at this period, the small-pox pustule. The red areola, which has been hitherto gradually augmenting in intensity, now as gradually fades away, and the cellular tissue, which was slightly œdematous, becomes infiltrated with plastic lymph. On the sixth or seventh day, the pustule is observed to be wrinkled, in consequence of the contents becoming thicker, and ultimately a crust takes the place of the pustule. If not interfered with, this crust assumes a conical appearance, increasing always at its base ; it may ultimately fall off, or, if removed, leaves an ulcer seated on a slightly œdematous base, in depth equal to the thickness of the skin : the bottom of the ulcer is covered with a whitish pulpy substance or false membrane, which adheres so firmly, that it can with difficulty be wiped off. The ulcer is generally circular, and appears as if made with a *punch*.

"The margin, if viewed by means of a microscope, will be found dentated, and covered with a secretion similar to that seen at the bottom of the ulcer. The border is slightly œdematous and raised, and the areola around it is of a browner tint than at the previous stages ; this œdematous condition of the border occasions a slight eversion of the edges, and hence the ulcer may assume a somewhat infundibuliform appearance."

This secretion, removed from the surface of the chancre, and kept in close bottles during seven days, will produce all its effects at the end of that period, proving that the vitality of the part is not necessary for the preservation of the peculiar effects of the virus. To show the very minute quantity of virus necessary for producing specific effects, one drop has been diluted with a pint of water, and the inoculated fluid has produced a pustule. If alkalies or acids be mixed with the virus, and inoculation afterwards attempted, no effects will follow. These same substances will likewise destroy the property with which inoculation has invested the sore, of producing an analogous secretion, provided they be employed at an early stage. Simple substances, or ointments, will have no influence either in destroying or aiding the effects of the secretion.

Mr. Acton does not believe that it has yet been proved that the lower

animals can be inoculated with it, and in a long and interesting note, narrates and criticises the experiments of M. Auzias-Turenne (pp. 354-5). He, however, is of opinion "that syphilis in the human race originally arose from some poison introduced into the economy from animals, and that, thus produced, it has been transmitted from one individual to another." Of course all *proof* of this is absent.

Mr. Acton does not believe that the syphilitic virus will act upon the skin or mucous membrane, while the epidermis and epithelium are uninjured. He also denies a period of incubation, believing that, in those cases in which there has been the appearance of such an event, the virus has entered a mucous or sebaceous follicle, remaining there until the irritation caused by its presence has destroyed the cuticular lining, when the specific effects have immediately shewn themselves.

We would particularly direct our readers' attention to the very sensible and judicious remarks of Mr. Acton on the subject of inoculation, to be found at pp. 363-4.

In regard to Diagnosis, our author believes that nothing but inoculation can *positively* declare a sore to be syphilitic.

In the Treatment of simple uncomplicated chancre, Mr. Acton is a strenuous advocate for the employment of caustic; and his remarks are so judicious, that we quote them *in extenso*.

"Experiments on inoculation have incontestably proved, that if caustic be employed soon after the receipt of the virus, all further effects may be stayed; they have, moreover, shewn, that up to the third day the disease is of a local nature, entirely confined to the parts with which the virus has come in contact; and the patient may be guaranteed against the occurrence of secondary symptoms. I would remark here, however, how different are the laws of animal poisons. Glanders, when inoculated, and the pustule destroyed in twelve hours, produces its effects as usual; the rattle-snake poison acts still more rapidly, each animal poison having laws of its own. We may be called in too late; but the surgeon must not be inactive, he must combat the disease with all his means.

"If, however, it may be desirable to cauterise abrasions or excoriations, the injudicious and continued use of escharotics may be fraught with great disadvantage, and caustic may act as an irritant, preventing the healing of a sore.

"This is often witnessed in patients who think that they can treat their own cases, and following, as they believe, the surgeon's plan, employ nitrate of silver most bountifully. Great pain is produced; a deep eschar comes away in the course of a few days, the irritability of the organ is greatly increased; and, being unable to uncover the glans, the patient now seeks the assistance of his surgeon, who, after carefully examining the parts, finds the original sore re-inoculated, and perhaps several other small ones in the neighbourhood. These cases clearly show that the employment of caustic, in injudicious hands, may often do more harm than good; that while the nitrate of silver destroys the virus of one sore, the irritation it produces prevents us seeing the mischief accruing to others; and probably the non-observance of these rules has led to caustic being very much abused. Before we employ nitrate of silver, the part should be carefully cleansed, by being soaked in warm water, as the virus may exist on the surface of the neighbouring skin, and, if not washed off, will re-inoculate the sore when the little eschar falls, and undue blame will be thrown on the caustic. Although, then, no other ulcer exists at the time of using the escharotic, still another sore, or a little pustule, frequently, in a few hours after, will be met with, which, if precautions be not taken, will go on increasing, and the disease will spread rapidly. These circumstances explain several anomalies which have thrown discredit on caustic. The parts should now be carefully dried; and, if it be an excoriation the surgeon is called on to treat, the skin should

be put on the stretch, and the solid stick of nitrate of silver lightly passed across it, so as effectually to whiten the surface in its entire extent. All cracks and crevices must be treated in the same way, and dry lint applied for the next eight or twelve hours after cauterisation.

"Should the surgeon be called upon to treat chancres at the orifice of the prepuce, presenting the appearance of cracks, he must draw back the prepuce gently, and he will be enabled to cauterise the entire extent of the chancre; but, in repeating the operation, let him take care not to rupture the cicatrix, or this linear chancre will extend. The same observation applies to the treatment of chancres on the frænum. To obviate the difficulty of healing such ulcers, I usually divide the frænum, and cauterise the whole of the cut surface. Without these precautions, it may be weeks before you will heal such sores. Reliance must not be placed alone on caustic, and previous ablution, but extension of the disease should be stayed by lotions of an astringent kind. The one I prefer is a solution of pure tannin, in the proportion of two grains to the ounce of water, which not only checks the discharge, but seems to tan or harden the skin. The private patient, however, should be told, that this solution slightly stains his linen with a brown mark, or the lotion may tell tales to the family. To obviate this, a weak solution of sulphate of zinc may be employed, or, if desirable, dry lint; but dry lint has the objection, in some instances, of irritating the part, and prevents the little eschar falling, thus preventing us from re-applying the caustic.

"We now come to consider how soon the caustic should be re-applied. The rule I follow is, to employ it as soon as the eschar is removed, and this will vary in many cases; generally speaking, it is sufficient to cauterise once in twenty-four hours, particularly if the sores be numerous or large. More frequent applications might be useful, did they not produce irritation; and, should swelling of the prepuce arise, the mischief will be greater than by allowing the disease to run its course, as, in the latter case, we should be unable to employ ablution. Before removing the lint, let the part be well soaked, or the little eschar may be detached.

"If, however, nitrate of silver is useful in abrasions and excoriations, reliance should not be placed upon this escharotic in severe cases, or where pustules or ulcers are formed. Experience teaches us that this salt is not sufficiently potent, its action being confined too much to the surface, and repeated applications are necessary, which may be oftentimes inconvenient. Whenever, therefore, the surgeon is called on to treat a pustule which he suspects to be a chancre, let him open it, remove the pus with a point of lint, and fill the little depression with Vienna paste, or cauterise it with the solid lime and potash caustic alluded to at p. 305. In cases where a scab covers the ulcer, the former must be first removed: this is readily done by a poultice or water-dressing, and then, after carefully washing the surface, a layer of one or other of the above-named potent caustics may be placed on the sore, and allowed to extend a little beyond the margin of the ulcer.

"The application of the escharotic is, of course, followed by considerable pain, which gradually goes off; the sore, however, should be exposed until the eschar is dry, or the paste would act on any part it comes in contact with. This eschar falls in due course, and leaves beneath it, generally speaking, a cicatrised spot, or a healthy sore, which has lost its specific action, and heals in a few days under a mild astringent wash.

"Cauterisation, however, will not be found of the same efficacy in very large ulcerations, nor have we seen such favourable results when sores are situated on mucous surfaces, or where they are kept damp; in these instances, the abortive treatment does not succeed. Furthermore, the escharotic is not generally applicable in chancres attended with inflammation. Experience proves here, as elsewhere, that although nitrate of silver may be useful in allaying irritability, and in curing subacute inflammations, its employment in acute inflammatory attacks is very doubtful, or, at most, useful in

but a very few instances ; and, though surgeons may derive great benefit from its employment in chronic ophthalmia, in scrofulous constitutions, and in subacute inflammation of the urethra, few, if any, ever recommend it in acute affections of these organs, unless in the single exception of erysipelatous affections of the skin, in which it has been, like many other applications, much vaunted, and subsequently laid aside. When chancres are attended with acute inflammation, caustic will be worse than useless. Experiments prove that phagedæna destroys the virus, and they likewise show us that caustic often increases instead of allaying inflammation ; therefore, when the latter is present, recourse must be had to opium, rather than to nitrate of silver, as I shall show when treating of that variety of chancre.

"But it is not alone in acute inflammatory chancre that we must lay aside the use of caustic ; we should never apply the salt when previous applications have irritated the sores, or we might continue its use *ad infinitum*, without healing the ulcer." (pp. 389-92.)

Another counter-indication to caustic, is induration of a sore; if it be applied in these cases, great pain will be produced, the sore will become irritable, and gangrene will often follow. In simple cases, Mr. Acton recommends no constitutional treatment, and argues strenuously, and we think with good reason, against the use of mercury.

Inflammatory Chancre is usually met with in young plethoric men, who live high. If it be not treated by active depletion, it may readily terminate in gangrene. Where this occurs, the specific nature of the virus is destroyed, and secondary symptoms never follow. A saturated aqueous solution of opium is the best local application, and opium internally, and in full doses, is generally necessary.

Phagedænic Chancre often occurs in anæmic, irritable, dissipated subjects. It presents the following appearances:

"The phagedænic sore may vary in size from that of a pea to a crown piece ; usually it is superficial, rarely extending deeper than the subcutaneous cellular tissue. The shape is more or less round, but still irregular ; the edges, of a brownish hue, are usually undermined, and the disease has a tendency to burrow, particularly if position assists it. The base of the sore is somewhat swollen, not, however, indurated ; the surface is uneven, covered with little eminences and depressions ; presenting here and there attempts at cicatrisation ; a more or less adherent yellow matter covers the ulcer, which it may be difficult to remove, or which comes away in shreds. Granulations are altogether absent ; or, if any exist, they are observed to be pale, few in number, transparent, and swollen, looking like vesicles ; more frequently, however, the surface is of a greyish yellow colour, interspersed here and there with little bloody points or reddish lines. The pus is thin and offensive, holding in suspension the detritus of the tissues and flocculi of pultaceous matter ; it is inoculable during the progressive period. The ulcer rarely extends, however, beyond the subcutaneous cellular tissue. It may last a long time, and cicatrisation may be much retarded.

"It is not uncommon to see, on the surface of phagedænic ulcers, a species of ecchymosis and sphacelated spots. There is pain, of a peculiar stinging, smarting kind, which keeps the patient very restless. The general symptoms seldom run high ; the fever is rather of an adynamic kind ; there is often prostration of the vital powers ; in advanced stages of the disease, the appetite is lost ; there is pain in the head, palpitation, neuralgic pains, and a peculiar unhealthy hue of the skin ; various eruptions may appear, either around the sore or on the body ; these may consist of ecthyma, eczema impetiginodes, or rupia, all of which have been and may be mistaken for secondary symptoms. The debility and general prostration of the animal powers gradually increase, and the patient, unless relieved, gradually sinks, worn down by diarrhœa and colliquative sweats. M. Ricord states he has found ulcerations in the intestines, in cases in which he has had an opportunity of performing post-mortems." (p. 405.)

In these cases, mercury is most injurious, but the greatest benefit will be derived from *iron*. Mr. Acton uses the tartrate, but probably any other form would answer as well.

In Sloughing Phagedæna, Mr. Acton has most confidence in opium given freely in large doses. Destruction of the surface of the ulcer by nitric acid is also useful in some cases.

He adds nothing to our knowledge of the best treatment for that most intractable of sores, the Serpiginous Chancre.

The next section contains a very full and interesting disquisition on Indurated Chancre, a most important form, for it is almost always the forerunner of secondary symptoms. In the treatment of this form, mercury is indispensable, and it should be continued as long as any induration remains. But it is not necessary to commence at once, on the first appearance of any hardness, for this may not be of a specific character, but merely the result of irritation, and may disappear under simple application. If, however, the symptoms persist for some days, the mineral should be administered without delay. We strongly commend to the notice of our readers Mr. Acton's plan of administration, which is characterised by great good sense.

In Syphilitic Cachexia, Mr. Acton finds iron of great value.

Urethral Chancre is the subject of the next section. This is the cause of *virulent* gonorrhœa; and its existence explains those cases which have so often given rise to the opinion, that gonorrhœa is capable of producing secondary symptoms. In all doubtful cases, where no sore can be seen on separating the lips of the meatus, inoculation should be practised, to clear up the diagnosis.

Bubo, under its different forms, is very fully described.

SECONDARY SYPHILIS, OR CONSTITUTIONAL SYPHILIS.

Under this head Mr. Acton includes diseases of the skin and mucous membranes, iritis, and affections of the testicle. They are the direct consequences of absorption into the circulation of the syphilitic virus, and are hereditary, or, in other words, capable of transmission from mother to child, but not inoculable. Our author believes that they can never be acquired more than once; *i. e*, that when once the patient has been *thoroughly cured* of secondary symptoms, he will enjoy an immunity ever afterwards, however often he may contract chancre. But really this statement amounts to very little, on further investigation; for who would undertake to say that a patient had been thoroughly cured, when, as he is told over and over again in this same section, relapses are known to be among the most common of occurrences? so much so, that M. Ricord states his belief that we are powerless as regards the diathesis, and always warns his patients of their danger when he dismisses them, after treatment, which, for the time, has been successful.

We would specially direct our readers' attention to the premonitory symptoms as detailed by Ricord (p. 483), and to the rules for diagnosis laid down by the same great authority (p. 496). The passages are too long for extraction, and a mere analysis would be of little value.

In the treatment, Mr. Acton places his chief reliance on mercury, and we believe he is quite right.

Syphilitic Cutaneous Eruptions may all be classed under the following heads: exanthematous affections, vesicular, papular, tubercular, pustular, and ulcerations.

Roseola is the common form of the first, and is often confounded with a similar eruption caused by the administration of copaiba, which disappears whenever the drug is omitted; and also with a form of *pityriasis*. In arriving at a diagnosis in this latter case, Mr. Acton is determined by the co-existence or absence of condylomata, psoriasis palmaris, and sore throat.

Syphilitic vesiculæ are exceedingly rare. Where a patient presenting an

eruption of this kind appears of good constitution, the vesicles being distinct and the intervening skin healthy, the disease is not syphilitic.

Lichen is the usual form of papular eruption: our author believes that both lepra and psoriasis are merely modifications of it.

"Those who have specially written on skin diseases, have, as it appears to us, rendered more difficult an acknowledged difficult subject; they have attempted to create distinctions between *lepra* and *psoriasis*, which, in our opinion, are both terminations of a papular eruption. The *lichen* above-described may become dry at its summit, scales may form, fall off, and be reproduced, and this process may gain the base, and extend itself in an irregular manner, constituting what authors call *psoriasis*. On the other hand, the base of the papule may become scaly, the centre or apex remaining in a natural condition; the result is, that a circle is formed of these little scales, surrounding and surrounded by healthy skin; and as this circle is somewhat prominent, from a slight swelling of the dermis now secreting the scales, it has been considered sufficiently characterised to be termed *lepra*. On the same individual *lichen*, *psoriasis*, and *lepra*, may be seen; and we may here observe, that the little white border, described by M. Biett as characteristic of the syphilitic affection, is often wanting." (p. 508.)

In the diagnosis, he again relies on the same indications as in the exanthemata.

In the treatment, he strongly recommends mercurial fumigations, and we can bear testimony to the value of the plan. The following is the method of administration:

"The patient, having undressed, is seated naked on a chair in a large box, his head being the only part exposed to the air. This box is heated by a furnace, on which the bisulphuret of mercury is placed, in the proportion of three drachms for each vapour-bath. The intense heat applied soon volatilizes the mercury, which quickly fills the well-closed chamber or box with a leaden-coloured vapour that condenses on the body of the patient, who is exposed to its influence for twenty minutes, during the last ten of which he perspires profusely. The box is then opened, and the surface of the body is gently wiped, so as only to remove the drops of perspiration; a gown is now thrown over the body, and towels twisted round his legs, and the patient laid on a bed, thus swaddled up, between two blankets, which are tucked carefully around him, and additional coverings added. The patient is now left for half an hour, during which he perspires freely, and a glass of toast and water may be given. At the end of this time, the wet clothes should be removed, and the patient thoroughly rubbed down; after dressing, he should not at once expose himself to the open air, but remain a short time in a cool room. The vapour, thus administered, may be repeated two or three times a week, for a month or five weeks, and a cure of some of the most rebellious forms of secondary symptoms may be attained. It may be readily assumed that this treatment is one that cannot be easily carried into effect in the country, as the necessary conveniences are not at hand. In these instances, the vapour-bath may be had recourse to, and the cinnabar may be placed on a metal plate over a little charcoal furnace; but, from some experiments which I have instituted, I find that the mercurial vapour is so heavy, that it will not usually rise more than a foot, and the good effects of fumigation will be slight, as compared with those arising from the real fumigating apparatus. The body should be covered with a dark powder when the apparatus is well applied, and gold leaf will detect the presence of mercury on every part of the body. The above remarks, perhaps, explain why fumigations have fallen into disrepute, as the proper means of application are not always at hand." (pp. 511-12.)

Mr. Acton does not believe that condylomata are inoculable. As local treatment, he recommends a solution of chloride of soda as a lotion to bathe the parts twice a day; the parts should be well dried, and calomel be sprinkled upon them, and dry lint kept between the excoriated surfaces.

Under the head of pustulæ, he includes rupia, bullæ, and impetigo of the scalp. He finds the emplastrum ammoniaci cum mercurio an admirable local application.

In the local treatment of alopecia, Mr. Acton recommends stimulating washes, as, equal parts of rectified spirits, eau de Cologne, and castor oil, or, if a stronger one be required, equal parts of vermy water and tinctura lyttæ, some pommade being used also.

The throat is very frequently the seat of secondary symptoms. Patches of erythema appear, which become prominent, and then pale in the centre, extending in size. They are often of a circular shape, or like the figure 8; they frequently ulcerate; their most common situation is on the tonsils, the sides of the tongue, or near the frænum; they are met with less frequently at the corner of the mouth, and on the dorsum of the tongue. Generally the patient has other secondary symptoms at the same time.

The remainder of this chapter is occupied with SYPHILITIC AFFECTIONS OF THE EYES AND TESTICLE, and GERMINATA, or TUBERCLES OF THE SCROTUM, for which we must refer to the original.

TERTIARY SYMPTOMS.

Under this term are included those constitutional syphilitic affections denominated NODES, INFLAMMATION OF THE PERIOSTEUM, EXOSTOSIS, CARIES, and TUBERCLES OF THE SUBCUTANEOUS and SUBMUCOUS TISSUES. Like secondary symptoms, they are not inoculable, and they are also incapable of transmitting constitutional syphilis hereditarily.

This chapter (which is almost entirely composed of extracts from M. Ricord's lectures), is full of interest; but we have already occupied so much space, that we can do no more than direct attention to it.

CAUSES OF DEATH FROM SYPHILIS. Here we must request attention to the following table, because it very strikingly illustrates the fallacy of general opinions, not based on figures. Few, we suspect, would have imagined that syphilis had so small a number of victims in the metropolis.

"TABLE, *showing the Fatal Cases of Syphilis in Adults, which have occurred in the Metropolis during the years* 1846, 47, *and* 48; *distinguishing the Males from the Females, and the Diseases of which they died, at different periods of ten years.*

	Females.						Males.						Male and Female of all ages.
	15 to 25	25 to 35	35 to 45	45 to 55	55 to 65	Of all ages.	15 to 25	25 to 35	35 to 45	45 to 55	55 to 65	Of all ages.	
Syphilis	3	12	7	7	2	29	4	4	2	..	4	14	43
Phagedænic disease	2	3	..	..	..	5	2	..	..	..	..	2	7
Disease of bone	..	1	1	..	1	3	..	1	..	1	..	2	5
Ulceration of larynx	1	2	..	..	..	3	1	5	..	..	..	6	9
Venereal disease	..	3	1	..	..	4	1	2	..	..	..	3	7
Consumption	2	6	1	..	..	9	1	6	..	2	1	10	19
Chest affection	1	2	..	..	..	3	1	1	..	..	1	3	6
Paralysis	..	..	..	1	..	1	..	1	..	..	..	1	2
Cachexia and debility	2	2	3	1	..	8	..	..	1	3	..	4	12
Erysipelas	5	1	2	..	..	8	3	5	1	..	..	9	17
All diseases	16	32	15	9	3	73	13	25	4	6	6	54	127

"On looking over this table, the first thing that strikes the surgeon is the paucity of fatal cases from syphilis in adults. Notwithstanding the frequency of the complaint in the metropolis, as shown from preceding pages, only 127 deaths are noted in adults, out of a population amounting to more than

2,000,000; during 156 weeks, the average is not one a week. This, and a succeeding table on the proportion of deaths from syphilis in infants, p. 645, shows that syphilis proves most frequently fatal to children under one year of age; a fact, previous to the formation of these tables, which was not known to the profession.

"This table, moreover, contradicts the very prevalent opinion, that a large number of women, particularly prostitutes, die annually of syphilis. In the above table we find 73 women only to 54 men; and this proportion is the more striking, if we recollect that the female population of London is much more numerous than the male, in the proportion of 120 females to 100 males, or about five males to six females." (pp. 595-6.)

Mr. Acton gives some interesting cases of a peculiar form of monomania, to which M. Ricord has applied the name of Syphiliphobia.

Syphilis in Infants. What is said on this subject deserves attentive study; we can merely indicate the points which Mr. Acton argues and illustrates. A woman may contract syphilis during the time she is pregnant, and infect her infant, the father being healthy; but the latest period at which this may occur is not ascertained. A man labouring under secondary syphilis may beget an infected infant, the mother remaining free. A mother labouring under syphilis may suckle her child without giving it the disease. Mr. Acton does not believe that a nurse labouring under secondary symptoms can infect a child. He thinks that an infected fœtus may contaminate the mother, and relates a case, which, however, is not conclusive. Mr. Acton does not believe that an infected infant can contaminate the wet nurse. We cannot assent to all of these propositions; but on the present occasion we have no space for a statement of our own views.

We have now brought our task to a termination: and, in taking leave of Mr. Acton, we feel that it is our duty to commend his work most cordially to the notice of our readers. Our analyses show that the book is essentially useful and practical; and we have left untouched much that is alike interesting and important. Still it is not faultless. The style is too diffuse, and almost every chapter would bear condensation with advantage. There are also too many typographical errors and literary inelegancies. Notwithstanding, however, its blemishes, Mr. Acton's work is the most useful in our language upon the subjects of which it treats.

An Inquiry on the Subject of Vaccination, Addressed to the Royal Medical and Chirurgical Society. By Benjamin Ridge, M.D. pp. 31. London: 1851.

This pamphlet is in a great measure made up of quotations, about one half of it being composed of extracts from the works of Dr. Jenner, and from a previous essay of the author. Dr. Ridge does not appear to think very clearly; and from this or from some other cause, he has failed to present his views in a perspicuous manner. As far as we have been able to deduce them from the work itself, they may be thus stated:

Dr. Ridge, aware of the recurrence of small-pox after Vaccination, and knowing that this result had been made use of to disparage the practice altogether, brings forward a theory of his own to account for the failure of the operation, and to show that an unsuccessful result is not dependent on any inherent want of prophylactic virtue in the cow-pock, but arises from the choice of unsuitable periods for its employment. According to an alleged discovery of Dr. Ridge, in 1842, and published in 1845, two membranes, not previously known, were found by him to exist in the fœtus, and young of man and other animals. The first was described as a true membrane for the meconium; the second, as a vascular network of vessels, lying between the meconic membrane and the true mucous membrane of the intestines, forming also a true membrane, named the rete vasculare. The use of the

meconic membrane, according to Dr. Ridge, is "to detain effete matters within the alimentary canal, instead of their lodging on the mucous membrane, and to prevent the bile flowing into the alimentary tube, where it could have no duty to perform, as chylification is not necessary to fœtal life." He adds, "were it not for the intervention of these new structures, there would be no hindrance to the absorbents acting on the contents of the bowels, and taking up and carrying into the system an excrementitious deposit. The meconic membrane is plainly a false mucous membrane, which is present for a certain time only, and for a specific purpose, as we find that that portion of it which is situated on the rectum, comes away, in some instances, entire with its contents, as a cul de sac; though probably, in the more numerous cases, it breaks and comes away piecemeal with portions of the meconium. The rete vasculare appears to be provided by nature, for the nourishment of the meconic membrane, as well as the mucous membrane on which it lodges, and to sustain the functional integrity of both during fœtal life. And if these new structures perform highly important duties during fœtal life, they appear to have equally important uses after birth. From this period, all animals are as dependent on what they make within themselves by the decomposition and appropriation of their own tissues, as on what they take of foreign substances to support life. The action of the oxygen imbibed, on the animal tissues, constantly consumes them; and these, being in an hourly stage of decomposition, produce carbon which they breathe, and ammonia, which generates nitrogen, the active and primary agent of their whole vital system. What is there to interpose between the metamorphosis of existing tissues in the new-born child, supposing, as we have hitherto done, that there are no such structures as the meconic membrane and rete vasculare?"

The existence of these membranes, which Dr. Ridge thinks he has discovered, is a question of fact, not yet confirmed by any one; and the theoretical purposes they are alleged to subserve in the animal economy, we have given in the words of the writer himself, for, not very clearly understanding his views, we fear we should fail in conveying any very distinct impression to the reader. But it will naturally be asked, "What has all this to do with vaccination?" The writer shall again speak for himself. "From what I have said in connexion with the presence of the meconic membrane and rete vasculare, it will be seen that light diet, with free air and oxygen, so act upon these structures, as to support life vigorously and healthfully; *and in doing this, infants are more able to throw off or avoid diseases of a character like the small-pox.* If infants, therefore, have this innate power of counteracting natural diseases, *they have equally the power of throwing off* that which is thrust upon them, or *whatever they are inoculated with.*" The writer adds, "I do not think that there is as much dependence to be placed in the preventive action of vaccination, if performed within the first three months, as when it is done after that time; and, if it must be done previous to this time for the parents' satisfaction, it should be done again within the year for the child's safety." Dr. Ridge further adds, "No child that I have attended during the last two years, has ever had the small-pox in that time; and none that I have vaccinated after the age of three months have failed in taking the virus. Before that age, the proportion was large of those I had to revaccinate a second and even a third time. What then was the cause why these threw off the vaccination, unless indeed it was the power of the healthy vital agents, in course of metamorphosis resisting the disease?" or as he further states, "the great transition, and consequently resistive state an infant's secretions are always in during the influential presence of these newly discovered structures, particularly the rete vasculare" Further on, the writer extends the proper period for vaccination from three months to a much longer period. "From subsequent reflection," he says, "and experience, I am now prepared to extend that time to nine, or even twelve

months, as the safest period—because it is impossible to say at what precise age a child may have arrived at that condition of body, most appropriate for the reception of vaccine virus." Again, "the proper time for vaccination is that time within the year when it may be reasonably supposed, that, the newly discovered organism being disposed of, the transition state of the system is less active." We should not, however, by any means, advise our readers to defer the vaccination of their little patients from the fourth to the twelfth month, on grounds so fanciful as those adduced by Dr. Ridge, even though further inquiries should shew that the new tissues which he describes are really distinct and special organisms. For, granting this, the functions which he attributes to them are purely theoretical, and it will take a long course of observations to establish the doctrine, that for the first twelve months of its existence, an infant is usually in such a state of high health (transition state), as to resist the influence of the virus of the human or cow small-pox. The reader who consults the pages of Dr. Ridge, will therefore be astonished to find on how small an amount of proof he attempts to establish opinions so new, and which if correct, are of so much practical importance. His facts have little to do with the points at issue; and they bear a less proportion to his mass of theory, than Sir John Falstaff's half-penny-worth of bread to a gallon of sack. It is well known, that infants of a few days old may take both cow-pox and small-pox. Why does Dr. Ridge fail to notice this class of cases?

We shall now conclude by noticing a very questionable assertion of the writer, viz., that "Virus allowed to dry between two pieces of glass, is deteriorated or destroyed, by crushing molecular continuity." This assertion is not likely to pass current in the sister isle, where the practice, both in the Dublin Vaccine Institution, and throughout the country, is to preserve the virus in the manner denounced by Dr. Ridge. In Scotland, also, and in extensive districts of England, Wales, India, America, and the British Colonies, it is the method most commonly adopted.

Principles of Physiology, General and Comparative. [*With* 321 *wood engravings.*] By William B. Carpenter, M.D., F.R.S., F.G.S., etc. *Third Edition.* pp. 1098. London: 1851.

This is a book without a rival: and Dr. Carpenter has laid the medical profession, as well as all who study and who love natural history, under deep and lasting obligations by its production. Our limits forbid us from indulging in comment or criticism; and we can only heartily commend the work to our readers.

We regret to observe from the preface, that the author does not even hope for any pecuniary recompense for the great amount of successful labour bestowed upon his book. We perused the following paragraph with interest, and much regret. "The whole of his" (the author's) "disposable time has been devoted to it for nearly two years, not merely without the anticipation of the slightest pecuniary reward, but under the certain loss involved in the relinquishment of other literary engagements of a remunerative character: and the sale of the entire edition will not do more than remunerate his liberal publisher, for the very large outlay which he has incurred in the production of the work, and more especially for the beautiful series of illustrations with which it is embellished, most of them having been executed expressly for it by Mr. Bagg." *(Preface.)*

The Laws of Health in relation to Mind and Body: a Series of Letters from an Old Practitioner to a Patient. By Lionel John Beale, M.R.C.S. pp. 306. London: 1851.

This is a sound and sensible book, which, if generally circulated, is likely to do much good. Though not beneath the perusal of the profession, it is more adapted to the wants of educated laymen.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

THERAPEUTICAL REVIEW OF TREATMENT ADOPTED IN THE DISEASES OF THE NERVOUS SYSTEM.

From the *Annales Medico-Psychologiques* for April 1851, p. 322.

Ferruginous Preparations in Chlorosis. The action of iron in the cure of chlorosis has long been known ; and its efficacy in this disease places its preparations in the rank of the most energetic medicines. But the same compounds do not suit all patients. There are some which produce upon chlorotic patients curative effects, which they have never succeeded in producing upon others. Hence arises the necessity of varying the administration of the compounds which have iron for their base. Here the following question naturally presents itself : Chlorosis being a blood-disease, it ought not to be classed with nervous affections, and the therapeutics of these last diseases has nothing to do with chlorotic affections. It is not proved, however, that the primary cause of chlorosis does not reside in the nervous system, and that it is not a particular modification of the nervous apparatus of digestion and assimilation, which impoverishes the blood and impresses upon patients that physical and moral character, which it is impossible to mistake when once it has been seen. Thus chlorosis, and many other diseases, belong to the department of psychology : and it is probable that they will be included successively in the ranks of affections of the nervous system, in proportion as we advance in the study of this class of diseases.

M. Sandras has treated some chlorotic patients, who had sunk by loss of blood to an extremely advanced state of decay, and a kind of stupidity, by the daily administration of ferruginous pills, with calcined magnesia, baths at twenty-five degrees (77° Fahr.) every two or three days, and the use of substantial food. By this treatment, the most severe symptoms disappeared very readily, and there remained no trace of chlorosis.

The iodide of iron, and iodo-ferruginous pills, have produced good effects in cases in which the ordinary preparations of iron, as the carbonate, the lactate, etc., did not produce any advantageous results.

Iron is not, according to M. Hannon, the only metal which succeeds in curing chlorosis. He has employed preparations of manganese with success. But he has since discovered, that neither manganese nor iron were assimilated : that they were eliminated, and that, consequently, they had no influence in the cure of chlorosis. The iron found in the blood would result from the food, and not from the remedies which were administered.

Gastralgia. Treatment by the Subnitrate of Bismuth, united with Belladonna. The subnitrate of bismuth enjoys a certain reputation in the treatment of gastralgia. It cannot be said, however, to be an active and faithful remedy. Sometimes it does not act even in a large dose ; at other times, its action is no longer exercised in cases where it had previously been administered with success. According to Professor Caizergues of Montpellier, the subnitrate of bismuth is more efficacious when it is united with belladonna. He orders this mixture in painful affections of the stomach, properly so called, and which are isolated from all inflammatory complication, and against affections of the stomach which are connected with a positive disease, or a general morbid state, like chlorosis, for instance. The Professor generally employs the following formula. ℞ Subnitrate of bismuth ten grammes, extract of belladonna one gramme ; make forty pills, two to be taken night and morning.

Lead-colic : Utility of Belladonna. The exclusive purgative method has its advantages; but it has also its inconveniences. It is directed against poisoning; for in provoking catharsis, it drives out, by over-exciting the excretory organs of the intestinal system, a part of the poison absorbed, and then it destroys the obstinate constipation which is one of the most marked characters of lead-colic. But antispasmodics supply a want, since the sensibility is energetically called into operation in this disease. The narcotic method may then have some success, and does not deserve to be entirely abandoned to give place to the purgative method. Stoll was a partisan of the pure narcotic method. Dr. Triberti of Milan employs the mixed treatment, in which opiates are administered internally and externally in a full dose, and with such success, as to obviate the necessity of having recourse to purgatives. When narcotics alone are sufficient for the cure, the mixed method becomes the pure method. M. Marion, physician of the Hôtel Dieu, at Nantes, has administered the extract of opium with great success in the dose of 30 to 60 *centigrammes* (gr. ivss. to gr. ix) a day, like Dr. Triberti; the pains quickly ceased, and, with a small dose of castor-oil and some emollients, the constipation likewise disappeared. M. Malherbe thought, in 1846, that belladonna might be advantageously substituted for opiates. Since the trials of treatment by this method, the success appears to have been sufficient to cause its adoption. The following plan is adopted by M. Malherbe, in the belladonna treatment: on the first day, five *centigrammes* of the extract, with 10 *centigrammes* of the powder of the root. When the first dose is without effect, that is to say, when neither the pains nor the constipation have diminished, the second is composed of 10 centigrammes of extract of belladonna with 20 of the powder. At last, M. Malherbe has gone as far as 20 centigrammes of extract, with 40 of the powder; but he has not carried the dose farther. With this treatment, the greater number of patients have been relieved, from the first to the third day; in the cases in which the symptoms offered a great resistance, and could not be subdued by opium, belladonna has triumphed. Belladonna is considered by M. Malherbe as an antispasmodic, and anticonstipant.

Enteralgia, or Nervous Colic. Treatment by Alum. The sulphate of alumina and potash has its advocates in the treatment of lead-colic. MM. Kapeler and Gendrin, and M. Brachet of Lyons, have been successful with this drug. The analogy of the symptoms of lead-colic and nervous colic, has suggested to M. Philipeaux, the employment of alum in this latter disease. The treatment consists in employing four *grammes* (ʒ i) of alum dissolved in a soothing potion, and given in spoonfuls. But, in order that the remedy may act efficaciously, and that it may not, on the contrary, produce an exasperation in the morbid state, there must be neither frequency of the pulse nor symptoms of intestinal strangulation; the colic must be purely nervous,—a fact which is often difficult to be ascertained.

Ammonia — its Efficacy in Hoarseness and Aphoni: Imperial Potion. After having disembarked at Cannes, on his arrival from the isle of Elba, and while he was stretching to Lyons, the Emperor Napoleon was seized with a sudden hoarseness. The next day he was to make his entry into Paris, where he had fatiguing duties to expect, for there would be orders to give, reviews to superintend, deputations to receive and to harangue. The emperor was forced to pay with his own person for the success which was to open to him, without a battle, the gates of the capital. He sent for his physician, Dr. Foureau de Beauregard, and declared to him that he must be positively relieved of his hoarseness. The physician prescribed the following draught: ammonia 10 drops, syrup of erysimum 45 grammes, infusion of tilia 100 grammes; to be taken at one dose. Foureau related that the cure was sudden, which procured him the thanks of the emperor; hence the name of *imperial*, which has been given to the potion. It is possible that, in

this imperial potion, the ammonia may, by its diffusive properties, modify favourably an inflammatory state, or a state of nervous excitement.

Eclampsia: Treatment by Ammonia. A lying-in patient, who had lost much blood, had an attack of eclampsia. The ordinary means not producing any result, Dr. Vanoye ordered a potion containing some drops of spirit of ammonia, with some syrup of mint. The convulsions diminished a little; and, as they were reproduced at the termination of an improper bleeding, the same means were repeated, and they finally disappeared. Although ammonia appears to be indicated in cases of eclampsia, it may fail to produce the effects which we may expect, particularly when the hæmorrhage has been considerable; for then the medicine may cause a state of over-excitement, and deceive us in the result which we think to attain.

Delirium Tremens: Ammoniacal Potion. Delirium tremens is frequently developed in wounded persons who have used spirituous drinks in excess. This disease is efficiently combated by opiates; but, according to M. Jobert, it is prevented by the administration of the following mixture. Distilled water of tilia 128 grammes, ammonia 4 drops, syrup 32 grammes. This potion is given in spoonfuls every two hours, to patients who have received wounds during intoxication; and to those who, having been addicted to drinking, present, during treatment, a state of exaltation sufficiently marked to cause us to apprehend an attack of delirium.

Chorea: Treatment by Chloroform in Frictions. Chloroform is an agent which will eventually become an extremely powerful instrument in obtaining very varied results. Since it deadens sensibility, it must calm and even completely appease the different states of over-excitement of the nervous system. We cannot therefore be surprised that Dr. Gassier has performed three cures of chorea by making, along the course of the vertebral column, frictions with a liniment composed of chloroform and oil of sweet almonds, in equal parts. But what is remarkable in these three cases is, that they were all caused by fear. Thus, then, there did not exist any initial morbid state; an accidental nervous derangement was developed on a particular occasion, and nothing more. In such circumstances, chloroform has stopped the chorea; but if the temperament had been concerned, as in cases which are developed without appreciable moral cause, chloroform would not have sufficed, but it would have been necessary to have recourse to other means.

LEMON JUICE IN ACUTE ARTICULAR RHEUMATISM.

In a certain class of cases, we believe the treatment of rheumatism by lemon juice, as advocated by Dr. G. O. Rees [London Journal of Medicine for 1850, p. 927], to be most satisfactory. For this reason, we state that it is being tried with good results both at home and abroad. Dr. Perkins of Brussels, and Dr. Giraud of Grenoble, have lately testified in its favour. (Vide *Journal des Connaissances Médico-Chir.*, Nov. 1850, and 16 May, 1851.)

AUTUMNAL DIARRHŒA.

As this disease is likely soon to be more or less prevalent, we would invite our readers, in those cases—and they are not few in number—in which may be traced an intermittent type, to combine the use of quinine with their other remedies. In our own practice, we have found nothing so successful in the majority of cases as an opiate draught, followed in two hours by a full dose of castor oil; and then a short course of quinine with minute quantities of iron. Dr. James Bird, two years ago, said, "Dr. Cormack, of Putney, informs me, that acting on a suggestion which he (Dr. Bird) had made to him, now nearly twelvemonths ago, he has found the citrate of iron and quinine one of the most useful medicines which can be given in the *cholerine*, now almost

universal on the Surrey side of the river". [London Journal of Medicine, 1849, p. 842.] Dr. J. P. Evans, of Tazewell, Tennessee, in an Essay on "*the Diarrhœa of the South*," in the *Charleston Med. Journal and Review* for May 1851, writes as follows:—"While in Mexico, I was furnished with various *recipes* for diarrhœa, of the precise elements of which I made no record, but some of them emanated from respectable sources, and I noticed that quinine entered into the composition of many of them, particularly of some which were reputed to be of great value in the region of the Rio Grande." . . . "It is very probable that it (quinine) might be profitably employed even where periodicity could not be traced, as, according to Professor Drake, it is a sedative and antispasmodic narcotic."

DR. PANUM ON THE TRANSMISSION OF MEASLES.

The *Archives Générales de Médecine* for April 1851, contains a memoir by Dr. Panum, of Copenhagen, on an epidemic of measles, which visited the Færoe Islands from April to October 1846. The article originally appeared in the *Archiv für Physiologische Heilkunde.*

Extraordinary facilities for making accurate observations were afforded to Dr. Panum (who, with Dr. Manicus, was sent to the islands by the Danish Government), by the circumstances, that not a single case of measles had occurred there since 1781; that the islands are separated from the rest of the world, both by their geographical position, and by a peculiar commercial monopoly in force there; that the islanders are congregated into small villages, of at most two hundred inhabitants,[1] having very little intercourse with each other; and that intercourse was rendered still more rare by the fears excited by the epidemic of measles. Out of 7,782 inhabitants, more than 6,000 were attacked; and, in some of the villages, more than 80 per cent. of the peasants were at the same time confined to bed.

Dr. Panum makes the following remarks on the period of incubation in measles:

The duration of the period of incubation in measles has not been satisfactorily determined: it would vary, according to authors, between eight, ten, and fourteen days. Some physicians, more cautious, refuse to assign a fixed duration to the first stage. In large towns, it is impossible to know the precise moment at which an individual is subjected to contagion: sufficiently accurate results can only be obtained by being placed in such a position as I was in the Færoe Islands.

The first islander attacked with measles was a labourer, living at Thorshavn. He had left Copenhagen on March 20th, and had arrived in perfect health on the 28th; on April 1st, he was taken ill. About fourteen days later, his two most intimate friends had the first symptoms of measles. This case, which I did not witness, awakened my attention, and led me to undertake researches on the duration of incubation.

On June 4th, ten men of Tjornevig, in the same boat, took part in a large fishing excursion with the inhabitants of another village; on June 18th, all were attacked with measles, after having had premonitory symptoms from two to four days. They had only been in contact with some fishermen from Westmannhavn, who were convalescent from the same disease, or who had at least lived among others who had measles. Twelve or sixteen days after the appearance of the eruption in these persons, almost the whole population of the village was attacked. This was already sufficient reason to lead me to suspect that the contagion may remain in the organism in a latent state, or at least without giving rise to a specific eruption, during an average period of thirteen or fourteen days. I collected accurately, in fifty-two localities, the names of the persons who were first attacked, the date of the eruption,

[1] Thorshavn, the seat of government, contains 800 souls.

and the date of the attack in the inhabitants to whom the disease was communicated. These observations all tended to confirm my supposition.

At Hattervig, a young man, the first who was attacked, assured me that the eruption appeared on him ten days after his arrival from an infected village. This was an exceptional case; but the patient himself afterwards contradicted the false account which he had given me. At Fuglefiord, the daughter of my host had recovered from the disease, from which the nine other members of the family had remained free. I inquired on which day the exanthem had appeared on her; and underlined the fourteenth day in an almanac, telling them that that was the period at which the disease should re-appear. On my return, I learned that the eruption had appeared on all the nine individuals on that day.

The Great Dimon is a very small isle, inhabited by only eighteen persons, of the same family. Some of the men went one day in a boat to Tveraa, where the epidemic prevailed, and remained only a few hours. Up to the tenth day, these men remained in perfect health; on the fourteenth day, the eruption appeared on all; and fourteen days later, it appeared on all the other members of the family. At Skaalevig, the only isle where the houses are much isolated, the contagion spread less rapidly; but it still afforded a confirmation of the rule which I have laid down.

It may then be admitted, as a constant law, that the contagion of measles, when introduced into the organism, does not manifest itself at once; and that, after a premonitory stage of uncertain duration, the eruption appears on the thirteenth or fourteenth day after the infection. Without doubt, the constitution, regimen, etc., of the patient, will somewhat hasten or retard its appearance; but their influence is much less than might at first be supposed. The greatest variation did not extend beyond twenty-four hours. . . . According to observations made at Copenhagen, the period of incubation of small-pox is fourteen days: the analogy which these two eruptive disorders thus offer is interesting.

The indeterminate duration of the precursory catarrh would seem to throw some incertitude over my researches. Some patients suffered from cough, slight ophthalmia, and febrile disturbance, six or eight days before the eruption; others only perceived these symptoms for four or six days; and most, indeed, did not experience them more than from two to four days. Exact results can only be arrived at, by comparing the time of infection and that of the appearance of the eruption.

If we admit that the incubation of measles lasts from thirteen to fourteen days, and that this period elapses between the appearance of the eruption in an individual, and its subsequent appearance in those infected by him, is it not evident that contagion takes place during the period of efflorescence? Measles certainly are not contagious during the latent stage; and it is difficult to decide whether they are so during the precursory stage. They are generally believed to be especially contagious during the period of desquamation. For my own part, I have not seen a single case to convince me that this supposition is correct. The transmission, if the duration which I have assigned to incubation be correct, is, almost always, if not constantly, effected when the spots make their appearance. In no case which I witnessed, was an individual attacked with measles more than fourteen days after the disappearance of the exanthem in those who might have infected him. In a word, measles are very contagious at the commencement of and during the eruption; it is doubtful, on the contrary, whether they are so in the catarrhal and desquamative stages.[1]

---

[1] Dr. Panum by no means proves that measles are not contagious during the period of desquamation; and some of the instances which he relates rather tend to confirm the opinion which we entertain—that they are so. Thus, the ten men of Tjornevig, to whom he refers, "had only been in contact with some fishermen

With regard to second attacks of measles, it is remarkable that all the old people in the Færoe Islands, who had been attacked in 1781, and who were still numerous, escaped in 1846: I could cite a hundred instances. This observation is the more conclusive, as even very advanced age did not diminish the susceptibility. As far as I know, very aged individuals, who were not exposed to the first epidemic, were all affected by the recent one; while some young persons escaped, though living among the sick.

The following facts may throw some light on the question, as to the degree of intensity which may be attributed to the contagious principle of measles. On June 2nd, some men embarked at Funding for Klaksvig, to buy goods: the buyers could not return, until they had assisted in unloading a vessel, on board of which were men just recovered from measles, which also prevailed in the port. The people from Klaksvig entered no house but the counting-house. On their return, they threw away the coverings of their goods, washed themselves carefully, and put on other clothes, etc. No one was attacked till July 3rd, when the disease appeared at Klaksvig. Five inhabitants of Nordre-Gjov, who did not take the same precautions on their return, after having been exposed to the same influence, were seized on the fourteenth day from their exposure to the contagion.

On my arrival in Klaksvig, the terror was so great, that no one would approach me, although the islanders do not commonly believe that medical men convey contagious miasmata. Three weeks before Whitsuntide, the surgeon of the country had to pass the night in the village, in attendance on a patient; the measles appeared fourteen days after, in the house where he had been. No inhabitant, either of the house or of the country, had had communication with an infected place; and no other stranger had come into the village. At Midtvaag, the measles were introduced by a midwife, who had attended the patients in a neighbouring island. The young girl who washed the midwife's linen was the first person attacked. These instances tend to show that measles possess a greater power of contagion than is generally supposed.

Whatever may be the value of simple prophylactic measures, isolation is without doubt the surest method of arresting the development of the disease. Houses have been preserved from infection, in several villages, by interrupting communication. I will refer to two families at Saxen, ten at Midtvaag, ten at Sandevaag, and half the village at Thorsvig. Various localities, with populations varying from twenty-six to two hundred and forty persons, were preserved by a vigorous *cordon sanitaire*. About fifteen hundred islanders may be considered to have owed their health to the establishment of quarantines.

Of 6,000 cases, of which I saw and treated more than 1,000, there was not one which authorised me to admit the existence of morbillar miasmata. Everywhere the disease was propagated from man to man, from village to village; contagion, mediate or immediate, was evident. The two physicians who practised in the Færoe Islands, believed measles to be miasmatic, and capable of transmission by the air; hence no precautions were at first taken to prevent communication. Experience had already shewn, in 1781, what good could be effected by quarantines; but these were not had recourse to until too late. It is to be hoped, that the experience so dearly bought in 1846, will be profitable. The exclusively contagious nature of measles is so clearly proved, that the practitioner would, I think, fail in his duty, if he did not act accordingly.

---

from Westmannhavn, who were *convalescent from measles*, or at least had lived among persons affected with them." Again, the infection of the men of Nordre-Gjov, after their visit to Funding, shows distinctly that measles can be taken from men "just recovering from them." We can scarcely imagine the convalescents at Funding to have been working on board a ship during the eruptive stage. Scarlatina and other disorders are contagious during the stage of decadence: the same may be reasonably expected in measles. [EDITORS LOND. JOURN. OF MED.]

EXTERNAL APPLICATIONS IN DROPSY.

The treatment of dropsy by the external application of diuretics was some time ago made the subject of an able article by Professor Christison, in the *Edinburgh Monthly Journal*. The following observations, by Mr. W. W. Finch, of Ausable Forks, New York, are contained in the *Boston Medical and Surgical Journal* for March 19, 1837:

Some six years since, I was called to see a child, two years old, with general anasarca and ascites. He had been under treatment some three or four weeks; but was steadily getting worse, and had been left by the attending physician as a hopeless case. His whole body was enormously distended; his features seeming hardly human. The appetite was voracious; he had constant thirst; the bowels were very loose; the urine scanty; the pulse feeble, quick, and very frequent; the patient was restless, and constantly moaning. The usual treatment with diuretics and cathartics would reduce the distension a little; but what was gained one day would be more than lost the next; for the patient was evidently losing strength, while the disease was steadily gaining ground. As a forlorn hope, I directed the following liniment to be applied to one half the surface of the body, three times a day. ℞. Volatile liniment, two parts; tincture of cantharides, tincture of digitalis, tincture of colchicum, tincture of iodine, of each one part. The patient was well in a few days, without taking a particle of medicine internally.

Since then, I have used the liniment repeatedly with advantage; several mild cases yielding to this alone, without any other treatment. The liniment is peculiarly adapted to the treatment of dropsy in old persons, children, or delicate females; where the powers of life are feeble, and the stomach and bowels too irritable to bear medicine internally.

I have lately treated another case similar to the one mentioned above:—the child having been more or less bloated for several months; the legs and body were as full "as the skin could hold". All appearance of disease was removed after a few days' use of the liniment.

That there is any especial virtue in the particular form or combination of remedies in the liniment, I do not believe; but that external remedies can be used with advantage in most cases of dropsy, I am sure.

TREATMENT OF CHOREA BY STRYCHNIA.

It is not irrational to use strychnia as a remedy in chorea, a disease which is undoubtedly cured by several other medicines, whose chief action is upon the spinal cord. We can even credit its producing some very striking recoveries; but, nevertheless, having in hospitals and elsewhere seen the hazards which attend the use of this medicine, we are not disposed to approve of the heroic plan of treatment recommended by M. Trousseau. The degree to which he pushes the medication actually amounts to poisoning, a proceeding which is never justifiable in therapeutics, when it can be shewn that other and safer measures have in like cases accomplished cures. Iron is a medicine which we have found not only safe, but also very efficacious in chorea; and one of the best forms of administering it is the citrate of iron and quinine. It may be well to make occasional changes, during the course of treatment, in the details of the medication, such as substituting the simple citrate of iron for the double salt, and giving a few drops daily of Fowler's solution of the arsenite of potash. It might not be wrong even to assist other remedies, in obstinate cases, by giving strychnia; but we would not take the responsibility of making the muscles of our patients rigid by it, to the extent advocated by M. Trousseau. The remarks at p. 54 of our number for January 1850, may be read with advantage, in connexion with this subject. The following is an abridgement of the paper of M. Trousseau, which has suggested the forgoing remarks.

Abstract of M. Trousseau's Memoir. M. Trousseau uses the syrup of sulphate of strychnia, containing five *centigrammes* of the sulphate in a hundred *grammes* of simple syrup (one grain to two thousand). The method which he follows is to give gradually increasing doses. According to the age of the child, he begins with two or three teaspoonfuls of the syrup for the first day, and the number is daily increased up to six. A dessert-spoonful is then daily substituted for a teaspoonful: when six have been reached, tablespoonfuls are then in like manner gradually substituted. The number of tablespoonfuls should be augmented beyond six, up to seven, nine, or ten, but more slowly, and at intervals of one or two days. These quantities should be regularly divided between the twenty-four hours, so that a portion may be taken every four hours. The dose should be increased so far as to produce tetanic rigidity; and this should be carefully watched for by the persons about the patient. When this appears, the dose must not be increased; and the quantity to be continued should be somewhat diminished. In general, the daily dose of the medicine varies from two to ten *centigrammes* (gr. $\frac{1}{3}$ to gr. iss).

One of the first symptoms of the tetanic effects of the strychnia is, itching of the hairy scalp and skin. The masseter muscles are first attacked; and when the patient complains of difficulty in opening the mouth, the dose should be continued, but not increased, as the medicine has a tendency to accumulate its effects. Sometimes there will be, after some rigidity, an interval of two or three days without any marked change; then tetanic symptoms will set in with alarming severity, as if the medicine had been accumulating. In other cases, the doses being the same, the effects will be much greater on one day than another: this may probably be due to meteorological influences. These irregularities ought to be borne in mind by the physician.

Sometimes the dose is not arrested when the first tetanic symptoms appear. The masseter muscles then become so rigid as to impede the speech; next, the patients are often seized with sudden cramps of the legs; and, when they attempt to walk, the body moves forward while the legs remain fixed, so that they fall to the ground. In other cases, instead of persistent tetanic rigidity, there are sudden contractions, so that the patients are thrown down by the rapid action of the triceps femoris muscle. The rigidity, and especially the contractions, appear when the patients make any sudden movement.

The medicine should be continued some days after the choreic symptoms have disappeared, in order to prevent relapses. In above ten years, M. Trousseau says he has seen no ill effects produced by the use of strychnia in the way he describes; and he believes it a safe and efficacious remedy, if carefully and properly administered. [*Révue Médico-Chirurgicale*, Jan. 1850.]

TREATMENT OF CHLOASMA HEPATICUM BY THE EXTERNAL APPLICATION OF TINCTURE OF WHITE HELLEBORE.

Dr. Lilienfeld, having proved the inefficacy of most medicines used as remedies for hepatic spots, and reflecting on the frequent employment of lotions of veratrum album in cutaneous affections, has been led to have recourse to the tincture of that plant, and has obtained most perfect success.

In the first place, especially when the bowels are at all constipated, a cathartic is given; and the patient is then made to use tepid soap and water baths for three or four days, to soften the skin. He is then directed to apply daily, while lying down, some of the tincture of hellebore to the coloured spots, and to wash these parts the next morning with hot soap and water, rubbing them well with a flannel. After three days, the spots usually commence to become pale, and diminish in extent; and, in a very short time, they are generally effaced. Relapses have occurred in no case.

One or two ounces of the tincture of white hellebore are sufficient for each patient: it should be made with the fresh root of the plant, and with alcohol of specific gravity ·830. [*Révue Médico-Chirurgicale*, Jan. 1850; from *Vierteljahrschrift für die praktische Heilkunde.*]

SURGERY.

PROFESSOR BOCK ON GENU VALGUM, OR KNOCK-KNEE.

The following is a translation of a paper published by Professor Bock in a Danish journal, the *Bibliothek for Læger*, for October 1850.

The most common deformities of the knee-joint may be arranged under the four following heads.

I. Contraction of the knee *(contractura genu)* is the name given to the condition in which the knee is in a state of abnormal constant flexion, with considerable, little, or no power of motion in the joint.

II. Recurved knee *(genu recurvatum)*. Here the knee is in a state of superextension, and the popliteal space forms the apex of an angle pointing backwards.

III. Genu varum, or bow-leg : called by the Danish wheel-leg *(Hjulbenet)*.

IV. Genu valgum, or knock-knee : in Danish, calf-knee *(Kalveknæet)* ; in German, goat's-leg *(Ziegenbein)*, X-leg *(X-bein)*.

The name genu valgum is borrowed from an imperfect analogy with pes valgus. In the latter, the foot is thrown outwards. In genu valgum, it is not the knee, but the tibia which is pressed outwards ; and the more correct denomination would therefore be tibia valga, if the analogy with the foot were preserved. The same is the case with genu varum.

Genu valgum has been but imperfectly described in surgical works. I have for some time been collecting materials for a more accurate knowledge of this deformity, and will now publish the results at which I have arrived.

The following is a list of the authors in whom I have found genu valgum slightly alluded to.

Andry. L'Orthopédie, ou l'art de corriger dans les enfans les difformités du corps. Paris : 1741. 8vo., avec figures. Tome i, p. 280.

Naumburg (J. S.) Abhandlung von der Beinkrümmung u. s. w. Leipzig : 1796, pp. 50.

Heidenreich (F. W.) Orthopædie, oder Werth der Mechanik zur Heilung der Verkrümmungen am menschlichen Leibe. Berlin : 1827.

Delpech (J.) De l'Orthomorphie par rapport à l'espèce humaine. Paris : 1828. Avec atlas.

Mellet (F. L. E.) Manuel pratique d'Orthopédie, etc. Paris : 1835.

Heine (J.) Beobachtungen über Lähmungszustände der unteren Extremitäten und deren Behandlung. Stuttgart : 1840.

Bonnet (A.) Traité des Sections Tendineuses, etc. Paris et Lyons : 1841.

Pathology. In the normal condition, the knee-joint deviates from the long axis of the lower extremity, on account of the greater extension downwards and inwards of the inner condyle of the femur. The thigh-bones hence converge downwards, especially in females, in whom the pelvis is wider, and the neck of the thigh-bone is larger and directed more outward. It is the unnatural exaggeration of this condition to which the name of genu valgum is given. It might be supposed, that this affection is more frequent in the female sex : such, however, is not the case, for it is far more rare in women and girls than in men and boys. Both knees may be affected, but one is generally more so than the other ; and it is then almost always the right knee which is the chief seat of the disease. When one knee alone is affected, it is the right in about twice as many cases as the left. The origin and progress of the disease are gradual and almost imperceptible.

The knee forms the apex of a triangle, the other angles of which are at the ancle and the great trochanter, so that the base consists of the straight line which may be drawn between these points. The altitude of the triangle, or the perpendicular line from the knee to its base, points out the greater or

less degree of the disease ; this may naturally be denoted by the anomalous proportions of the angle at the knee, which, from being very obtuse, becomes, in the more advanced stages, a right or even a very acute angle.

On examining the knee, the following changes are found. On its anterior surface, the united large tendons of the extensor muscles, and the ligamentum patellæ, are found much stretched ; and the more so, in proportion as the knee is bent backward as well as inward. The patella is displaced outwards ; so that, in a more advanced stage of the disease, it rests on the external edge of the knee, in front of the condyles of the femur and tibia. The knee loses its natural convexity forward, and becomes acute-angled on its anterior and outer edge ; and the anterior part which lies more interiorly forms a plano-convex region in front of the inner condyle. On the outer surface of the knee, or in the angular bend, we often find the tendon of the biceps much stretched, as well as one or two portions of the external ligaments extended into sharp strings. The external condyles, both of the femur and of the tibia, are small, and can scarcely be felt in the more advanced stages of the disease. When the curvature is very remarkable, there is a transverse furrow in the skin on the exterior part of the knee. The natural hollow of the ham is obliterated ; and the posterior surface of the knee-joint is more or less plano-convex. The inner surface of the knee forms the obtuse apex of the angle ; and here the internal condyles of the femur and tibia are felt always prominent, usually hypertrophied, and, in rachitic cases, enormously swelled.

The condition of the whole extremity is at the same time changed. The thigh assumes an oblique direction downwards and inwards, towards the opposite knee. The knee is directed inwards, against or behind the sound knee, and the shin-bone assumes a direction downwards and outwards, so that the foot is at a great distance from that on the sound side. As the disease advances, the direction of the foot is changed : but this will be treated of under the head of complications. In children, where the affection is of a truly paralytic nature, and has followed convulsions, there has been constantly observed a sinking of the temperature, as much as two degrees, in the diseased limb. In grown persons, I have not found this symptom. In consequence of the bending of the limb, the distance from the pelvis to the sole of the foot is diminished ; the direction of the pelvis in walking consequently becomes oblique, so that the anterior superior spine of the ilium may be found an inch lower on the affected than on the sound side. This obliquity of the pelvis becomes gradually permanent, so that it is observed both during walking and standing. In cases where the deformity has not yet reached a high degree, and in children, the limb can generally be brought back with the hands to its natural position : but the tension is felt to increase in the biceps femoris and external ligament of the knee-joint ; and, when the force is removed, the limb instantly resumes the bent position. In rachitic cases, not only the internal condyle of the femur, but also, in a still higher degree, that of the tibia is enlarged. The concavity inwards, which is naturally formed by the tibia, is obliterated : and, in the more advanced stages, there may even be a pretty conspicuous convexity, so that the whole extremity more resembles a bow curved inwards than an angular bending. The knee-joint generally retains its mobility. In the higher degrees of curvature, this is indeed somewhat limited ; but either true or false anchyloses are seldom met with as consequences of the affection of the knee which has been described.

When both legs are curved, the right leg is always slightly more bent than the other, and the apices are turned towards each other. This has given rise to the German designation of the disease—X-leg *(X-bein)*.

In this affection, the patients halt in a peculiar manner. If one bone only is affected, there is lameness—(*a*) because one extremity is too short ; (*b*) because the foot of the diseased limb falls beyond the centre of gravity of the body ; (*c*) because the affected knee, in walking, both hinders the free

swinging motion of the healthy knee, and is in its turn impeded by the latter. Each of these causes has distinct results, which modify both the direction of the limb and the lameness. When the extremity is too short, there is a natural attempt to compensate the defect; and this is effected partly by the already mentioned obliquity of the pelvis, and partly by the formation of a curve in the healthy leg. In healthy individuals, who have for some time had genu valgum, there will almost always be found a slight but true contraction of the knee in the sound leg. But in children, almost without exception, the other knee will become curved, either as genu varum or valgum. The outward direction of the tibia and foot causes the peculiar up-and-down lameness to become rotatory and swinging, like mowing, and this swinging is increased, to prevent the collision of the knees during walking. In the more remarkable modification, the body seeks to maintain its equilibrium; and it attains this object more completely than in many other forms of lameness—*e.g.*, from congenital dislocation of the thigh. This is partly affected by the position of the pelvis, and partly by a greater degree of mobility in the lumbar vertebræ. The diseased leg is generally sufficiently powerful, in persons affected with genu valgum, to enable them to walk for some distance. Naumburg has compared their gait to that of ducks; but this is scarcely correct. The gait is more swinging than waddling, as in persons with rachitic distortion of the pelvis or double congenital dislocation of the hip-joint. The patient who has genu valgum in one leg, endeavours, while standing, to preserve the centre of gravity by moving the sound leg somewhat outward beyond its natural position. Hence the points of support in the feet are at a greater distance from each other, and the surface within which the centre of gravity of the body can fall is greatly increased. Patients with double genu valgum usually, when standing, support the knees against each other, so as to form there a mediate resting point for the body, while the feet stand out from each other.

Complications and Secondary Deformities. These are more various in this than in any other deformity whatever. Where the disease has commenced in youth, a curvature of the spinal column will generally be produced by the obliquity of the pelvis and the lameness. The affected limb is not unfrequently more or less atrophied. Anchylosis of the knee-joint rarely occurs, unless some chronic disease have preceded or accompanied the deformity. I have, however, seen two cases of anchylosed knock-knee in elderly persons; in these the limb was also directed backwards. But it is the feet which are especially influenced by the gait produced by genu valgum; and hence knock-kneed patients have, almost without exception, some deformity or other of the feet. The patient may, in consequence of the abduction of the tibia, tread and walk on the inner edge of the foot, which hence often becomes callous. Hence there is a disposition to flat-foot, which is the most frequent complication. But, almost as frequently, the genu valgum is complicated with club-foot; and, as the shortness of the limb leads the patient instinctively to endeavour to touch the ground with the points of his toes, it is evident that these forms will be accompanied by a greater or less degree of talipes equinus. It has been hitherto impossible to determine the reason, why these secondary deformities of the feet should in some cases assume one form, and in others another. In certain peculiar cases, the deformity of the knee is secondary. A patient in Dieffenbach's ward had had, from childhood, *cyphosis accurvata* of the lumbar vertebræ: in his youth, varus had been developed in both feet, and, in his sixteenth year, he had become knock-kneed in both legs. Not uncommonly there is genu valgum on one side, and genu varum on the other, accompanied by the same, or by distinct deformities in the feet.

Causes. There is no doubt that genu valgum may be congenital; this is, however, a rare occurrence. The causes of the development of the affection

in later years are partly external, partly internal, but most frequently both are combined. The greater convergence of the thighs in women may be supposed to be a predisposing cause ; and Lessing[1] says that this affection is more frequent in females than in males ; this is, however, incorrect, for the deformity is twenty times more frequent in the latter sex, than in the former. Scrofula and rickets may be considered as predisposing causes, especially the latter. It still more frequently produces genu varum, in which case the external condyles of the femur and tibia are most affected and enlarged, while a similar swelling of the internal condyles gives rise to genu valgum.

Genu valgum may, as a general rule, be considered as a disease of a paralytic nature, and its most usual cause as a depressed state of innervation. Hence the commencement of the affection is limited to certain periods of life, in which the nervous centres undergo a more than ordinary degree of disturbance, connected with the state of development. Genu valgum is developed either during the first dentition or during puberty. This rule is so constant, that the only exceptions are the cases in which some local malady has given rise to the deformity : but these are comparatively very rare. In children, the disease has always, in my cases, arisen between the eighth month and the completion of the second year, and has always been preceded by difficult dentition, with fever, convulsions, violent hooping-cough, or, as in one case, acute exanthematic fever. This agrees with what has been stated by Heine, with regard to nine cases of knock-knee observed by him. The external causes, which may give rise to the affection at this age, and under the circumstances which have been mentioned, are, that the children *walk* too early, or too soon after a weakening illness, while they have not yet recovered strength, or that they are constantly carried on one arm, by which one knee is pressed inwards.

Among 221 cases of genu valgum, which I have observed, 17 originated during the first dentition. In a few instances, I have not been able to ascertain the period ; but in almost all the rest, or about 200, the deformity commenced between the fifteenth and eighteenth years, or at the time of puberty. In all these cases, there was an evident external cause for the deformity—the patient's position or occupation ; but the limitation of the age referred to above, together with the fact that many following the same occupation, under apparently similar external circumstances, do not become deformed, seem to shew that the external conditions are not sufficient to produce the disease, unless they meet with a corresponding disposition in the system of the individual, or rather in his development. We correctly consider the periods of dentition and of puberty as stages of development, in which the body is more obnoxious, than at any other period, to the hurtful operation of various extrinsic or intrinsic influences. That the deformity in question less frequently arises during dentition than during puberty, may be ascribed to the fact, that the influences above referred to, are more easily resisted by the system in the former than in the latter period.

This deformity is most frequent in smiths, joiners, bakers, and grocers. In 1846, there were in Copenhagen 644 smiths, among whom were

225 blacksmiths and anchorsmiths ; of whom 42 had genu valgum in the right leg, 7 in both legs=19 per cent.

359 locksmiths ; of whom 23 had genu valgum in the right leg, and 3 in both legs=7 per cent.

30 nailsmiths ; of whom 17 had genu valgum in the right leg, and 5 in both legs=73 per cent.

There were thus, in all, 97 cases of the deformity among 644 smiths, making an average of 15 per cent.

The following are the immediate causes of the frequency of the deformity among smiths. Almost all smith's work necessitates the long maintenance

[1] Lessing. Chir. Diagnost. Berlin : 1845. pp. 593-4.

of the same position, whether at the bellows, the anvil, or the vice; and, while standing in this position they often have to use much force, which leads them to seek a firm and solid footing. The feet are hence removed from each other, either both sideways, or one—always the left—forwards. In both these positions, any powerful effort will tend to produce genu valgum; for a great part of the weight of the body will, under the powerful movements of the arm and upper part of the body, act on the knee like a pressure from above and below. In blowing bellows, a work in which apprentices are generally employed, they must often stand uninterruptedly at work for several hours. At the vice and anvil, the left foot is placed forwards, the right backwards and rotated outwards, so that the toes are turned to the side. In this position they often stand with the leg and foot unmoved for several hours, while the upper part of the body is subject to constant and violent swinging, in order to use the file or hammer. The influence of the position on the knee will be easily seen by any one who will make a trial of it. Blacksmiths and anchorsmiths are besides constantly liable to have to bear heavy burdens. The fact that nailsmiths are most liable, in spite of their work being least laborious, is explained by the circumstance that they almost constantly use a kind of vice, which is fixed near the ground, and against which they all, without exception, place the inner surfaces of both knees, "because it is impossible for them to work in any other way."

Of 1340 journeymen carpenters, about 60, or 5 per cent, had genu valgum. It has been impossible to make very accurate observations on this class, as they endeavour to conceal the deformity as well as they can. It does not reach in them so high a degree as in smiths. Notwithstanding that the work of carpenters is less laborious than that of smiths, considerable exertion is required: most of the labour of carpenters, as sawing, planing, and polishing, requires the same positions as we have described in speaking of smiths. I have also observed that carpenters carefully watch for this deformity, and endeavour to prevent its development. Many masters have told me that they have had to set free their apprentices, or, in the first year, to caution them against habituating themselves to the posture which favours the commencement of the disease.

Of 334 journeymen bakers, 27 were knock-kneed; 24 were affected in both knees, the right being generally more bent than the left. One individual had the curvature only in the right knee. In 16, deformity had not reached a very high degree. Notwithstanding that bakers seem to be affected with this malady more than the other classes above-named, and several of them have some difficulty in walking, the deformity is not strongly developed. The disease does not arise from the position in which they stand while kneading dough; for in the first years, when this malady is developed, the apprentices are not employed at this labour. But the deformity is produced by standing at night at the board, often half asleep or contending with sleep, seeking for rest in the most varied positions; or partly by carrying water or sacks of corn. It is possible also that the great changes of temperature in attending to the oven may have some influence; but I consider the night-watching as the most essential cause, for the constant struggling with sleep produces a relaxation of the muscles. All the bakers in whom I observed genu valgum, also had flat-foot; and the latter deformity, in several cases, had preceded that of the knees.

The generally received opinion, that grocers' apprentices should be liable to genu valgum, from standing long, or from shutting drawers with their knees, I have not found supported by facts: for, among two thousand individuals of this class, I have in vain sought for any examples of this deformity. It is said to have been more frequent formerly; and what has most surely contributed to its removal, is the reform in working hours, it having been formerly the custom to keep the shop open much later at night, and to open it more early in the morning.

It hence results, that the general causes of this deformity are certain positions and habits, where these are often repeated, and especially at times when the body is more susceptible of their influence than at others. Other more accidental causes are, allowing children to walk too early, carrying heavy burdens, ulcers on the inner border of the foot, a burn on the outer side of the knee, resection of the upper end of the tibia, tuberculosis in the legs, caries, necrosis, rickets, syphilis, chronic abscesses, inodular bodies, etc.

The knee-joint is, properly speaking, a ginglymoid articulation, and its essential movements are merely flexion and extension; but the hinge-like movements are not so absolutely limited as in other analogous joints. The knee possesses a slight power of pronation and supination, but only when bent; and this power is dependent on the rotation of the tibia on its long axis, being limited, when the limb is extended, by the crucial ligaments. It is not connected with any peculiar apparatus, as in the rotatory movements of the radius and ulna, and may properly be considered as a slight twisting, which becomes possible on the tolerably flat upper surface of the tibia, when the knee is in such a position that rotation is not prevented by the extensor muscles. The knee has hence no power of abduction or adduction; and therefore the motions of this joint do not help to explain a deformity, which is characterised as an abduction of the tibia. Its immediate cause must be sought for in the parts which form, hold together, and strengthen the joint.

Although the part which these structures play in the production of this deformity is for the most part passive, the biceps femoris seems to be active in those positions in which genu valgum is chiefly produced, and to exercise the greatest influence on the increase, if not on the origin, of the deformity.

Supposing that one of the external influences which have been referred to should steadily act on the knee-joint, at a time when either convulsive disease (first dentition) or an unequally powerful development, perhaps in connexion with a rapid slender growth (puberty), have weakened the nervous system; then the parts on the inner side of the knee have no power of opposing the pressure outwards. They are overstretched and slackened; and thus the conditions arise for the commencement of genu valgum. The most important relaxation takes place in the internal lateral ligament, which is lengthened and thinned in its whole extent: in the more advanced stages, the four tendons on the inner side of the knee are also lengthened. On the other side of the knee, the tendon of the biceps, and both the external lateral ligaments, as well as the posterior, are strongly stretched.

When the deformity commences, the angle at which the biceps femoris acts constantly becomes more and more favourable to its increase. This is, however, still more favoured by the circumstance, that the weight of the body, which in the normal state is uniformly diffused over the upper surface of the tibia, is now transferred to the upper surface of the outer condyle of that bone. The inner condyle of the tibia, and that of the femur to some extent, are atrophied, even in cases which are not of rachitic origin. This hypertrophy is greater, in proportion to the youth or small size of the patient at the time when the deformity commenced. In rachitic cases, it sometimes attains an enormous degree. It is probable, also, that the internal semilunar cartilage is somewhat atrophied.

Prognosis. As genu valgum is a deformity which depends rather on relaxation than on any active contraction, the prognosis in general may be considered as scarcely favourable. It is, however, curable, when it comes under treatment in an early stage, and, which is more important, when the circumstances which have produced and kept it up can be removed. In young children, the knee can be brought with the hand into its normal situation; and in these the prognosis is most frequently good, when the necessary continued watching of the growth can be maintained, and when

the general condition of the child does not give a tendency to the continuance of the disorder, or to relapses. In young men, also, the deformity can be cured, when there are as yet no consecutive changes. But, under all circumstances, the removal of the deformity must not be looked on as complete; for, even when the curvature is completely removed, it will still be necessary to employ fitting means, to ensure the result desired.

Treatment. The treatment of genu valgum in young children, consists in mechanical means to keep the knee outwards; and this must be always supported by such general treatment, as the constitution of the child may indicate. The most simple apparatus is a splint, either straight or convex outwards, reaching from the hip-joint over the outer ankle, and fastened at the ends with circular bands. This apparatus, however, hinders the child from walking, and therefore can only be used constantly at night: hence it can only be used in the more unimportant cases. It is preferable to make use of a steel spring, convex outwards, furnished at the height of the knee with a hinge, fastened at the hip to a bow which can be stretched round the pelvis; just over the outer ankle, the lower end of the spring passes into another bow, which can be fastened round the tibia. The spring is furnished on the outside, through its whole length, with buttons, on which are fastened small leather straps, four or six in number. These are brought round the legs; and on the inner side of the knee they glide between flat *pelottes* which exert a pressure from within outwards, when the straps are stretched or buttoned. An apparatus of this kind may be worn for a long time, and its action gradually increased. It must be used for at least a year after the deformity is removed, and even then it must be gradually ascertained whether it can be left off.

The same apparatus, on a larger scale, and with greater strength of spring, can be used in grown persons. The patient can easily accustom himself to use it—indeed, he feels comfortable with it. In grown persons, it will generally be an indication, before employing mechanical treatment, to divide the tendon of the biceps, or of the most stretched fibres of the lateral ligaments, but generally only of the posterior lateral ligament. The mechanical treatment, after tenotomy, may appear tedious; but the result will be more perfect: but without great perseverance on the part of the patient, and careful watching of the deformity for several years, the treatment of genu valgum will in general be ineffectual.

CHRONIC OPHTHALMIA AND SPECKS ON THE CORNEA; THEIR TREATMENT BY SULPHATE OF CADMIUM AND TANNIN.

Fronmüller is in the habit of using, with great success, sulphate of cadmium, according to the subjoined formula:

Take of sulphate of cadmium, 20 centigrammes; distilled water of roses, 45 centigrammes; Sydenham's laudanum, from 2 to 6 grammes.

This collyrium is to be dropped into the eye.

Tannin is employed by Fronmüller in specks of the cornea, both in the form of collyrium and of ointment. The *ointment* is thus composed:

Take of tannin, from 40 to 60 centigrammes; prepared lead, 8 grammes. Make them into an ointment.

The *collyrium* is thus prepared:

Take of tannin, from 30 to 60 centigrammes; distilled water, 60 grammes; laudanum of Rousseau, from 2 to 4 grammes.

This formula is stated to be—though unchemical—very useful in chronic ophthalmia of an indolent character. The bottle requires to be kept well stopped. The tannin is a milder astringent, according to Fronmüller, than the mineral substances commonly employed in collyria. It produces a very powerfully astringent effect upon the vascular tissues. [*Annales d'Oculistique.*] The readers of the London Journal of Medicine may remember

that it was mentioned, at p. 1070 of our volume for 1850, that Dr. Cummings considers tannin superior to all other articles of the Materia Medica for astringent collyria, especially in purulent ophthalmia. The opinion of M. Hairion of Louvain of its great utility in similar affections was reported at p. 268 of the current volume.

SEPARATION OF WEB-FINGERS.

M. Pauli recommends the following method, in the *Medicinisches Corresp.-Blatt Bayerischer Aerzte.* The intermediate membrane is divided with a bistoury or scissors, close to one of the fingers, and in the whole length of the finger, till a little beyond the abnormal junction; the two fingers being at the same time forcibly separated by an assistant. In this way, enough of skin is left to cover one of the fingers; and the wound, being put up with agglutinative bandages, heals by the first intention. As to the wound of the other finger, it is covered with charpie, and treated so as to heal by granulation. As the whole of the wound of one finger is closed by skin, reunion of the fingers is impossible. The author states that, in several instances, he has successfully adopted the method now described.

CASES OF DOUBLE VISION AND STRABISMUS; CAUTERISATION WITH THE NITRATE OF SILVER.

Dr. K. A. Hille reports the following cases in *Ammon and Walther's Journal;* and we quote them from the *Journal des Connais. Médico-Chirurgicale* of the 17th April, 1851. They bear a strong resemblance to cases published by M. Deval in the latter periodical, for 10th Nov. 1850, in a paper entitled "*On Cauterisation of the Sclerotic Conjunctiva in some cases of Paralytic Strabismus.*"

Case I. A man, aged 28, was admitted on the 27th October, for the cure of double vision, and a chronic inflammation of the right eye, which Dr. Hille regarded as rheumatic. The latter affection readily yielded to diaphoretics, and slightly irritant treatment. There remained the diplopsia, and a slight squint. Aware of Dieffenbach's favourable opinion of the nitrate of silver as an heroic remedy in certain cases of passive strabismus, Dr. Hille resolved to try cauterisation with it, as a remedy for both affections. He operated on the 1st November. The patient being seated, and his upper eyelid fixed by an assistant, he was directed to look at the root of his nose; the solid nitrate of silver was then applied to the conjunctiva, at the external angle of the right eye, above the rectus externus muscle. The patient left the hospital entirely cured.

Case II. A patient suffering from venous cardialgia (?) applied to Dr. Hille during the following year. She had likewise convergent passive strabismus of the right eye. The globe of the eye being turned upwards, and towards the internal angle, the cauterisation was made between the rectus internus and rectus inferior muscles. Some inflammatory symptoms followed the operation; but, at the end of three weeks, the patient left the hospital, as radically cured as the other, whose case was above detailed.

TREATMENT OF GONORRHŒA AND SYPHILIS IN NEW YORK.

In the Report of the Venereal Hospital attached to the New York Penitentiary, we find the following remarks:

The Croton water has recently been introduced into the hospital, and Dr. Kelly has availed himself of this extensively in the treatment of blennorrhagia, uterine diseases, and many cases of primary syphilis. In the water closets of each ward, a hose with a stop-cock and vaginal syringe termination has been attached to the water pipe, and a convenient seat, with a pipe for

the waste water, fitted up. On this seat each of the aforesaid patients place themselves daily or oftener, and introducing the hose, enjoy a most thorough irrigation and purification of the parts. The doctor sanguinely anticipates much good, both moral and physical, from this addendum to his plan of treatment.

The *Iodide of Potassium* is administered only in a few forms of constitutional syphilis, but in many of these it is given in large doses. From two to six drachms daily is not unusual. Opium, iron, and good living, are considered indispensable in the treatment of almost every form of constitutional syphilis. [*New York Register of Medicine and Pharmacy*, 1 June, 1851.]

OBSTETRICS.

CASES OF IMPERFORATE VAGINA AND OS UTERI.

Two interesting cases of imperforate vagina and uterus have recently been recorded in the *Gazette Médicale:* one by Dr. Debrou of Orleans, in the numbers for January 18 and 25; the other by M. Armand Trumet, in the number for May 31, 1851.

Abstract of Case recorded by Dr. Debrou. *Summary.* Complete Congenital Obliteration of the Vagina, with Imperforate Cervix Uteri: Formation of a Vaginal Canal and Uterine Orifice: Marriage: Pregnancy: Delivery at the Full Period: Convulsions: Application of Forceps: Child Dead; Metro-Peritonitis: Death on the Tenth Day. In the beginning of 1847, Dr. Debrou was consulted by L., a girl nineteen years old, who had, since she was seventeen, suffered monthly from menstrual pains, without any catamenial flow. For three months before she consulted Dr. Debrou, the pains had become very severe, and lasted for several days each time; and, in the intervals, instead of regaining her health, she had lost sleep and appetite, and become very thin. Her abdomen had also become enlarged. On examination, an oval tumour, of the size of a hen's egg, painful on touch, and slightly moveable, was discovered on the right side. In the hypogastrium there was a more extensive tumour, reaching from the pubes to two finger-breadths below the umbilicus: it was regularly rounded, slightly painful, and firm, but somewhat elastic. Between the nymphæ, clitoris, and frænum, there was a slight depression, without an aperture, in the situation of the orifice of the vagina. On examination, with the finger introduced into the rectum, and a female catheter in the bladder, these organs were found to be separated by an interval of three or four lines, formed of a firm material.

Dr. Debrou hence concluded: 1. That the hypogastric tumour consisted of the uterus distended with menstrual fluid. 2. That the small moveable tumour at the side of the other, in the right flank, was the ovary or Fallopian tube similarly distended, and perhaps ready to burst into the peritoneal cavity. 3. That the vagina was almost or entirely absent, being replaced by a fibrous tissue. 4. That, in order to rescue the patient from inevitable death, the fibrous tissue between the vulva and cervix uteri must be divided by an operation.

On February 22, 1847, the operation was performed by Dr. Debrou and M. Vallet of Orleans. The patient was placed on the edge of a bed, with her thighs separated, as in the operation of lithotrity. The bladder was first emptied. The right index finger having been placed in the rectum, Dr. Debrou penetrated with a bistoury the centre of the space between the frænum and urethra. He gradually divided the resistant fibrous tissue to the depth of about an inch, and then tried to complete the operation by tearing with his finger nail or the handle of the bistoury. He was obliged, however, to divide the tissue with the point of the instrument for an inch deeper, and he then felt with his finger a solid round body at the bottom of

the wound. With his nail and a large director he exposed this projection, which was situated two and a half inches from the vulva. Little blood escaped. On exploration *per rectum*, the projection felt was discovered to be a portion of the uterus—probably the neck. As the os uteri could not be in any way discovered, Dr. Debrou made an incision with a bistoury, and afterwards introduced a female catheter : a little blood escaped. The opening was still further enlarged by a bistoury guided on a director, and gave exit to a large quantity of semi-coagulated blood, like thick chocolate. A portion of it presented a redder colour the next day, and coagulated ; yielding, however, very little serum. On introducing the index finger into the uterus, this organ was found to form a large cavity, with very smooth walls. By placing one finger in the uterus and another in the rectum, the walls of the former were found to be very thin. Dr. Debrou thinks that this shows that *the uterus, when mechanically distended by an accumulation of the menstrual fluid, does not become thickened,* as it does when filled with the products of conception.

The subsequent treatment consisted in keeping the orifice dilated by means of a sound and charpie, and sometimes by a sponge placed in the vagina. On May 4, 5, and 6, the menses flowed in abundance. They were absent, however, in June and the following months ; and in March 1848, the uterus was again distended. Dr. Debrou, having in the meantime succeeded in dilating the vagina by charpie, sponge-tents, etc., made another orifice in the uterus, which he carefully kept dilated. The catamenia were absent in April, but they appeared in May and each subsequent month, with the usual symptoms : and the patient became quite well.

In February 1849, the patient married. Dr. Debrou examined her on the 24th of that month. She presented *embonpoint*, and her breasts were well developed. There had been no irregularity in menstruation ; and her health was excellent. A small quantity of mucous fluid exuded from the vulva. The vagina was nearly three inches in length, and easily admitted two fingers ; its walls were soft, supple, and lined by a covering analogous to a mucous membrane. At the extremity, the uterus could be felt, and a round aperture, with hard borders, which easily received the end of a female catheter. The cervix uteri could not be recognised. The bottom of the vagina, which was somewhat narrower than the rest, was attached round the orifice of the uterus. The abdomen was firm, and gave a clear sound on percussion, as far as the pubes : there were no signs of either of the tumours above described. The pelvis was well formed.

She had been married on February 12, and became pregnant very soon after. Dr. Debrou saw her at the end of April, when she had been pregnant above three months : the catamenia had not appeared since her pregnancy.

Nothing very remarkable occurred during gestation : she had an attack of diarrhœa in August, which lasted for three months, and much weakened her. Delivery took place on November 2, two hundred and sixty-two days after marriage. The pains commenced at five in the morning, and Dr. Debrou visited her at noon. The uterus then presented an aperture of the extent of a centimètre, through which a little liquor amnii had escaped. The head could be felt ; it had descended into the pelvis. The pains came on regularly every three or four minutes, and all seemed going on favourably.

At one p.m., the opening was of the size of a franc piece, so that Dr. Debrou could introduce his finger. The tissue round the orifice was firm and tense, although thin ; and Dr. Debrou divided it at the sides by means of a probe-pointed bistoury guided on his finger. Dilatation did not become much more rapid ; and at two o'clock, the orifice was as large as a two-franc piece. The pains were still frequent, and strong. Dr. Debrou made more incisions, but not quite so extensive as before : he could now pass his finger between the head of the fœtus and the walls of the uterus. At five p.m., the orifice was dilated to the extent of a six-livre piece, and the scalp of the

child projected into the vagina. The pains were more continuous, but less effectual; and the patient began to lose courage. She had frequently taken broth since Dr. Debrou's arrival.

At a quarter to six, the patient complained of severe pain in the head, and immediately had an attack of convulsions. Dr. Debrou took about two ounces of blood from the arm. The patient came to herself in about three minutes, and complained of pain in the epigastrium and head. A sinapism was applied to the region of the stomach. In about a quarter of an hour, another attack of convulsions occurred. Dr. Debrou, as soon as it was over, applied the forceps without difficulty, and extracted a still-born female child, which could not be reanimated. It had probably died during the attack of convulsions in the mother.

November 3. The patient had slept well. The uterus reached as high as the umbilicus, and was slightly tender on pressure. The perinæum had been torn for about an inch; but rather more than an inch remained sound in front of the anus. The recto-vaginal septum was uninjured. A poultice was applied to the abdomen.

November 4. The hypogastrium was tender; and the lochial discharge was diminished. The pulse was 120. Twenty leeches were applied to the hypogastrium. After this, the patient got better for some days.

November 7. At six p.m. she was attacked with colicky pains, without evident cause. They continued through the night: but Dr. Debrou was not sent for.

November 8. Dr. Debrou visited her at noon, and found her flushed; pulse 135, full and tense. The lochia were suppressed. The abdomen was tense, inflated, and painful everywhere. The uterus reached above the umbilicus—having been two finger-breadths below it on the proceeding morning. The urine had to be drawn off by the catheter. There had been no rigors. Twenty-four leeches were applied to the abdomen. The subsequent treatment consisted chiefly in the application of mercurial ointment and cataplasms to the abdomen. The patient continued much in the same state: and died on November 11, at one o'clock in the morning. An autopsy was not permitted.

Two questions are suggested by a consideration of this case:

I. Is it proper to operate on girls arrived at puberty, who have complete obliteration of the vagina, with imperforate uterus?

II. If the operation succeeds, can marriage be permitted, with the hope of a successful delivery? The last of these questions is first treated of, as being most interesting.

I. THE OPERATION FOR IMPERFORATE VAGINA AND UTERUS HAVING BEEN SUCCESSFUL, CAN MARRIAGE BE PERMITTED, WITH THE HOPE OF A FAVOURABLE DELIVERY? M. Amusat recorded, in the *Gazette Médicale* for 1835, pp. 785 and 817, a case in which he had operated for congenital absence of the vagina. He pronounced in favour of marriage; but there were no facts by which to prove the correctness of his opinion. Dr. Kluyskens also related a case in the *Annales et Bulletin de la Société de Médecine de Gand*, July 1845. The patient married; but did not become pregnant. Dr. Debrou hence considers that his case is the only one which throws light on the above question.

The ready manner in which conception took place, and the regularity of the pregnancy, appear remarkable: I. Because the long retention of the menstrual fluid, and the operations required to liberate it, might be supposed to unfit the uterus for the development of a fœtus; and II. Because the tumour formed by the ovary or Fallopian tube on the right side might be imagined to interfere with fecundation.

In the accouchement, there were three circumstances worthy of note: the

difficult dilatation of the uterine orifice, the convulsions, and the application of the forceps.

In ordinary circumstances, it may be easy enough to make incisions in the os uteri: but this becomes very difficult when the vagina is not of its natural size, and especially when the uterus does not project into the vagina. Hence the incisions made by Dr. Debrou did not produce the full effect which he desired; and from this cause, and the resistance of the orifice, resulted the tardiness of labour, and the long duration of the pains, which, having but little effect, were, he thinks, the principal cause of the convulsions. The forceps he would not have applied unless under pressing necessity: and the escape of the perinæum and recto-vaginal septum from any injury of importance were fortunate results, which he scarcely expected.

The metro-peritonitis could not be attributed to the length of the labour, which lasted thirteen hours. Could the combination of the incisions, the convulsions, and the application of the forceps, have produced the fatal affection? Dr. Debrou does not attempt to give a decided answer to this question; but believes it his duty merely to relate the facts, and leaves others to form their own opinions.

The following are the conclusions at which he arrives.

It was proper to advise the patient to marry. If she had been stronger, and not weakened by diarrhœa lasting for three months, she might have been delivered without the aid of the forceps. The convulsions were doubtless attributable to the resistance of the uterine orifice, and were the cause of the death of the infant: but they form no argument against marriage. The metro-peritonitis was not necessarily connected with the manner in which delivery took place, nor with the peculiar condition of the genital organs: but it was produced in the same way as in other women. If the patient had recovered, she might have again become pregnant, and have had a favourable delivery. With regard to the induction of abortion at the seventh or eighth month, this would not, in Dr. Debrou's opinion, be necessary. He believes that, *if another woman should become pregnant, after the formation of a vagina and uterine orifice by operation, she might be delivered without sacrificing her life, or that of the child.*

II. Is it proper to operate on females arrived at puberty, who have complete obliteration of the vagina, with imperforate uterus? Dr. Debrou objects to the term, *absence of the vagina*, which is frequently applied to cases of imperforation, as not sufficiently precise. He would use the term *imperforation* to express generally the absence of an external aperture, employing the term *occlusion* to denote that variety where there is merely imperforate hymen; *obliteration*, perfect or imperfect, where the situation of the vagina is more or less occupied by fibrous tissue; and *absence*, when there is no interval between the rectum behind, and the bladder and urethra in front. Of the latter variety, he believes there is only one case—that of M. Amussat, already mentioned—which has been operated on. These distinctions are useful, as the danger and difficulty of operation increase from the first towards the last; yet operations in each form have been successful.

The motive which should lead the surgeon to operate, is the danger of the inevitably fatal result to the patient, if she is not relieved from the accumulation of the menstrual fluid. We must not, however, follow the example of Stoltz, who formed an artificial vagina in a female who had no uterus: the operation has sometimes proved fatal, even in able hands, and can only be justified by necessity.

An important sign *is the presence of an ovoid tumour, slightly capable of rotation, distinct from the uterus, and situate at its side in one of the flanks.* In Dr. Debrou's case, he feared that it might burst into the peritoneum. M. Amussat also noticed this tumour in his case; and says that it opened

into the rectum, and gave exit to large quantities of blood, similar to that which escaped from the uterus. The bursting of this ovarian or tubal sac produced severe symptoms: and this should form an additional reason for speedily operating when it is perceived.

The operation for forming an artificial opening in the uterus, has been objected to by Sabatier-Dupuytren,[1] Bégin,[2] and Pigné,[3] on the ground of its being likely to produce metritis. Yet the operation is not necessarily attended with danger; and Barré,[4] Hervez de Chégoin,[5] Wattmann,[6] and Delpech,[7] as well as Dr. Debrou, have performed it without any such bad effects. Dr. Debrou believes, that if the opinion attributed to Dupuytren be fairly examined, he will be found to refer to those cases, where it has been necessary to operate also on an obliterated vagina. It is this, almost entirely, which constitutes the severity of the operation.

Dr. Debrou next offers some remarks on the fact, that he was obliged to make an opening into the uterus a second time.

Excluding those cases in which the os uteri has become closed in pregnant females after conception, and in which it has been necessary to make an artificial opening to render delivery possible, he finds nine cases recorded which throw light on this subject. These he divides into two categories. In the first, including four cases, those of Barré, Hervez de Chégoin, Wattmann, and Delpech, the vagina was of ordinary conformation. In the second, the vagina was more or less obliterated, or even entirely absent. This category includes five cases: one by William de Metz;[8] one by Desgranges;[9] Amussat's case; one by Dr. de Bal; and one by Dr. Kluyskens;[10] Dr. Debrou's case makes a sixth.

Two questions have to be considered: How long should a foreign body be left in the wound? What means have been used for opening the uterus?

All who have operated, except Delpech and Desgranges, have used a foreign body to prevent cicatrisation of the orifice. M. Hervez de Chégoin first introduced a gum elastic sound, and on the third day, a female catheter, which he kept in nearly two months. Dr. Barré introduced a large gum elastic sound, which he kept in only fifteen days, even taking it out several times on account of the pain which it produced. M. Delpech left the case to nature; the orifice is said to have remained open, and the menses to have flowed for two periods, after which he lost sight of the patient. Wattmann introduced a leaden canula: it is not stated how long it was retained, but his patient seems to have been cured. William de Metz introduced a plug of charpie; and says that "in a month, the patient was cured"; hence probably it was not kept in beyond that time. M. Amussat employed sounds for forty-four days, gradually increasing their size; and several times was obliged to suspend their use, on account of the pain occasioned, and because the patient was attacked with peritonitis. Desgranges merely introduced charpie between the *labia majora* and the vagina: but it appears probable that his case was not one of congenital imperforation, but of incomplete obliteration of the vagina and occlusion of the os uteri, resulting from

syphilitic vegetations and from adhesions following chancres. Dr. de Bal used a gum-elastic sound ; but for how long, he does not say ; he merely mentions that the vagina was very small and undilatable. Dr. Kluyskens introduced from time to time a gum elastic canula ; the cure was complete at the end of five weeks. Dr. Debrou at first used charpie, then a No. 8 gum elastic sound for thirty-four days, occasionally suspending its use towards the termination.

The instrument employed to make an opening in the uterus has been generally a trocar, a pharyngotome, or some analogous instrument. Three surgeons only—M. Amussat, Dr. Kluyskens, and Dr. Debrou—used a bistoury ; but they also enlarged the aperture, so that, in Dr. Debrou's case, he could introduce the finger into the uterus.

It hence appears, that neither the method of making the opening, nor of maintaining it, had much effect on the result ; which was persistance of the orifice, in every case except that of M. Debrou. His failure, he says, must be explained in some other way. We must take into consideration the coexistence of occlusion of the uterus, and complete obliteration of the vagina ; the difficulty of keeping open the orifice at the bottom of the newly formed canal, which itself has a tendency to close, especially at its upper part ; and the great importance of restoring the vagina to its natural dimensions—even greater than keeping open the uterine orifice. Most of those who have operated, have been content with making the vagina merely large enough to allow the escape of the menstrual fluid.

Sometimes the vagina is not obliterated at the upper part, and this will diminish the difficulty ; for it is the upper part of the vagina which especially tends to contract, and to narrow the new uterine orifice.

Dr. Debrou believes that he arrived at a more complete result than the other operators, and sums up his remarks as follows : " In the first place, the efforts of the surgeon should be directed rather to the restoration of the vagina than to the establishment of the uterine orifice ; because the first object is the more difficult, and much more important. Even though my case has only the merit of shewing the difficulties in the way of forming a vagina of sufficient dimensions, I believe that it will still be useful. In my opinion, this point is more important than the other, because, when life is assured by evacuating the uterus, if the orifice made cannot be easily maintained, on account of the contraction of the vaginal canal, it may be left alone until the vagina is restored. When this is once effected, a new incision in the uterus will not be attended by danger, and may easily be rendered permanent."

II. Case related by M. Trumet. *Summary.* Malformation of the Uterus and its Neck : Retention of Menses : Operation : Quinsy : Peritonitis : Death : Necropsy. A countrywoman, aged 23, was admitted on April 27, 1850, into the Hôtel-Dieu, under M. Jobert de Lamballe. She had been married ten months. Menstrual pains commenced at the age of fifteen, and occurred regularly every month ; but no discharge took place. When she was twenty-one, an operation was attempted ; but the only account she could give was, that the surgeon made incisions with a sharp instrument, and then placed pieces of charpie in the vagina. This was repeated three times, but still the menstrual fluid did not appear. The same surgeon subsequently advised marriage, assuring her that it would cure her. She therefore married in July 1849, and menstruated, for the first time, four months afterwards, and again two months before her admission into hospital. M. Landouzy operated on her in September 1849, " by raising a flap of the tissue in some part of the genital canal, and leaving there an instrument for three weeks ; after which he withdrew the instrument, and did nothing more."

On admission, she was of a good figure, slightly coloured, without any

expression of suffering. Her health was good, except during the menstrual periods. She then had severe pains in the whole abdomen, radiating to the groins, loins, and thighs, constipation, loss of appetite, general *malaise*, fever, and even vomiting. In the intervals, the abdomen was supple and painless almost in its entire extent, but was tender on pressure in the hypogastric region. There was in this situation a swelling in the pelvis, rising slightly above the brim, and probably formed of the body of the uterus. There was no pain on pressure in the iliac fossæ, and nothing could be felt there. The external aspect of the vulva was normal. The vagina was narrow and shallow, and terminated in a cul-de-sac, presenting some cicatrices, probably the results of the former operations. The cervix uteri did not project into the vagina ; in its place there was a hard firm tissue, not painful on pressure. On examining *per rectum*, the tumour lying behind the pubes could be felt in front of the intestine. There was nothing remarkable in the urinary or other functions ; except that the stools were difficult during the monthly uterine congestions. Since the last menstruation, she had had pain, first in the right thigh, and then in the left lower limb.

May 10. M. Jobert operated on her. She was placed on a table in the position for lithotomy ; and chloroform was administered. The vagina was held open, and the recto-vaginal septum was held down by an univalve speculum. M. Jobert then introduced a large trocar into the part corresponding to the neck of the uterus. Nothing appeared at first ; but in a little time there escaped from the canula one or two spoonfuls of thick, dark, pitchy blood, just like that which is found in the vessels of cholera patients, or rather like treacle. When this had ceased flowing, M. Jobert enlarged the opening with a bistoury and scissors. He then fastened the edges of the opening which he had made to the vaginal mucous membrane, by interrupted sutures, and then introduced a large gum-elastic sound. For some days, some of the same kind of blood continued to escape. The patient appeared to do well till May 17, when she had a rigor ; symptoms of peritonitis appeared the next day, and quinsy on the 26th ; and she died on the 31st.

Necropsy. False membranes were found in the peritoneum and on the pharynx. The uterine appendages were involved in the inflammatory exudations, and could not be recognised. The uterus was larger than in the normal state. It, with the vagina, was divided in the median line, and presented :

1. A highly developed fibrous texture.

2. A small round circumscribed cavity, of the size of a Provence nut, hollowed in the body of the uterus, in its tissue ; this cavity contained several clots of blood, and had no communication with another cavity, which will be presently described in the interior of the neck.

3. The neck of the uterus was of normal length and appearance, but was imperforate above, and had no communication with the uterine cavity : it was entirely surrounded by the vagina. The neck contained a cavity, elongated from above downwards, and having no communication whatever either with the cavity in the uterus, or, before the operation was performed, with the vagina. This alone can have been reached by the trocar. The peritoneum had not been wounded by the instrument.

CASE OF CATHETERISM OF THE FALLOPIAN TUBES; CONSEQUENT REMOVAL OF AN OVARIAN TUMOUR, PER VIAS NATURALES.

Dr. S. A. Cartwright reports a very strange case, which we give in an abridged form from a New Orleans Journal, as quoted in the *Boston Medical and Surgical Journal* for May 21, 1851, p. 318. We are surprised to observe that he does not allude to what Dr. Tyler Smith has written on catheterism of the Fallopian tubes. [*Vide* London Journal of Medicine, vol. for 1849, pp. 590, 676, 1068.] To apply a strong solution of nitrate of silver to the

inside of the Fallopian tubes, is certainly a step in advance of Dr. Tyler Smith!

Case. On the 10th March, 1850, Dr. Cartwright sent for Dr. Warren Stone to consult with him as to the removal of "a large and hard ovarian tumour from" a small, delicately-formed lady, aged 19, of sanguine temperament, and scrofulous constitution. When Dr. C. told the patient that it would require an incision two feet long for the extirpation of so large a tumour, she replied, that "she did not care if it were three feet, as she had rather die than live to suffer as she did". The lady had been married two years. She was pale; and looked as large as a woman in the ninth month of pregnancy. The tumour had been growing from her earliest recollection; but it had not been so large as to incommode her much till after her marriage. Treatment by iodine, etc., had been of no avail.

On the 18th of March, an examination by the speculum was made. The mucous surfaces were pale: there were neither leucorrhœal discharge, nor inflammation, nor congestion. A very small gum-elastic catheter, with a wire in it, after repeated efforts, was introduced into the uterine cavity. The passage of the catheter through the coarctation, called the os internum, gave some pain, and caused a faintish sick sensation. The small catheter was withdrawn, and a larger sized instrument was passed, with some difficulty, through the cavity of the cervix into the uterus. It penetrated about two inches: on being withdrawn, a little blood as usual followed. Dr. Cartwright now resolved to try catheterism of the left Fallopian tube. The catheter containing a wire was flexed like the male catheter, and passed through the fusiform cavity of the neck, into the triangular cavity of the uterus itself: the wire was withdrawn about half an inch, so as to make the point of the instrument more flexible, and was carried forward in the direction of the *ostium uterinum* of the left Fallopian tube. It entered the tube after a few trials, and after penetrating about an inch, it seemed to enter a cavity or expansion of the tube itself: it was pushed forward about an inch and a half more, seeming in its passage to encounter a soft yielding substance: it was then withdrawn, when a gelatinous substance followed, which was recognised to be a hydatid formation. The same catheter, with a very tapering point, was dipped into a solution of nitrate of silver (a drachm to the ounce of water). Several minims of the solution were drawn into it, by working the wire in the calibre of the instrument; it was then passed through the uterine cavity into the Fallopian tube, until it had penetrated the tube three inches, when it was moved about in the cavity of the tube, and the wire moved so as to eject the caustic solution through the eyes of the catheter, among the hydatid cysts that the instrument had reached. On withdrawing it, a semi-membranous, tenacious substance, with dark specks interspersed through it, not unlike frog-spawn, presented itself at the mouth of the uterus, seeking an exit, but too thick and glutinous to pass freely. Finding it too soft and yielding to be drawn away with the forceps, a little raw cotton was passed around a probe, so as to entangle the viscid substance, and by turning the probe, the stringy matter was wound around it, and pulled out of the uterus in long mucilaginous ropes. The supply seemed to be inexhaustible. The patient being much fatigued, the operation of drawing away the hydatids was at length suspended; nevertheless they continued to come away, *per vias naturales*, for a week or more. In the meantime, the tumour was reduced to less than half its former size, and grew softer and less painful. The "catheterism of the Fallopian tube" (?), *with the catheter filled with a strong solution of nitrate of silver*, was repeated on the 3rd of April, the 1st, 7th, and 13th of May. At the last operation, no more hydatids or viscid fluid were brought away; but at all the other operations, they were; and they continued to pass off for a week, or more, after each catheterism.

The day after the last operation, the patient left town for the sea-shore;

her health had begun to improve rapidly, her pains were gone, and her abdomen was reduced to near its natural size. While absent, her health appeared to be entirely reinstated.

Last autumn she returned to the city, quite well, though some fulness and hardness could still be felt in the hypogastric region, the effects of the former adhesions. Her general health improved during the winter, and she was enabled to dance, waltz, and walk about town as actively as almost any other woman. Although she suffers somewhat from painful distension in the abdominal and pelvic regions during her menstrual periods, and is dyspeptic and flatulent at such times, yet, when that is over, her form is quite sylph-like. The leucophlegmasia is giving way to the rosy hue proper to her original sanguine temperament.

Dr. Cartwright concludes his paper with the subjoined paragraph; we hope that he may yet tell us how he knows that he *did not* MAKE *a passage with his catheter*, in place of pushing that instrument up the cavity of the Fallopian tube?

"As this is the first case of ovarian tumour, as far as I know, which has been treated by catheterism of the Fallopian tubes, I have thought proper to report it. I do not consider the operation as always a difficult one, because, when the ovaries are in a morbid state, the Fallopian tubes are, in general, much more easily catheterised than in the healthy condition. I doubt its practicability in a state of health; possibly it might be effected during the catamenial period. The same important practical law obtains in regard to the uterus itself, it being generally easier to probe when in a morbid state. I have succeeded in curing some cases of dysmenorrhœa and sterility by catheterism of the Fallopian tubes, selecting the proper time for the operation; but, as its virtues in this respect are already known to the profession, it is unnecessary to dwell upon the subject, farther than to say, that New Orleans can show some as unquestionable evidences of its efficacy in sterility as London."

DR. JOHN APPLETON ON PUERPERAL ANÆMIA.

We abridge the following from the *Boston Medical and Surgical Journal* for February 19, 1851.

CASE. Mrs. E., aged 26, had for two years previous to the period at which DR. APPLETON was first consulted, suffered with "dyspepsia". She first came under his care in January 1849, being then in the seventh month of her first pregnancy. She complained of dyspeptic symptoms, with obstinate constipation. The tongue was coated; the pulse slightly accelerated. The more urgent symptoms yielded to the use of aperients, with the subnitrate of bismuth and extract of henbane.

She was next seen by him on the day of her accouchement, which took place on the 8th of March. About a fortnight before, she had taken a severe cold, producing catarrhal cough, attended with considerable fever; not sufficient, however, to induce her to call any medical aid. The labour was natural, and easily terminated. The hæmorrhage, although free, was not remarkably copious; and the first few days after delivery were unattended with any unpleasant symptoms, except the cough and daily exacerbations of fever.

After the first week, her strength declined, and any attempt to assume the erect posture produced faintness. Her pulse varied from 104 to 120. The mucous expectoration was not profuse. Dyspnœa was occasionally urgent, although the patient was generally able to lie down. Headache, with intolerance of light and sound, frequent sighing, and extreme despondency, alternately with a high degree of excitement, now appeared. Epistaxis had occurred once or twice in the early period of her confinement.

She was visited by Dr. Longley, of Haverhill, in consultation, on the

eighth day after delivery; the bronchial inflammation and febrile excitement were the most prominent marks of disease. Percussion and auscultation gave no signs of organic disease, or of effusion into the thoracic cavities.

During the succeeding week, the heat of the surface subsided; the tongue, which had been coated, became clean; the appetite improved; there was an abatement of the cough, and a slight increase of muscular strength. The improvement, however, was but temporary. The prostration again became extreme; the pulse continued frequent, while it diminished in strength; the stomach became more irritable, rejecting both medicine and nutriment. The pallor of the face, which had for a few days been less remarkable, assumed more of the waxy, bloodless appearance, peculiar to the disease; the lips, tongue, and mucous membrane of the mouth, became pale; and she finally sank, on the 31st of March, twenty-three days after delivery.

Examination of the Body, Sixty Hours after Death. There was much fat in the subcutaneous cellular tissue, and also about the heart and abdominal viscera. The external muscles were somewhat coloured, but scarcely any blood followed the scalpel. The cartilages of the ribs were much ossified. There were some small petechial spots on the surface.

Thorax. The lungs crepitated perfectly in every part; their colour externally was a very light gray. There were no adhesions to the costal pleura. The cavity of right thorax contained 1½ pint of straw-coloured serum; the left nearly 1 pint. There was a solitary tuberculous deposit in the right lung. The pericardium contained more than ʒxiv of serum. The heart was large, flabby, and loaded with fat; its muscular texture was extremely pale, soft, easily torn, and resembling sodden meat. A small quantity of pale, watery blood, was found in the right cavities.

Abdomen. There was a considerable quantity of yellowish serum in the peritoneal cavity. The stomach was distended, containing ʒviij of brownish fluid; it tore by the weight of its contents, when raised. The intestines were loaded with fat; but they were not otherwise unhealthy, except exhibiting, together with the stomach, a pale, bloodless aspect. The liver was nearly one half larger than the normal size, of a pale lead colour; the texture was somewhat friable. The spleen was of natural colour, soft. The kidneys were pale and bloodless. The uterus was somewhat larger than usual at this period after delivery, pale, flaccid, and contained a small quantity of nasty slate-coloured substance, which, when removed, exhibited a dull white internal coat, on which the orifices of the uterine vessels could be discerned.

Head. Not examined.

There had been but a scanty secretion of milk at any time after confinement. Abscesses had, however, formed in both mammary glands, containing much pus.

Remarks. The actual morbid change in the characters of the blood in this disease, appears to be a diminution in the proportion of red corpuscles, without any alteration of the absolute quantity of fluid in the vessels, although the serum exists in undue proportion, and the specific gravity of the blood is diminished. The analyses of this fluid in chlorosis, by Lecanu, have shown it to contain, in 1000 parts, nearly 862 water, 83 albumen, and 55 red corpuscles; 115 being the average proportion of the last in the normal condition.

It is chiefly in connexion with the puerperal state that anæmia is most malignant, and seems in most cases to bid defiance to all remedies.

What is the peculiar influence of the uterine system upon the condition of the blood, which predisposes the circulating fluid to assume the peculiar character of chlorosis or anæmia? The term "hypæmia" has been suggested by Andral, as more correctly indicating the actual pathological condition in these diseases.[1]

[1] Should the present name be retained, "anhæmia", as proposed by Good, and by Professor Channing, in his valuable notes on this disease, may be the more correct orthography.

Dr. Appleton has reduced to a tabular form the symptoms in twenty-one cases of this disease, which have been described by different authors, including that of which the history has been given above. The results derived from this table show the greater or less frequency of the more prominent characteristics of the disorder.

In the records of these twenty-one cases, extreme pallor or bloodlessness of the surface was noticed in all. Emaciation, which both Good and Copland have mentioned, was only observed in three cases. Petechial spots were seen in two. The loss of muscular strength was noticed as remarkable in ten cases of the twenty-one. In three, syncope was induced by assuming the erect posture. Headache was prominent in five cases, and intolerance of light and sound was excessive in five. Eight patients complained of noise in the ears. Delirium is only noticed in two cases, and confusion of mind in one; while the mental faculties are described as remarkably clear in others. Restlessness was present in three cases. Dyspnœa was urgent in seven, and probably existed to a greater or less extent in others. Cough was noticed in three cases. Five patients suffered from palpitation, while the action of the heart was greatly accelerated in eleven. The digestive organs were affected as follows: Two patients had sore mouth. The appetite was diminished in five, and voracious in one. Nausea and vomiting were present in four cases. Diarrhœa supervened in seven, while the bowels were constipated in two. Four complained of excessive thirst. Chills were noticed in three cases. Among the puerperal patients, the secretion of milk was scanty in two, and milk-abscess was formed in three. Many of the descriptions are more or less imperfect, and some of the more prominent symptoms probably existed in other cases than those in which their appearance is recorded.

Pathology. The most important and constant lesion revealed by autopsic investigation of this singular malady, consists in the change in the character of the blood.

On collating the morbid appearances shown by *post-mortem* examinations, in six cases among the twenty-one to which reference has been made, the vessels are described as nearly empty of blood in three cases, while in all the six the fluid was of a pale red, watery, coagulating firmly in one case; while, in three others, the fibrinous deposits were whitish and soft. In one case, the blood was mixed with a thick, whitish, opaque fluid. No appearance peculiarly characteristic of the disease has generally been found in the cranial cavity. Increased firmness and density of the brain was noticed in a single case. There was considerable effusion in the cavities of the thorax, in five subjects; amounting to $1\frac{1}{2}$ pint in each cavity in one instance. The lungs were permeable to air in every part in all the cases, but slightly œdematous in two. Emphysema was present in one case. The quantity of serum in the pericardium was unnaturally increased in two cases, in one to more than a pint. The heart was pale and flabby in four, and in one the muscular substance was soft and easily torn, while in another it was moderately firm. The peritoneum contained a considerable quantity of serum in two cases, and was healthy in three. The intestinal canal was healthy in three cases: its coats were pale in two, slightly injected in another. The liver was pale in three cases, greatly enlarged in one, extremely friable in one, and healthy in one. The spleen was large in two cases, and healthy in another; it was soft in one case. In all the cases, the kidneys were pale, and in one flaccid. In every case in which the disease supervened on the puerperal state, four in number, the uterus was found to be pale; the muscular tissue was soft and easily torn in one case; and in two the tongue was flaccid.

In the present state of our knowledge, we cannot trace all the circumstances under which this disease is developed, or account satisfactorily for the phenomena presented during its progress.

Treatment. The most satisfactory results have followed the use of iron in some of its preparations. Of these the sulphate seems to have been most

generally used. The phosphate was principally relied on in the case above reported. Sir H. Marsh, in a communication to the *Dublin Journal of Medical Sciences*, considers iron to be most efficient, when combined with some one of the preparations of cinchona and other vegetable tonics. In those cases in which iron cannot be borne by the stomach, other metallic tonics, as the salts of bismuth, have been recommended in its stead. Pure and dry air, light, and a nutritious diet, are important adjuncts in the general plan of treatment.

THE OBSTETRICIAN'S TOILET: HINTS BY PROFESSOR SIMPSON.

In a recent discussion upon Puerperal Fever, before the Medico-Chirurgical Society of Edinburgh, Dr. Simpson urged "the great importance of carefully ridding the fingers from all matters in the least degree likely to prove hurtful, if inoculated into the vagina of a puerperal patient". Chloride of lime, he said, "has been recommended by various practitioners as a good wash for ridding the fingers of morbific matter". Dr. Simpson "has used for the same purpose for years, daily (or rather, generally, often during the day), a solution of cyanide of potassium, which is more effective even than chloride of lime; and it had this other advantage, that it removes, readily and at once, all such stains as the fingers of the accoucheur are apt to receive in treating uterine diseases—with nitrate of silver, iodine, and the like."

Dr. Simpson objects to the use of *gloves*. "He had been informed of an instance by Professor Patterson, in which a medical gentleman, after having lost several cases of puerperal fever, got rid of the disease in his practice by changing his clothes, and using chloride of lime, etc.; but it again returned to him, when he happened to deliver a patient, immediately after wearing a pair of gloves which he had used during the time of the puerperal epidemic: and certainly, if there was any piece of dress more apt to retain the contagion than another, it was this *useless and superfluous appendage* to our attire." [*Edinburgh Monthly Journal*, July 1851, p. 75-77.]

SUCCESSFUL CASE OF TRANSFUSION OF BLOOD.

In the London Journal of Medicine for June, p. 570, we gave an account of a case in which transfusion of blood had been practised by M. Nélaton, and in which the patient ultimately died. The operation, so far as its immediate effects were concerned, was successful; and we scarcely believe it to have had any influence in the production of the fatal attack of metro-peritonitis. We will now quote from the *Gazette Médicale* for July 5, a case, in which transfusion was performed by Dr. Marmonier under circumstances similar to those occurring to M. Nélaton, and in which the patient completely recovered. It is extracted from the *Revue Médicale* for 1851.

Case. On January 3, 1851, Dr. Marmonier was called to the woman M., aged 30 years, of a lymphatic constitution, slightly weakened by several frequent pregnancies, by tedious labours, and by moral and physical troubles. On his arrival, the pains had almost ceased. The patient was feeble, and exhausted by long and fruitless attempts to expel the child, which was prevented by anteversion of the uterus. Turning was performed. Unusual hæmorrhage followed; the placenta was rapidly extracted, and the uterus excited to contraction. The hæmorrhage was soon arrested.

In an hour and a quarter, hæmorrhage occurred in abundance, and was terminated by syncope. It soon recurred; and this time left the patient in a long fainting fit, and in a state of great weakness. Dr. Marmonier was called back to her; he found her extremities cold, the pulse almost imperceptible and sometimes absent; the sight was obscured, and there was frequent fainting. He employed astringent and refrigerant applications, the

concentrated infusion of ergot, dry frictions on the surface, and hot cloths to the limbs, for three quarters of an hour, without the least amendment. The death of the patient seemed inevitable, when he determined, although unprovided with the necessary apparatus, to perform transfusion of blood.

The apparatus which he was able to obtain consisted of a child's syringe, capable of holding 70 grammes (between two and three ounces), some hot water, basins, and linen. A young female, a neighbour of the patient, consented to supply the blood.

Dr. Marmonier laid bare the right basilic vein for about an inch and a quarter; he then isolated it for about four-fifths of an inch, so as to pass a thread under it, which might tie it down to the canula of the syringe. He then made an incision in the vein for one-fifth of an inch; only two or three drops of blood escaped. The vessel was compressed above and below. He then caused the blood to flow from the young woman into a cup placed in a vessel of hot water. Having first warmed the syringe, he filled it with blood, taking care to introduce no air, and introduced it into the opening in the vein. After carefully pushing down the piston about a third of its length, the flow was found to be retarded; this inconvenience was obviated by wrapping the syringe in cloths dipped in hot water, when it was again introduced. All the blood contained in the syringe now entered the vein. The total quantity introduced was about 90 grammes (about 4 ounces). The operation was unattended by pain or any other inconvenience.

Almost immediately after the transfusion, the respiration became more regular, and the pulse stronger. The disposition to syncope ceased suddenly. The obscurity of vision was rapidly dissipated. Dr. Marmonier ordered the frictions and hot cloths to be continued; and administered rhatany and ergot. The circulation and the animal heat were gradually reestablished. Two hours after the operation, the patient slept for some minutes; and this was followed by an unhoped-for amelioration. From this time, convalescence was rapid; the milk was secreted regularly. In ten days, the patient could sit up for an hour each day; on the twentieth day, she was quite well; and on the thirtieth day, she had resumed her ordinary occupations.

MATERIA MEDICA AND PHARMACY.

CHLOROFORM AS A SOLVENT OF CANTHARIDIN.

Mr. William Proctor, after noticing the discoveries of Rabourdin regarding the solvent powers of chloroform, makes the following very interesting statement.

An ounce (480 grs.) of Spanish flies in powder, and two ounces of chloroform, were macerated together for forty-eight hours, and thrown on a glass percolator, the diaphragm of which consisted of a thick sheet of lint, and fitted with a cover to prevent loss by evaporation. The superior density of the menstruum causes the flies to float in it, for which reason it is better, after the solution has drained off, to place a heavy diaphragm on the flies, and return the solution to the percolator; after it had passed a second time, a little chloroform was added, and finally alcohol ·835, until all the first menstruum has passed, which is known by the difference in density and colour of the alcoholic liquid, which contains the brown colour left by the chloroform.

By spontaneous evaporation, the dark green chloroform solution yielded a crop of crystals of cantharidin, admixed with the green fixed oil peculiar to the insect; the whole residue weighed forty-three grains. After standing forty-eight hours, that the crystals might have time to separate, the whole was thrown on several thicknesses of filtering paper, to absorb as much as possible of the oil. The crystals were then dissolved in a mixture of chloro-

form and a little alcohol, and by spontaneous evaporation were obtained in nearly a pure form.

The particular merits of chloroform as a menstruum in obtaining cantharidin, are, that it is a better solvent than ether or the oils; that a less quantity can be used with more effect, employing alcohol to displace it, and that the cantharidin crystallises more readily from chloroform than from ether. The expensiveness of chloroform precludes its use in the preparation of the ordinary blistering liquids, or tissues, but where the object is to isolate the cantharidin, the advantages above-mentioned, together with the fact that most of the chloroform may be regained by distillation, will render its use altogether eligible.

Cantharis Vittata. Not being aware of any chemical examination of this insect with a view to demonstrating the existence of cantharidin in it, I have applied the solvent property of chloroform to this purpose. One hundred and twenty grains of the flies, reduced to powder, were percolated with chloroform, slowly added, until three times the weight of the flies had passed. The tincture had a greenish brown colour, the brown predominating. A few drops of this, by evaporation on glass, deposited a coating of minute crystals visible to the eye; and their shape was discoverable with a common lens. The whole of the chloroform solution was then suffered to evaporate in a suitable vessel, and yielded a residue of twelve grains. This consisted of crusts of minute crystals, admixed with a greenish brown fixed oil, the latter in much less quantity than the green oil obtained in the same manner from Spanish flies. The whole was laid on thick filtering paper to absorb the oil, the crystalline matter dissolved in a little chloroform and alcohol mixed, which by spontaneous evaporation yielded it in a much purer form, though not entirely colourless. The cantharidin appears to be associated with less fixed oil in the potato fly, than in the Spanish insect; the oil has much less colour, and is more fluid. The cantharidin separates in sword-shaped prisms, terminated obliquely.

Mylabris Cichorii. Having in my possession a specimen of the Spanish blistering fly, mylabris cichorii, the same trial was made with it. One hundred and twenty grains, in powder, were percolated with chloroform till exhausted. The solution possessed a deep brown colour, without a tinge of green. A few drops evaporated yielded a crop of crystals admixed with a transparent brown oily matter. The crystals were larger than those yielded by either of the preceding flies under the same circumstances. The tincture was then suffered to evaporate spontaneously, and yielded an oily crystalline residue, weighing fourteen grains. The crystalline matter was separated from the brown oil by absorption with filtering paper, and was purified in the same manner as in the preceding experiments. The crystals corresponded in shape with cantharidin from the two varieties of cantharis.

In stating the weight of chloroform extract obtained from each of the three species of insects examined, no conclusive evidence can be drawn relative to their activity, as in the two first experiments the flies were not exhausted. Besides, the amount of oil and colouring matter varies; and, as in neither case was the whole of the cantharidin isolated from the extract, its absolute amount is undetermined. The fixed oil must be well pressed out from the crystals before purifying them by recrystallisation.

In order to feel assured that the substances obtained were really the blistering principles of the insects, a small quantity of each, mixed with a little oil, was applied to my arm, and left on for eight hours. Vesication had occurred before their removal in each instance, but more perfectly with the Spanish and Chinese flies than with the indigenous variety, owing, as was afterwards observed, to the crystals of cantharidin in the latter substance not being properly comminuted and disseminated through the oil. On the application of cerate, however, they were all equally developed. [*American Journal of Pharmacy.*]

CAFEIN: ITS CITRATE AND LACTATE.

The high price of cafein is at present an insuperable obstacle to its general use in medicine; but it appears from an article in the *Journal des Connais. Medico-Chi.*, for the 1st of April, 1851, that if it were economically prepared on a scale sufficiently large to admit of its therapeutic properties being fairly tried by different practitioners, some important results might be obtained. The citrate and lactate, but especially the former, seem to merit clinical investigation.

SULPHATE OF ZINC AND TANNIN COMBINED IN LOTIONS AND OINTMENTS.

It can be no objection in practice to the combination of these substances, that the sulphate of zinc is decomposed, provided it appear that by the combination we obtain a better astringent than is afforded by either separately. We are inclined to think that Ricord and others are right in supposing this to be the case. In gonorrhœa, Ricord frequently prescribes the following as an injection to be used two or three times daily; and it is obviously applicable as a lotion to other cases. Take of tannin and sulphate of zinc, each one gramme; rose water two hundred grammes. If the sulphate of zinc be perfectly pure, the solution will be colourless; but if (as is generally the case) it contain some oxide of iron, it will be of a deep red hue, from the formation of a tannate of the oxide of iron, which, being a good astringent, does not injure the lotion.

In France, ladies who suffer from leucorrhœa and relaxed vagina use a famous pomatum, known as the *pommade virginale à la Comtesse*. The basis of this nostrum is also a tanno-sulphate of zinc. The following is the formula for the preparation of this pommade. Take of sulphate of zinc, forty grammes; galls, and cypress-nuts, and pomegranate-bark, of each twenty grammes; myrtle leaves, and sumach, of each thirty grammes. Pulverize them: and mix them in rose ointment, the quantity used depending on the degree of astringency required.

NITRATE OF SILVER CAST IN BALLS.

Dr. Gideon Smith thus describes his method of using the solid nitrate of silver. He casts the salt in ordinary pistol and musket bullet-moulds. "Fuse the salt (crystallized) in a porcelain capsule, warm the iron bullet mould, and cast as you would a leaden bullet. You can then cement the bullet firmly, to a wood or other holder, with black sealing wax. In this form it presents a smooth surface, and you can make it as large as you please; and in the application of it to erysipelatous inflamed surfaces this is important. With the small bullet you can touch the surface of the eyelids, in scrofulous conjunctivitis, and the erysipelas of the face, very comfortably; and, let me add, with infinitely more effect than with the solution. In applying the nitrate to the cervix uteri, and the vaginal cavity, I use the ball attached to a rod sheathed with a glass tube; withdrawing the ball into the tube until I have reached the extremity of the cavity, then projecting it, I sweep the cavity around the cervix circularly, gradually working it outwards until the whole or such part of the cavity has been touched as I desire, then withdraw the ball into the tube, and withdraw that. By this means I save entirely the disagreeable and painful use of the speculum; and by shielding the ball with the glass tube, I avoid touching the external parts, or any part not desired to be touched. To old ulcers and sores, I use a nearly saturated solution of the nitrate with the happiest effect. I wet the whole diseased surface with a camel's-hair pencil, dressing afterwards with lint." *Boston Medical and Surgical Journal*, 23rd April, 1851. The method of Dr. G. Smith has obviously many and great advantages.

THE HOSPITALS OF LONDON. No. VII.

BY DR. CORMACK AND DR. SEMPLE, ASSISTED BY NUMEROUS REPORTERS.

HOSPITAL FOR CONSUMPTION AND DISEASES OF THE CHEST, AT BROMPTON.

Consulting Physicians — Dr. Forbes, F.R.S., Dr. C. J. B. Williams, F.R.S., Dr. Walshe.

Physicians — Dr. Hamilton Roe, Dr. Theophilus Thompson, F.R.S., Dr. Cursham.

Assistant-Physicians—Dr. R. P. Cotton, Dr. R. Quain, Dr. J. Hutchinson.

Consulting-Surgeon—W. Fergusson, Esq., F.R.S.

Resident Medical Officer—Vertue Edwards, Esq.

It has always been a maxim—and a very proper one—with the general hospitals of our metropolis, *to do the greatest possible amount of good to the greatest possible number of individuals;* and this has led unavoidably to the rejection of certain chronic and other affections, ordinarily looked upon as incurable, from their portals. Consumption having been necessarily included in this list, phthisical patients have long required some institution where medical skill might be sedulously devoted to their relief, and, after this may have failed, where tenderness and care might soothe their passage to the grave. In the hospital at Brompton, these objects are combined—both an hospital and an asylum are offered to the consumptive sufferer; whilst an opportunity is afforded, for the first time in this country, for extended scientific and practical observation upon a disease which annually destroys at least one in every 300 persons.

In the patronage given to this charity, England has set a brilliant example to other nations; for, notwithstanding the universality of consumption, no other hospital exists for its reception, except at Rome, where that of St. John in Laterano, containing 400 beds, admits females affected with phthisis; but it is not exclusively devoted to this disease, a certain proportion of the beds being employed for cases of fever.

The benevolent scheme of founding an hospital for consumption, in this country, was first entertained by Philip Rose, Esq., and communicated to several friends; and these gentlemen have now the satisfaction of seeing the fruit of their early efforts in the permanent establishment of the present institution.

In the year 1842, the charity commenced its operations in a private house in Chelsea, capable of containing twenty patients, and having a small out-patient department. But it was not destined to a long continuance in such comparative insignificance, and in so limited a sphere of action. In the summer of 1844, H.R.H. Prince Albert laid the foundation stone of the present building, which was completed in 1846.

The style of the building is worthy of remark, since it was the first attempt to adapt the collegiate and domestic architecture of England, as it prevailed towards the close of the fifteenth century, to the purposes of a modern hospital. It probably suggested itself to the mind of Mr. Francis, the architect, that something of a more cheering and inviting character than the plain and massive edifices of the present day was desirable for an hospital which was intended as the future scene of a somewhat unusual share of gloom. The architecture is Tudor. The walls are of red brick, with blue headers, interlaced in pattern; and Caen stone dressings are applied to the gables, windows, buttresses, etc. In form, the building resembles the letter H, consisting of a centre and two wings; one wing, however, yet remains unfinished. In the quadrangle facing the high road, the plainness of the walls is relieved

by oriel windows, buttresses, and battlements, and a tower with octagon turret rises from the centre; the doorway is deeply recessed and its top battlemented. The centre of the building is chiefly devoted to domestic and business offices; and the two wings are principally intended for male and female patients respectively. The wards differ in size, being constructed to receive from two to ten patients in each; they are light and lofty, and afford upon an average 950 cubic feet of air to every patient. The total accommodation, at the present time, extends to forty-five beds for males, and the same number for females; but the hospital will contain, when completed, not less than two hundred patients. All the window-sashes are fitted with double panes of glass, for the preservation of warmth and the avoidance of drafts; and there is a large corridor upon each gallery, well warmed and ventilated, where the patients can take exercise when unable to walk in the grounds attached to the hospital.

The mode of heating and ventilating the building occupied from the very first the anxious attention of the managing committee. The whole subject was referred to Dr. Arnott, under whose direction the present arrangement was carried out. It consists of an apparatus for propelling air warmed to a regulated temperature through the entire building. The warming and ventilating chamber is in the basement of the building under the central tower, and contains:—

1. A steam-engine for working the pump.
2. A pump for drawing in the external air, and propelling it through the building.
3. A series of copper plates arranged in a large chamber, so constructed that hot water passes freely between them, and imparts its heat to the air immediately after it has escaped from the pump.
4. Channels for conveying the heated air to every part of the building.

Two thousand one hundred and sixty cubic feet of air per minute are thus drawn from the exterior of the building, and forced between the heated copper plates, which are placed between the pump and the main channel. The admission of the air thus warmed into the wards and corridors, is regulated by a number of openings close to the floor, whilst its escape is provided for by one or more of Dr. Arnott's valves introduced into the chimneys. The fireplaces are not absolutely required for this arrangement, and therefore are generally kept closed.

Such is a brief sketch of this ingenious method of combining the heating and ventilating processes. A difference of opinion, however, has long existed as to its efficiency. Whether or not this is attributable to a defective manner of pursuing it, is equally disputed; and the whole subject of ventilation to be applied to the new wing is, as yet, under consideration.

The chapel, which is an elegant specimen of ecclesiastical architecture, built from the designs and under the direction of Mr. Lamb, was munificently founded by the Rev. Sir Henry Foulis, Bart., and consecrated in 1850. This building is likewise of the style of church architecture as it prevailed about the end of the fifteenth century. It is divided into nave, transepts, and chancel. The roofs are of arched wood framing, and the spandrels filled with tracery. The sittings are divided into classes; those in the chancel are for presidents or clergy; those next the transepts, for the governors and officers of the institution; and behind these are the seats for the patients. The whole of the seats are cushioned. All the fittings are of oak, and in appropriate positions are decorated with the arms and crest of the founder. Most of the windows have been filled with stained glass, presented by patrons of the institution. The chapel is approached by a corridor from the entrance hall, which, together with the chapel itself, is warmed by hot water.

Having described the general purposes and character of the building, at a greater length than may have been usual in this series of hospital records, but in a manner which could scarcely have been abridged, and may not,

perhaps, be deemed uninteresting, in consequence of its novelty, it remains that we should add some remarks upon its medical reputation as an hospital and school.

We might point to the "First Medical Report of the Hospital for Consumption" as an evidence of the zeal and ability of its medical officers. This publication, which has received the general approbation of the profession, and which was noticed in this JOURNAL (vol. for 1850, p. 37), was founded entirely upon the statistics of the hospital, and resulted from the *combined* efforts of the physicians and assistant-physicians,—a result of harmony and good feeling amongst colleagues, of which we hope, in coming years, to see many similar examples, not only in this, but in other hospitals. Observations upon a still larger scale, and embracing points not yet treated of, are steadily progressing at Brompton, and we look forward with no little pleasure to the appearance of the Second Medical Report.

In order to supply materials for these reports, a very perfect system of registration of cases, embracing their history, progress, and treatment, is carried on by two resident clinical assistants upon the in-patients; and a complete statistical record of the out-patients is likewise adopted by the assistant-physicians.

The following tables, derived from the hospital books, illustrate the kind and extent of these observations.

TABLE I. IN-PATIENTS.

OBSERVATIONS.

Date.	No.	Name.	Age.	Sex.	M. or S.	Mode of living.	Colour of hair & eyes.	Fingers clubbed.	Predisposition.*	How long ill.	Previous diseases.†	Catamenia.	Hæmoptysis.	Pulse.	Respiration per minute.	Cough, how long.	Expectoration.‡

N. Sweats.	Diarrhœa.	Urine.¶	Height.	Weight.	How long losing flesh.	Capacity of lungs.	Disease.	Complications.	Treatment.	Result.	Date of Discharge or Death.	Remarks.

* Under this head are arranged the various grades of relationship, viz., father, mother, etc.
† This is divided into "Nature of" and "How long since."
‡ Includes "character" and "quantity."
¶ Under this is given the Sp. gr., Quantity, Acid, Alkaline.

TABLE II. OUT-PATIENTS.

Date.	No.	Initials.	Age.	Sex.	M. S. or W.	Character of			Has had			Predisposition.	Disease.	Complications.	How long ill.
						Occupation.	Residence.	Living.	Scrofula.	Rheumatism.	Syphilis.				

Parts most affected.	Hæmoptysis.	Catamenia.	Pulse.	Respiration.	Height.	Weight.	Vital capacity.	Treatment.	Result.	Duration.	Remarks.

Careful and extended notice is also taken of the post-mortem appearances of fatal cases; a leaf of the book kept for this purpose is here transcribed.

TABLE III.

No.	Case Book.	Name and Age.	Date and Weather.	Hours after Death.	Rigor Mortis.	Condition of the				
						Body.	Brain.	Lungs.	Air Passages.	Pleura.

Condition of the							Remarks.
Heart.	Alimentary Canal.	Liver.	Spleen.	Kidneys.	Organs of Generation.	Glands.	

A pathological museum is in progress of formation, which must ultimately contribute important aid to the study not only of phthisis, but of other tuberculous diseases.

Pupils are admitted to the hospital practice, and some of the medical officers have already delivered lectures upon the diagnosis and treatment of phthisis; and hopes are entertained of thus rendering the charity useful as a school for the study of diseases of the chest.

Since the opening of the new building, 1,524 in-patients have been admitted; and between 3,000 and 4,000 persons attend annually as out-patients.

The in-patients are chiefly the subjects of phthisis; but sufferers from other diseases of the chest are frequently admitted. No selection is made of cases, so that phthisis may be studied in all its different phases. The period for patients remaining in the hospital is limited to three months; but cases which have arrived at the very last stage, and must soon close in death, are not dismissed at the expiration of this time; and the physicians are privileged to recommend an extension of residence to any particular cases, by which the purposes either of charity or medical science are likely to be advanced. The out-patients are not so limited as to the nature of their cases, any form of real or supposed thoracic disease being considered within the operation of that department: heart affections, dyspepsia, bronchitis, asthma, etc., are consequently common amongst them, and afford an excellent field for comparative diagnosis.

Cod-liver oil is pretty generally administered, in some form or other, by all the medical officers, whose good opinion of its effects, as originally expressed in their Report, still remains unshaken. This cannot be better shown than by the extent to which it is employed. In the year 1849, £260 were expended in this medicine alone; and during the first quarter of the present year, 156 gallons were disposed of. The best pale-coloured oil only is used; none of an inferior quality being now ever received into the hospital. During its administration, the patients are carefully and periodically weighed; and the results compared with the other symptoms. Some of the physicians have employed other animal and vegetable oils; and will, it is hoped, inform the profession of their comparative effects, when such have been sufficiently tested.

In closing this account of the Brompton Hospital for Consumption, we have only to express our approbation of the scientific and charitable zeal evinced in its operations. On future occasions, we hope to be able to place before the profession occasional reports upon the interesting points which must ever be presenting themselves to the notice of the physicians.

THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST.

[*With two Woodcuts.*]

In our last number (p. 688), we mentioned that the first stone of this Hospital was laid by his Royal Highness Prince Albert, on Wednesday the 25th of June last. We now propose to give a brief notice of the history and objects of the institution.

The City of London Hospital for Diseases of the Chest was established in June 1848; and differs in some degree in its objects from the Hospital for Consumption at Brompton, being established for the treatment of all forms of pulmonary and cardiac disease; while the hospital at Brompton was originally intended to be limited to the reception of cases of consumption. This rule, however, as we have stated, is not rigidly acted upon at Brompton. We think the promoters of the new hospital have done wisely, in deciding to admit to its benefits persons labouring under all forms of affection of the chest. Owing to the great prevalence of consumption in this country, the number of persons applying for relief, to any institution specially devoted to the treatment of that disease, will almost necessarily exceed the amount of accommodation; and thus many persons will constantly be waiting for admission, and comparatively few will be received till after the period has gone by during which medical treatment can be of much avail: and we can conceive few things more disheartening, both to the patients and their medical attendants, than to see constantly around them only those who are sinking rapidly under incurable disease, or whose sufferings are only susceptible of very partial alleviation.

Of late years, the number of institutions specially devoted to the treatment of particular forms of disease have too much increased; but, within just limits, we conceive that the practice is conducive to the advancement of medical science. Such institutions should, however, be limited to the reception of cases which require, for various reasons, to be placed apart from the mass of cases in a general hospital, or of which the cure can be best conducted in wards specially adapted for the purpose. They should embrace a sufficiently wide field of observation; and the attention of the medical men connected with them should not be too exclusively directed to the study of the class of diseases, for the relief of which they are established. The former of these requirements is, we think, fulfilled in reference to the institution in question; and of the seven medical men attached to it, five are connected with large general hospitals. The out-patient department has as yet only been in operation; but we observe by the reports that already 9,000 persons have been under treatment, and that the daily attendance of patients varies from 70 to 140; facts which sufficiently attest the want which existed for such an institution in the eastern portion of the metropolis. Though the hospital has been so short a time in operation, it has already been deprived by death of the services of two of its medical officers, Mr. Aston Key, the consulting surgeon, and Dr. Allen Williams, one of the acting-physicians. The present medical staff is as follows:

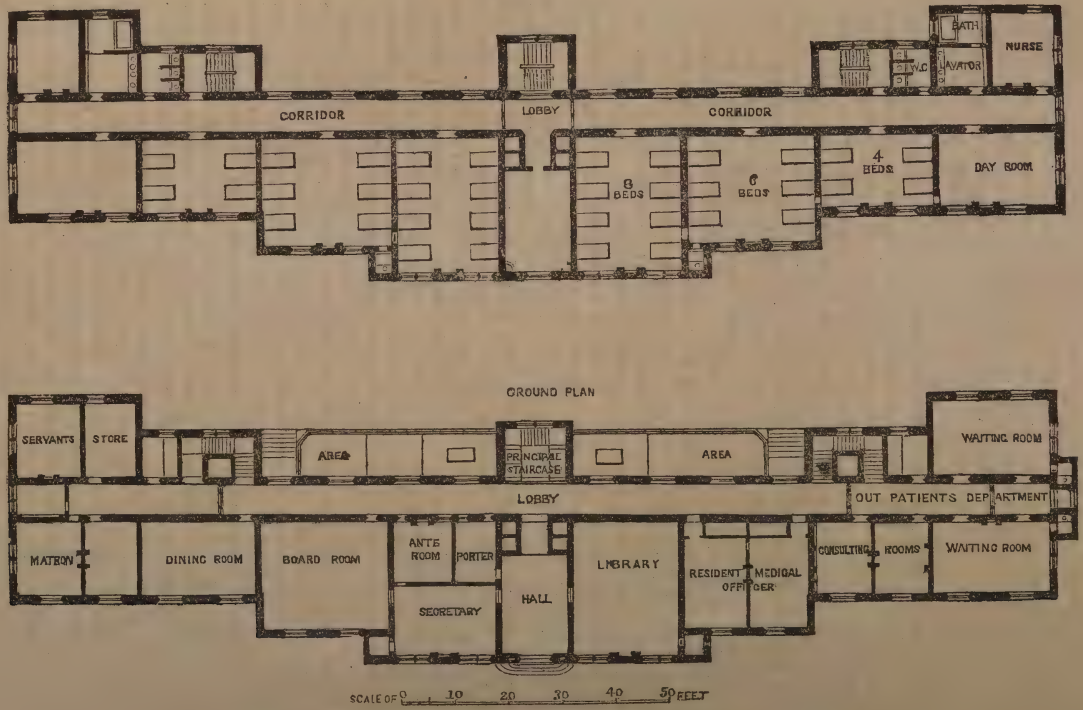
Consulting Physicians. Dr. Babington, and Dr. Jeffreson.

Physicians. Dr. Peacock, Dr. Bentley, Dr. Risdon Bennett, and Dr. Birkett.

Surgeon. Mr. Hilton.

It would be premature at present to speak of the institution as a field for medical study; but, with its present large number of patients, the opportunities for investigating the various forms of disease of the respiratory and circulatory organs must be considerable; and when the hospital is completed, its sphere of usefulness will be greatly extended. A system of statistical registration has been in use since the first opening of the dispensary, and will in time yield valuable results; and there already exists a collection of

Elevation of the City of London Hospital for Diseases of the Chest, Bonner's Fields, Victoria Park.



Plans of the First and Second Floors, showing the accommodation for In-patients.

preparations illustrative of cardiac and pulmonary affections, and which, though small, contains some rare and interesting specimens of disease. We trust that when fully in operation, the institution will form an useful school for the study of the particular class of diseases for the relief of which it has been established, and that it may conduce, along with the sister institution at Brompton, to the advancement of our knowledge of those affections.

The Hospital, the erection of which is now actively proceeding, will be situated immediately adjacent to the principal entrance to the Victoria Park, where a plot of ground, upwards of three and a half acres in extent, has been obtained from Government. This site is in every respect a favourable one. Its vicinity to the centre of the city, and to some of the most crowded and unhealthy districts of the metropolis, will render it easy of access to those who are likely to avail themselves of its advantages; while, being well drained, on a deep bed of gravel, and immediately adjacent to the park, it must ever be a dry, open, and healthy situation. The building has been designed of red brick and stone, in the style which prevailed at the early part of the last century. The central portion only will be first erected, and will contain wards for eighty patients, and full accommodation for the out-patients' department. The wards, which will be situated on the first and second floors, will be arranged for four, six, and eight beds each; the space allotted to each patient varying from 800 to 1200 cubic feet. A day room will be provided for each set of wards, in which patients capable of leaving their beds may sit and take their meals, apart from those more severely indisposed; and wide, lofty, and cheerful exercising corridors will occupy the whole length of one side of the building. Hot and cold water will be supplied throughout, and two complete sets of baths will be placed on each floor. Separate waiting rooms for males and females, with other accommodations, will be provided in connexion both with the consulting rooms and dispensary.

The ventilation of the building will be effected by a fresh air shaft, placed about fifty feet from the hospital, and raised twelve feet above the ground. This will lead into a chamber extending under the whole length of the basement, and sufficiently large to admit of being entered for cleansing, etc. By the side of this chamber will be placed a second, of the same dimension, with which it will communicate at frequent intervals. The air in this chamber will be warmed by hot-water pipes in connexion with a boiler and furnace, and will be thence distributed by flues which pass direct from the chamber into all the wards and corridors. The foul air will be extracted by a shaft passing up a lofty campanile, into which ducts will open from all parts of the building, and in which an ascending current will be maintained by means of a coil of hot-water pipes, heated by a separate furnace and boiler situated in the basement. The communications between the chambers in the basement will be so arranged, that a larger or smaller proportion of hot or cold air may be thrown into any part of the building; and a provision will be made, by which the whole current of air may be passed from the chambers into the exhausting shaft, in order that the air chambers may be kept pure and free from damp. Standard thermometers will be placed so as to show the temperature of the air; and an apparatus will be introduced, to regulate its hygrometric condition.

The hospital was designed by Mr. F. W. Ordish, and the plan was selected out of twelve presented in competition. The sum of £1,200 has already been expended in the enclosure of the site, and tenders have been accepted for the erection of the building at a total cost of £10,732. Mr. Joseph Paxton, the architect of the Crystal Palace, has furnished a design for a Sanatorium, to be erected at the back of the hospital, of glass and iron, and used as an exercising garden by the patients during cold weather. It is proposed to consist of an elegant building, 212 feet long, 72 wide, and 45 high, with a circular roof, on the ridge and valley principle. The interior will be divided

by a partition, 12 feet high, into two equal portions, having separate communications with the hospital, so that the male and female patients may take exercise at the same time. During cold weather, the air will be admitted by flues, running under the floor and up the partition. The requisite degree of warmth will be obtained from coils of hot water-pipe placed in the partition; and at the top of the building there will be a series of apertures, through which a portion of the air will escape, while another portion being cooled by its contact with the glass, will sink and re-enter the air-flues, so that the fresh air will be gradually diffused over all parts of the interior of the building, and a constant and agreeable current will be maintained, while all direct or cold draughts will be avoided. In summer, the warming apparatus will of course not be required, but ample ventilation will result from the effect of the sun upon the glass. The fresh air will then be admitted at the sides of the building, and in front of the apertures will be placed a screen, which, while it will interrupt the direct current of the air, and cause it to diffuse itself over the interior, will afford support to the roof. It is proposed to regulate, by a special apparatus, the amount of moisture to be contained in the air, both during summer and winter, and the conservatory will be stocked with plants which will flourish in the atmosphere maintained. The cost of the erection of the sanatorium is estimated by Mr. Paxton at £4000.

We do not suppose that the managing committee of the hospital will be disposed to take any part at present in the carrying out of Mr. Paxton's suggestions, nor would it indeed be desirable for them to do so till the hospital is advancing towards completion; but we hope the medical officers will give the plans their attentive consideration, and be prepared to urge upon the committee the erection of the sanatorium so soon as the financial condition of the charity will admit. For ourselves, we think Mr. Paxton's proposition, if carried out, would materially increase the means of usefulness of the institution. Among the many persons who in this country suffer from consumption, or other chronic pulmonary diseases, there are indeed very few who can afford to spend the winter at Malta, Madeira, or the south-west coast of our own island; and in the inferior grades of society, any change is often unattainable; and thus it too frequently happens, that complaints which, under favourable circumstances, are readily and completely curable, become, from too early exposure to the vicissitudes of our climate, or to the fruitful sources of disease which abound in the homes and workshops of the poor, either the cause of permanent indisposition, or of premature death. To all persons so circumstanced, the opportunity of resorting, during the cold weather, to a large and cheerful building, in which a pleasant exercising temperature will be maintained, and plants and other objects of interest will be placed, must certainly be very preferable to being constantly confined to their own rooms, provided, however, that the patients be not exposed to the external temperature in going or returning, for otherwise the result would more probably be injurious than beneficial. To the poor, the combination of a well adapted hospital, with a sanatorium of the description suggested by Mr. Paxton, will, we believe, be of great advantage, and we therefore sincerely hope that the plan may be carried out, and the patients of the new hospital be so placed in the circumstances most conducive to their entire restoration to health. In the treatment of consumption, and other chronic diseases, the employment of means calculated to invigorate the powers of the system, and to cheer and refresh the mind, are not less important than the use of direct remedial agents.

REPORTS OF SOCIETIES.

ROYAL MEDICAL AND CHIRURGICAL SOCIETY.

JOSEPH HODGSON, ESQ., F.R.S., PRESIDENT, IN THE CHAIR.

CASE OF POPLITEAL ANEURISM TREATED BY COMPRESSION; WITH REMARKS, AND A LIST OF THE CASES TREATED IN DUBLIN. By O'B. BELLINGHAM, M.D., F.R.C.S.I., Surgeon to St. Vincent's Hospital, Dublin. A labourer, aged forty-two, was admitted into St. Vincent's Hospital, under Dr. Bellingham's care in November 1850. The aneurism, which was of large size, was seated in the right popliteal space, had a strong, heaving impulse; and a short, harsh bruit was heard on auscultation. The treatment was commenced by placing the patient upon a very restricted diet, particularly as regards fluids (six ounces only being allowed in the day, with eight ounces of solid food), confining him strictly to the horizontal posture, with a dose of purgative medicine each night. Under this treatment, continued for some days, the pulse, from being hard and incompressible, became soft, small, and slow. Compression was commenced December 4th, at eleven A.M., by means of two instruments, one upon the artery where it crosses the ramus of the os pubis, the other at the lower third of the thigh. At half-past eight P.M., the outlines of the aneurismal sac were more distinct; the patient's skin was cool, and he did not complain of pain. He remained awake during the night, and kept up the compression himself, the points upon which the pad of the instrument should rest having been marked with ink. Next morning, between nine and ten, on unscrewing the instrument, the pulsation of the aneurism was found to have ceased; the tumour was hard, solid, and circumscribed, and an enlarged collateral vessel was felt over the centre of the popliteal region. Moderate pressure was continued for some days; the patient was kept in bed, and the diet was gradually improved. The tumour diminished in size, and became harder; and when the patient returned home, the limb was as strong as the other, and his general health perfectly good.

The author contrasted the results of compression and the ligature, and pointed to the advantages likely to ensue from combining constitutional with local treatment.

In a table appended to the paper, was given a list of all the cases of external aneurism treated by compression in Dublin during the last seven years, in which the seat of the disease was mentioned, the hospital or other locality where the treatment was conducted, the surgeon's name who had the management of the case, and the results were stated. Twenty-six were cases of popliteal aneurism, twenty-one of which were cured; six were cases of femoral aneurism, of which five were cured, the sixth having been a form of traumatic aneurism, in which amputation of the limb was the only resource. Three were cases of brachial aneurism, of which two were cured; in the other, a high bifurcation of the brachial artery existed, and two vessels required to be tied. One was a case of radial aneurism, which was cured by compression. Of the remaining five cases of popliteal aneurism, amputation of the limb was performed in one, the patient recovering; in a second, the ligature was used with success; in a third, the patient was obliged to return to his employment before the cure of the disease; the aneurism diminished in size, and the patient continued to work for above three years afterwards, when symptoms of aortal aneurism supervened, under which he sank. In a fourth, the patient died of pulmonary disease; and the fifth patient, who was of a broken-down constitution, died of erysipelas.

DISSECTION OF A CASE IN WHICH TWO POPLITEAL ANEURISMS HAD BEEN TREATED BY COMPRESSION OF THE FEMORAL ARTERIES. By PRESCOTT HEWETT, ESQ. A man, aged thirty-eight, was admitted into St. George's Hospital, in the middle of 1848, under Mr. Cutler, with an aneurismal tumour in each popliteal space. That on the right side, completely filling this region, was compressible, but could not be emptied; that on the left, not larger than a small egg, was hard, and to a great degree apparently solid, and with much less pulsation. The tumour on the right side had only existed three months, and nothing had been done for it. From the account of the patient, it appeared that the disease on the left side, which had begun about eighteen months back, had been treated by compression of the femoral artery, at the Wexford Infirmary, where the pressure had been kept up, more or less, for seventeen weeks. During this time the limb had regained its natural size, and the tumour was reduced to its present state, from which it had never since varied, and had caused him but little inconvenience. His general health, which had begun to give way about two years and a half back, had prevented him from following his business of musical instrument maker. When admitted into the hospital, he was pallid, and apparently suffering from great debility. At a consultation of the surgeons, it was determined, under existing circumstances, that compression should first be applied to the right femoral artery; and the instrument, a ring tourniquet, was so adapted as only to lessen the circulation of the limb, and to be worn for a few hours daily. In some little time the limb was reduced in size, and the tumour became smaller and firmer; but pulsation still remained. Some six weeks after his admission, and whilst he was under surgical treatment, cough and expectoration, with difficulty of breathing, made their appearance. Auscultation detected nothing abnormal about the heart, but the lungs were found to be engorged at the back part. The chest symptoms went on increasing in severity; and the patient one day suddenly brought up a large quantity of arterial blood, and died shortly afterwards. The tumour in the right ham had gone on decreasing in size, and had become firmer and more solid; but some pulsation was still felt. No change had occurred in the left ham.

At the examination of the body, which took place thirty-one hours after death, the left aneurismal tumour, deeply imbedded in the popliteal space, was found lying between the joint and the artery, of the size of an egg; it was pyriform in shape, and apparently quite solid, but on cutting into it, the lower half only was filled with long-standing coagula; the upper part, still presenting a cavity lined throughout by a perfectly smooth membrane continuous with the coat of the artery, merely contained some small recent clots. Of the two openings into the sac, the upper one was large, and nearly of the size of the artery; the lower one, on the contrary, was much contracted, and scarcely admitted a common-sized probe. The portion of the artery lying upon the sac was also very much contracted, but its coats were healthy, as well as those of the posterior and anterior tibial vessels, which were of their normal size. In the upper part of the popliteal, and in several parts of the femoral, there were large patches of atheroma, with three distinct aneurismal dilatations, one in the former vessel and two of the latter. The femoral artery and vein were pervious in their whole length, and the surrounding cellular tissue was not thickened. The vein and the nerve in the popliteal space were firmly adherent to the sac, with a few of the fibres of the gastrocnemius muscle. The aneurism on the right side, larger than a cricket-ball, was also lying between the artery and the knee, to which it was firmly adherent. It was filled with laminated coagula, except at the back part, where there was still a small channel leading from the upper into the lower part of the vessel; this channel was rough throughout, and covered with recent fibrine. The upper opening of this channel was free and smooth; the lower one was small, and below it the artery was reduced to the size of

the posterior tibial. Above the aneurism, the coats of the artery were much thickened by atheroma; and here too, about an inch and a half above the tumour, was another small aneurismal dilatation. The femoral artery presented several patches of atheroma; but it was otherwise healthy, and, as the vein, pervious throughout its whole course: the surrounding cellular tissue was not thickened. With regard to the popliteal vein and nerve, the appearances were the same as those observed on the left side. The thoracic aorta was extensively affected with atheroma throughout a great part of its course, and it was somewhat dilated. In its arch, it presented three distinct aneurisms, one of which, the largest, was lying between the large vessels and the windpipe, into which it had burst by a small ulcerated opening, about an inch above the bronchi: the cavity of this sac was partly lined with long-standing coagula. The bronchi were filled with blood, in addition to which the lungs themselves presented several large patches of pulmonary apoplexy, and were extensively affected with emphysema. All the abdominal organs were healthy, excepting the kidneys, which were somewhat smaller than natural, rough on their surface, and with several small cysts in their structure.

Abstract of the Discussion. Mr. Partridge was inclined to think that the London surgeons were open to the remark of Dr. Bellingham, of having neglected the plan under consideration. In King's College Hospital, pressure had been but little employed, and the result was by no means encouraging. This was partly attributable to the imperfect instrument employed, and partly to the circumstance of the patients being entrusted a good deal with the treatment themselves. Thus, a stout healthy-looking man was admitted into the hospital with a popliteal aneurism, and the management of the instrument was mainly left to himself. He screwed up the instrument so tightly that it eventually broke, but not until a large slough formed on each side of the aneurism, which remained in the same state. A ligature was afterwards applied; the man lost his toes by gangrene, but the aneurism was cured. If he (Mr. Partridge) had such an instrument as that exhibited on the table, he should use it, as it was a great improvement on the one usually employed in London. He inquired the experience of surgeons on the state of the artery after compression had been employed unsuccessfully; it having been urged by some that the artery, after the failure of compression, was not in so favourable a condition for the application of a ligature as before.

Mr. Quain had observed good results from compression in a few cases of popliteal aneurism; and he was favourably disposed to that treatment. He feared that a portion of the remarks in the paper first read were not calculated to conciliate support to the practice it advocated; he alluded to the remarks made in connexion with the statement that surgeons out of Dublin "decry" compression as a mode of treating aneurism. This statement, too, he believed to be erroneous; at least, he had not heard anything that would bear it out. But the question really was not, what is thought in Dublin, or in Edinburgh, or in London, but what was the fact as to the utility of compression in the management of the disease. While he listened to the paper, he was struck by the circumstance that no mention was made of the treatment in question being resorted to in aneurisms, other than the popliteal and femoral. He (Mr. Quain) had seen the late Mr. Liston use compression of the brachial artery in a case of aneurism of the hand from injury. Though the compression was made under favourable circumstances (for it was well applied, and the patient gave every aid to the surgeon), still it entirely failed. The disease in this instance was cured by ligature of the brachial artery. In the operation, this artery was by no means so easily secured as it usually is, owing to the thickening of the cellular substance and fascia by the compression; but there was no such difficulty in the case as would jus-

tify, in his opinion, any opposition to the use of compression upon that ground. He thought, at the time, that the want of success in this instance might perhaps have been attributable to the large nerve which courses over the brachial artery. The femoral artery, it would be remembered, has no nerve in of magnitude in company with it.

Mr. Partridge said that the statistics should state whether the patients were cured or not, and how long they remained well. Dr. Bellingham was right in saying that in London we did not habitually employ pressure, and that there must be some reason for it.

Mr. Quain had seen compression employed successfully in cases of femoral and popliteal aneurism, but at the moment he did not recollect the number of cases.

Mr. Prescott Hewett differed from Mr. Partridge respecting the employment of compression by London surgeons; at all events, he could speak for St. George's. During the last three or four years, there had been five cases of aneurism in the hospital, including the one detailed in the paper before the Society. Two of these were cases of popliteal aneurism, one of which was of very large size. In both cases, compression was applied to the femoral artery, but, owing to some peculiarity in the patient, compression was discontinued, and the artery was ligatured: and both did well. The instruments employed were not so clumsy as had been represented: in both cases, compression was kept up by two tourniquets in two parts of the artery. The patients were under the care respectively of Mr. Cæsar Hawkins and Mr. H. C. Johnson. In neither of the cases did the effects of compression render the application of the ligature more difficult. The third case was one of diffuse aneurism of the ulnar artery, consequent upon a wound; in this case, the tourniquet was applied over the brachial. He did not think that the failure in Mr. Liston's case of aneurism in the hand was attributable to the contiguity of the nerve to the brachial artery; for, in the case in St. George's, the pressure was applied over the brachial, and the patient was cured in a fortnight. In the fourth case, compression was tried, and acted apparently with good effect; but in two or three months the pulsation was again detected; the patient was unwilling to submit again to pressure; the artery was consequently ligatured, and a cure effected. The fifth case was the one related in the paper before the Society. In answer to Mr. Partridge, respecting the influence of compression on the after operation of ligature, he might say, in the case operated on, there was no thickening of the sheath surrounding the vessels.

Mr. Curling would have no disinclination to try compression, when a suitable case presented itself. It was a valuable plan of treatment; and the Society was indebted to Dr. Bellingham for bringing it forward. The instrument on the table was not sufficiently known in London. He thought, that in cases of compression on the femoral artery, obliteration of the vein, as in the case mentioned by Mr. Quain, might be avoided by having the pressure applied either just above or below Poupart's ligament. The instrument required management. Where did Dr. Bellingham apply pressure on the femoral artery? He thought Mr. Quain's observations respecting the brachial artery would be borne out by other cases. The pain would be very severe from pressure upon the nerve.

Mr. Cock said that his experience of pressure was limited to two cases of popliteal aneurism. In these cases, the only reason he believed the plan did not succeed was, that the patients did not persevere in the employment of the means—one discontinuing it in four, the other in six days. There was no reason to doubt that if the patients had gone on, they would have got well. The instruments employed in Guy's Hospital were by no means so perfect as the one on the table, and were more irksome. In each of the cases to which he had referred, the femoral artery was tied at the urgent request of the patient. Both patients got well; but in one case the

operation was rendered somewhat more difficult from some thickening and inflammation of the sheath of the vessels. Beyond this, the pressure had not interfered with the application of the ligature. He (Mr. Cock) had no doubt that the failure of the pressure in these cases, and the inability of the patients to bear it for any length of time, had arisen from the clumsy character of the instruments, and the bad manner in which they had been applied, The patients in these cases had not been sufficiently watched, and were seen only daily or every second day. Much more watching and care was required in the proper management of these cases than were usually bestowed on hospital patients, and to a neglect of these the failure in the cases he had related might fairly be attributed, as well also to the neglect of instructing the patient carefully in the mode of applying the pressure. He thought, however, that pressure in the treatment of aneurism would soon be much more extensively employed in London than it had been.

Mr. Hodgson hoped, that if Dr. Bellingham were in the room, he would give some further particulars of his mode of treatment. He thought the profession in England were very much indebted to their Dublin brethren for the great attention they had bestowed on the treatment of aneurism by compression, and to the improved method they had carried out. They had rendered compression much less irksome by the form of apparatus which they employed, and their substitution of an elastic material, like india-rubber, for an inelastic one. Another point alluded to was the application of pressure at two distinct points, so that pain and weariness might be prevented by changing the place of pressure.

Dr. Bellingham referred to some casts on the table of a limb taken before and after pressure had been applied to it, to cure aneurism. In one case, a popliteal aneurism was cured in twenty-four hours ; but an aneurism of the opposite side presented itself, and took a much longer time to cure. The patient eventually died from aneurism of the descending aorta. The artery over which the pressure had been applied was found quite normal ; the aneurism was obliterated ; the vein was normal. In another case, in which pressure had been applied to the femoral artery for popliteal aneurism, galvanic punctures having been also employed, the patient had died, at the end of ten days, from erysipelas. The aneurism was found nearly filled by layers of fibrine ; the artery under the seat of pressure was healthy. He had dissected a patient who had suffered from aneurism in both popliteal arteries. One of these was treated by compression ; the other by ligature. The latter returned at the end of three or four years ; not so the former. The vein and artery were found healthy. It was difficult to apply pressure to the femoral artery, without involving the vein in the compression. In almost every case which he had treated by compression, the pressure had been made at two or more points. He begged to say, that his observations referred to the Edinburgh surgeons ; not to those of London, on whom he had no cause to reflect. In the list of cases which had been alluded to in the reading of the paper (but had not been read) instances were recorded, in which the radial artery was the seat of aneurism, and which had been cured by pressure made on the brachial artery. [Dr. Bellingham sat down, amid much applause.]

Tuesday, June 24, 1851.

Joseph Hodgson, Esq., F.R.S., President, in the Chair.

On some Secondary Physiological Effects produced by Atmospheric Electricity. By Professor C. F. Schonbein. After referring to the more obvious effects of electricity upon the organs of sensation, and more especially those of smell and taste, and stating his belief that the peculiar odour observed when an electrical discharge takes place, or in the neighbourhood of points from which electricity is passing, is not due to the electricity itself, but caused by the presence of a peculiar matter which he had named ozone,

the author stated the opinions held respecting it—viz., that either pure or atmospheric oxygen, when exposed to the action of electricity, is transformed into this odoriferous body, which he was at first inclined to consider a peculiar peroxide of hydrogen, but which other eminent chemists believe to be merely an allotropic modification of oxygen. With reference to its exact composition he declined, however, to give a decided opinion. This body is a most powerful oxidizing agent; at ordinary temperatures oxidizing silver, forming iodic acid from iodine, nitric acid from nitrogen; converting the acids ending in *ous* into those which end in *ic*, the salts which terminate in *ite* into those which end in *ate;* metallic sulphurets into sulphates. It decomposes the gaseous components of hydrogen with sulphur, selenium, phosphorus, iodine, arsenic, and antimony, and exerts many other energetic chemical actions, both on organic and inorganic substances. It has a strong electro-motive power, similar to that of chlorine, bromine, and iodine; and lastly, it has certain physiological effects upon the animal system, similar to those of chlorine and bromine, acting powerfully as a poison, even in minute doses. Ozone is being constantly generated in the atmosphere by the electrical action going on. When in excess, it has a sensible effect upon the mucous membranes of those exposed to its influence, and its presence is indicated by starch containing the iodide of potassium being turned blue. The author availed himself of this fact in the construction of his ozonometer, which consists of a box containing test-paper thus prepared, and a chromatic scale. He believed that certain catarrhal affections were produced by the presence of ozone in the atmosphere, and he had, with the assistance of medical friends, ascertained the co-existence of unusual prevalence of catarrh with what he termed his *blue days*. The author then referred to the existence of poisonous miasmata in the atmosphere, which are generated by certain "purely chemical, or physical, or physiologically chemical actions", taking place within the earth, or on its surface, in stagnant or running waters, or in the atmosphere itself. Of these poisonous gases or vapours, there are two sorts which are antagonistic to and destroy each other. Of the first class, sulphuretted, and perhaps phosphuretted hydrogen, alone, are produced by natural causes, and in such minute quantities that they do not, except in a few localities, exert any general influence upon animal life. Of the second class, there is one, namely ozone, which exists in appreciable quantities in the atmosphere. But the abundant source of gaseous matters, is the decomposition of vegetable and animal substances. Some of these are well known, such as carbonic acid and ammonia; others are of unknown chemical nature, and though the absolute quantity of such deleterious matters may be small in comparison to the immense volume of the atmosphere, their accumulation would render the air unfit for the support of animal life, unless some agent neutralized or decomposed them. The purification of the atmosphere which we attempt to effect on a small scale by chlorine fumigations, is accomplished in the great processes of nature by the agency of ozone, a task for which it is peculiarly fitted by its high oxidizing powers. He gave the details of some experiments upon air tainted by putrid flesh, which was purified by ozone disengaged by the action of moistened phosphorus. Ozone decomposes the oxidizable miasmatic gaseous matters which contaminate the air, and thus the atmosphere is preserved in a state fit for the support of animal life, and, at the same time, the ozone, which, if allowed to accumulate, would become deleterious, is in its turn neutralized or decomposed by the miasmata.

During a thunder-storm, large quantities of ozone are formed; and the author supposed that the unhealthy state of the atmosphere which exists in the hot season of the year, may be caused by the accumulation of miasmata produced by animal decomposition; and that it is by the generation of ozone that thunderstorms purify the air. The author considered that there are probably certain states of the atmosphere, in which the quantity of ozone does not bear a due proportion to the miasmata it has to act upon, and that

under such circumstances it is that certain diseases—cholera, for instance—make their appearance. He was also of opinion, that in the winter there is more atmospheric ozone than in summer, and that the higher strata of the atmosphere contain more than the lower; and as the generation of some diseases, such as the yellow fever, appears to be connected with certain seasons and geographical positions, he thought that by an extended series of observations, it might be ascertained whether these diseases bear any relation to the ozoniferous state of that portion of the atmosphere where they happen to occur. The paper concluded with a reference to experiments, which proved that ozone produced by the action of electricity or by the agency of phosphorus is identical.

On a New Method of treating Certain Cases of Epiphora. By William Bowman, Esq., F.R.S. Some cases of epiphora depend on a displacement of the puncta lacrymalia out of the course of the tears, or on an obstruction of the canaliculi between the punctum and caruncle, the inner extremity of the canals, together with the lacrymal sac and nasal duct, remaining healthy. The author described the exact nature of these cases, and related examples. The treatment consisted in slitting up the canal from the punctum on the conjunctival aspect, so as to carry backwards the orifice at which the tears are received, on to the mucous membrane near the caruncle; the tears are taken up by the remaining portion of the canal, while the end towards the punctum is converted into a groove. For the cases of obstruction from injury or other cause, he suggested a modification of this operation, by which the canal between the obstruction and the sac may be slit up for some way, so as to receive the tears at a new opening. The cases to which these new operations are applicable, have been for the most part abandoned by surgeons as incurable.

Description of an Operation for the Radical Cure of Obstinate Stricture of the Urethra. By Dr. Nevermann of Mecklenburgh. [Communicated by B. Phillips, Esq., F.R.S.] Having tried all methods of treating obstinate stricture, the operation with a trocar catheter appeared to the author the most rational. The patient is placed as for lithotomy, and the catheter introduced as far as the seat of obstruction. The operator introduces one or two fingers into the rectum as a guide to the instrument; he then grasps the handle of the instrument, whose point is exposed, with the right hand, and pushes it steadily and forcibly forwards in the axis of the pelvis towards the bladder. When the resistance is found to cease, the trocar is drawn out and the catheter is left in the canal. In four or six days it is replaced by an ordinary elastic catheter. The paper was accompanied by drawings of the instruments and a description of them.

Case of Obturator or Thyroidal Hernia successfully relieved by Operation. By Henry Obre, Esq. [Communicated by Professor Erichsen.] After commenting on the extreme rarity of this form of hernia, and stating that he had been unable to find any record of its having been detected and relieved by operation during life, the author related a case in which he operated successfully. The patient, a female aged 55, the mother of a large family, was seized with symptoms of rupture. She denied that this was the case, and a careful examination shewed that there was no hernia in the usual situations. A little below the femoral region on the right side, however, there was a degree of hardness resembling a small gland, and deeply seated; with some general fulness about the part. The author saw this patient on the fourth day after the symptoms had begun. At this time, she was suffering extreme pain in the umbilical region; during the previous twelve hours, her vomiting had been stercoraceous and incessant; the countenance pale and contracted; voice faltering; pulse weak, small, and intermitting—in short, all the symptoms of pending dissolution from strangulated

intestine were present. On careful examination, nothing could be detected but a slight degree of fulness in Scarpa's triangle on the right side ; that on the opposite side being well marked. On using firm pressure with the ends of the fingers over the neighbourhood of the femoral artery, and a little below the saphenous opening, a distinct hardness was to be felt, slight in extent, but giving the impression as if the sheath of the vessels was being pressed on. The state of the patient was such as to induce the author to make an incision into the upper part of the thigh, down to the hard structure, in the hope that he might find confined intestine low in the femoral canal. He made a straight incision into Scarpa's triangle, as in the operation for tying the common femoral artery ; beginning about three inches below Poupart's ligament. When the cribriform fascia was opened, and the saphenous opening exposed, no hernial sac was found, but the hardened structure could be felt lying deep to the inside of this opening. The dissection was with some difficulty continued downwards ; the fascia lata was divided, and the pectinæus muscle exposed. The fibres of this muscle were divided transversely for about an inch and a half or two inches, and a hernial sac was exposed, which rose up into the wound to the size of a pigeon's egg. The finger, being passed along the sac, entered the obturator opening. The sac was opened, and the intestine was found to be a portion of the small gut, blue and congested. The opening through which it passed did not tightly enclose its neck, but it was considered prudent slightly to divide the edge. In doing this, the saphena vein was wounded, and it was necessary to apply a ligature to its upper part. This was the only ligature required. After the operation, no medicine was given ; in the course of the day the bowels acted three times, and in a few days the patient had quite recovered.

Some Observations on the Pathology of those Affections of the ear which produce Disease in the Brain. By Joseph Toynbee, Esq., F.R.S. The author had a two-fold object : the first was to point out the nature of the several affections of the ear which produce disease in the brain ; the second, to show that each of the cavities of the ear has its particular division of the encephalon, to which it communicates disease. Thus—

1. Affections of the external meatus and mastoid cells produce disease in the lateral sinus and cerebellum.

2. Affections of the tympanic cavity produce disease in the cerebrum.

3. Affections of the vestibule and cochlea produce disease in the medulla oblongata.

1. The intimate relations of the external meatus with the lateral sinus and cerebellum were pointed out ; and the affection most frequently producing disease in these parts was shown to be catarrhal inflammation of its dermoid layer, hitherto classed with numerous diseases under the term otorrhœa. This affection of the external meatus was fully described ; it may endure during many years, without pain or any other symptom of a formidable disease, while the bone may be becoming slowly carious, and portions of the dura mater and cerebellum disorganized.

2. The tympanic cavity is the part of the ear from which disease is most frequently propagated to the brain. This circumstance is accounted for, firstly, by the great liability of the mucous membrane of the tympanum to undergo pathological changes ; and, secondly, by the existence of very intimate relations between this membrane and the dura mater. The affection of the tympanum which most frequently produces disease in the cerebrum, is chronic catarrhal inflammation of the mucous membrane, an affection thus far only known as an otorrhœa. The four changes in the dura mater and cerebrum produced by the affections of the tympanum are—

a. Inflammation of the dura mater, and its separation from the surface of the petrous bone by serum.

b. Ulceration of the dura mater, and its complete detachment from the petrous bone.

c. An abscess in the substance of the cerebrum.

d. Undefined suppuration of the substance of the cerebrum.

From a careful examination of cases, it appeared that chronic catarrhal inflammation of the mucous membrane of the tympanum may exist twenty or more years, without the production of any disease beyond it, or at least without the existence of symptoms by means of which such disease can be diagnosed; nevertheless, in the great majority of cases, vital structures become sensibly affected in a much shorter period.

3. Purulent matter in the vestibule or cochlea sometimes causes disease of the auditory nerve, which is transmitted to the medulla oblongata, producing suppurative inflammation of the meninges, and death, without any caries of the bone.

The author showed the necessity of abolishing the use of the term otorrhœa, and of using in its place the names of the several diseases, eight in number, of which a discharge from the ear is one of the symptoms. The facts which he was desirous of impressing upon the minds of medical men were, that the bone, dura mater, and substance of the brain, may be slowly undergoing disorganization, without the presence of any other symptoms calculated to reveal the existence of formidable disease, than a discharge from the external auditory meatus; and that, consequently, no person suffering from catarrhal inflammation of the dermoid layer of the meatus, the membrana tympani, or of the mucous membrane of the tympanum, can be assured that disease is not being prolonged to the temporal bone, the brain, and its membranes; and that any ordinary exciting cause, as an attack of fever or influenza, a blow on the head, etc., may not induce the appearance of acute symptoms, which, as a general rule, are speedily fatal. Appended to the paper were tables, giving the particulars of sixty-five cases of disease extending from the ear to the brain, in which tables the duration of the chronic and acute symptoms, and the *post-mortem* appearances, were concisely detailed.

A Case of Obstruction of the Colon, relieved by an Operation performed at the Groin. By James Luke, Esq. (Communicated by James Moncrieff Arnott, Esq.) The subject of this report was a man aged sixty, who on December 16, 1850, first complained to the author of feeling generally unwell. He had no pain, but his countenance was depressed, his eyes sallow, and his tongue coated. The bowels were confined, and lately medicines had acted with difficulty on them. An aperient was ordered, and on the following day he passed a small lumpy motion, but without relief to the symptoms; castor-oil was ordered, but after a time was rejected by vomiting. On the 18th, there was no relief from the bowels; and he vomited everything he took. From this time, he progressively got worse, in spite of all the means resorted to for his relief. He complained of pain chiefly about the region of the cæcum. The transverse arch of the colon could be felt distended and tympanitic. A careful observation of the case had led the author to believe, that there was obstruction in the bowel about the sigmoid flexure of the colon, and it was resolved, as a last resource, to operate. The operation was performed on the 23rd. Mr. Luke opened the abdominal parietes near the groin, by an incision four inches in length, a little to the outside of the course of the epigastric artery, the lower extremity of which incision terminated a little above Poupart's ligament. The peritonæum was opened to about two inches. On passing the finger down the surface of the intestine, which now protruded, a diseased mass could be felt, which appeared to encircle the intestines. The bowel was then opened above this part; a large quantity of fæculent matter came away, and the patient expressed himself as relieved. On now passing the finger into the bowel, it was found to be impervious about two inches below the aperture.

After the operation, the recovery of the patient was rapid. On the second day, fæces passed *per anum*, and continued to do so for more than a month, when their passage through the natural opening ceased; it was again partially restored, but from this time the greater part of the fæces passed by the wound. This was closed by a well-fitted pad, and he had been enabled since to pursue his ordinary occupation almost without interruption.

The author then remarked on the danger of protracted delay in relieving such cases; a delay which is, however, to a great extent rendered necessary by the difficulties of diagnosis. The distension of the colon, and the evidence afforded by the proper introduction of the long tube, were pointed out as the two most accurate means for determining the seat of obstruction, when it is situated at the lower part of the colon. The advantages of the operations of Amussat and Littre were then compared, and the author, while admitting the advantage gained by operating in the loins, as proposed by the former—of not opening the peritonæal cavity—yet thought that the operation in the groin offered certain advantages. By the operation in the loins nothing more could be done than opening the intestine; but this might in some cases be improper—as where obstructions were produced by fibrous bands overlying the intestine, or by strangulations, the result of causes acting exteriorly to its tunics. In these cases, the proper treatment is to divide the bands, or relieve the cause of strangulation. In the event, too, of an error of diagnosis, the opening in the loins does not provide any facilities for correcting the error. The danger of total failure of affording relief, consequent upon this state of things, must therefore be attributable as a demerit to the operation in the loins. Besides, the opening cannot be conveniently attended to by the patient himself, and there exists frequently a great disposition to contraction, from the great depth of the wound, which requires renewed surgical interference. With the exception of the necessary peritonæal section, the operation of opening the abdominal parietes at the groin, in all cases of obstruction, or suspected obstruction, in the lower part of the colon, appeared to the author to be preferable. It affords facilities for modifying the treatment, either by opening the intestine, when incapable of relief by other means, or by dividing or removing any existing cause of strangulation. It enables the surgeon to extend his search within a limited range, in the event of the diagnosis proving incorrect; it allows him to open the bowel as close as possible to the seat of obstruction, and it secures to the patient the facilities for attending to his own comfort.

Abstract of a Paper on the Variations of the Sulphates and Phosphates excreted in Acute Chorea, Delirium Tremens, and Inflammation of the Brain. By H. Bence Jones, M.D., F.R.S. Having determined the variations of the sulphates in the states of health when different diets, amount of exercise, and medicines were taken, the variations of the sulphates in disease were examined. At the same time, the total amount of alkaline and earthy phosphates was determined, partly in order to see whether the amount of sulphates and of phosphates bore any relation to one another, and partly to test the conclusions which were drawn in the author's previous paper on the Variations of the Phosphates in Disease. The cases were thus classified:—

1st. Acute and chronic diseases, in which the muscular structures were chiefly affected, as chorea.

2nd. Functional diseases of the brain, as delirium tremens.

3rd. Acute inflammatory diseases of the nervous structures, as inflammation of the brain.

4th. Chronic diseases of the nervous structures.

5th. Acute diseases, in which neither the nervous nor the muscular structures were chiefly affected.

6th. Chronic diseases, in which neither the muscular nor the nervous structures were chiefly affected.

The three last classes gave only negative results.

In illustration of the first class, three cases of most intense chorea were detailed; the urine was examined frequently from the third to the eleventh day. The phosphates were diminished. The sulphates were present in very great excess. The urine was so loaded with urea, that nitrate of urea crystallized out before the urine was concentrated. The specific gravity of the urine was as high as 1036 in one case; 1035 in another; and, in the third, 1031.

In illustration of the second class, three cases of delirium tremens were given. The urine was examined from the fifth to the fourteenth day of the disease. The phosphates were not so remarkably diminished as in the cases reported in the previous paper. The sulphates were exceedingly increased. The amount of urea was so great, that nitric acid caused an instantaneous crystallization. The specific gravity was in one case, 1041; in another, 1037; and in the third, 1027. In other words, there was the most remarkable correspondence between the state of the urine in acute chorea and in delirium tremens.

In illustration of the third class, four cases of acute inflammation of the brain were given. The urine was examined from the fourth to the twenty-sixth day. Though the inflammation was not so intense as in those cases recorded in the author's previous paper, yet they confirmed the statement, that in inflammation of the brain the phosphates in the urine are increased; they also led to the conclusion, that the sulphates are at the same time increased in the same degree.

In conclusion, the author stated, that the phenomenon common to acute chorea and to intense delirium tremens is increased and unceasing muscular action. The muscles are highly complex organic compounds, in which sulphur exists in an unoxidized state, and the muscular action is accompanied, if not caused, by an action of oxygen, which, among other results, gives rise to the formation of sulphuric acid and urea, the amount of oxidation being proportioned to the intensity of the muscular action. The result produced is an increase of the sulphates and of the urea in the urine, just as in health they would be increased, if continued strong exercise were taken. The increased amount of urea does not constitute a disease resembling diabetes, but it is only an evidence of the changes taking place within. The increase of sulphates and phosphates in inflammation of the brain is also an evidence of increased oxidation of the nervous structures. These simultaneous variations depend on the fact, that the amount of sulphur in the brain is nearly the same as the amount of phosphorus. Thus, at one time, we have evidence of increased oxidation of the elements of the nervous structures, and at another time increased oxidation of the elements of the muscular structures; and we may thus conclude, that at one time the function of the nerves, and at another that of the muscles, is inordinately increased.

Successful Case of Ovariotomy. By John Beale, Esq. [Communicated by John Dalrymple, Esq., F.R.S.] The patient was a woman, aged 30, unmarried. The ovarian tumour was hard to the touch in the left iliac region and left hypochondrium, but soft and fluctuating on the opposite side, evidently in two distinct sacs, moveable, and not tender. It was removed on December 4, 1850, about a year after it was first perceived. The incision was ten inches in length, extending from the scrobiculus to the pubes. Two cysts were punctured, and their contents removed, before the tumour could be extracted; the pedicle was tied by a double ligature passed through its base, and the tumour was then separated as near as possible to it. The uterus and right ovary were healthy. Everything went on favourably; on the 15th Dec. she was able to walk about the room; and on the 25th, the ligature came away. The tumour was 3 ft. 2 in. in its largest cir-

cumference, and 2 ft. 1½ in. in its smallest; it weighed 25 pounds; it was multilocular, marked on the surface by bands of white fibrous tissue corresponding with the septa of the cysts. The cysts varied very much in size, and in the density and tenacity of their contents; in the smaller ones, the fluid was clearer and thinner. The average specific gravity was 1010, but the fluid contained a very large quantity of albumen. The total amount of fluid was from 21 to 23 pints.

Development of a large Cyst containing Hydatids at the Root of the Neck: Death from Rupture of the Left Subclavian Artery. By James Dixon, Esq. J. M., aged 24, a waterman, was admitted into St. Thomas's Hospital, January 14th, 1851. Nine years previously, a swelling had formed above the left clavicle, which slowly increased, producing occasional numbness in the left arm. At a later period, there was total cessation of the pulse at the left wrist. The swelling seemed to rise from about the situation of the first rib, having in front the sterno-mastoid muscle and the carotid sheath. The larynx was pushed a little to the right, and the voice had become hoarse and weak. No sign of aneurism or of heart-disease could be detected. A very indistinct fluctuation was felt about an inch above the top of the sternum, between the inner edge of the sterno-mastoid muscle and the common carotid artery, which lay on the median plane. A drachm of clear colourless fluid was evacuated from this spot by pushing in a trocar. Some weeks later, an incision was made in the line between the sternal and clavicular portions of the sterno-mastoid, commencing an inch above the sternum. A fascia-like membrane was exposed beneath the muscles; a trocar was passed in, and let out a few drops of colourless fluid. The opening was then enlarged towards the angle of the jaw, and a small collapsed hydatid escaped. The sac was large, and crowded with hydatids of various sizes. The wound was enlarged upwards; a small amount of arterial hæmorrhage occurred, which was arrested by pressure. The pulsation in the left radial artery was felt after the operation. Hydatids, some whole (one being of the size of a hen's egg), and others in fragments, were discharged through the wound, which was kept open. The patient went on well, the discharge of hydatids having ceased for some days, until the 27th, when profuse bleeding suddenly occurred from the wound. Pressure was applied, and a bladder of ice laid on the part. A second jet of blood took place fourteen hours after the first; a large hydatid, with a broad strip of sloughy fascia-like membrane, having been in the meantime voided. On the 28th, bleeding came on again; and the patient died on the morning of the 29th.

The sac in which the hydatids had been developed was of a fascia-like texture, and lined with shreds of sloughy fibrin. It reached, vertically, from the left side of the third cervical vertebra to the convexity of the aortic arch and apex of the left lung; and sideways from the middle line of the vertebral column to the scaleni muscles. Nearly the left half of the bodies of the fifth, sixth, and seventh cervical vertebræ, and of the second dorsal, had been absorbed; as also the head and neck of the first and second ribs. On examining the interior of the sac, the left subclavian artery was laid bare at about three-quarters of an inch from its origin, and presented a rent in its coat rather more than half an inch in length. The pressure between the hydatid sac and the border of the first rib had totally obliterated the calibre of the vessel for about half an inch; external to the scaleni it regained its proper dimensions. The left lung was healthy; there were slight traces of recent pleuritis. A single collapsed hydatid remained in the sac. Those which, during the progress of the case, had escaped entire, were carefully examined with the microscope. In several of the size of pigeon's eggs, clusters of echinococci were found in various stages of development; but neither in the largest, which was equal in bulk to a hen's egg, nor in those about the size of peas, could any of these bodies be discovered.

STATISTICAL REPORT ON DISEASE OF THE HEART, DERIVED FROM A CONSIDERATION OF ALL THE CASES ADMITTED INTO ST. GEORGE'S HOSPITAL DURING THE LAST TWO AND A HALF YEARS. By DR. BARCLAY. Rheumatism was first considered as one of its causes. Divided into two nearly equal classes—those really inflammatory or acute, and those less so, or sub-acute—the former class was found to contain sixty-seven cases with cardiac lesion, sixty-four without, and twenty-one doubtful. Endocardial murmur was found not to be certain evidence of disease, even in the most acute cases. Females were slightly more liable to acute rheumatism than males, but less liable to a recurrence of the disease. Females were more decidedly liable in a larger proportion to cardiac complication, and this was especially proved by the existence of friction-sound in the proportion of three females to two males. Cardiac complication existed eighteen or twenty per cent. more frequently in subsequent attacks than in primary ones. It was in the proportion of three to two of all the cases up to the age of twenty-five, and fell very rapidly after that age. The cases of sub-acute and chronic rheumatism furnished no examples of recent inflammation of the heart, but a considerable number of cases of old disease. So far as could be ascertained, these were almost all traceable to previous acute attacks, and were only about one-third of the cases which had previously suffered from acute rheumatism. The post-mortem appearances of recent inflammation were found associated with acute rheumatism, with disease of the kidney, with inflammation of the peritoneum and pleura, and with old disease of the heart, especially when hypertrophy existed, and with turbulent action during life. The cases of old disease of the heart were divided into sixty-one rheumatic, seventy non-rheumatic, and sixty-nine doubtful. They showed a very considerable preponderance of males, especially among fatal cases. Up to the age of twenty, almost the whole, and even as far as thirty, more than half the cases, were associated with acute rheumatism. In the next twenty years, the non-rheumatic almost doubled the rheumatic cases, and after fifty, there were scarcely any derivable from rheumatism at all. The duration of rheumatic cases, dating from the first attack of acute rheumatism to death, was generally much longer for females than for males, varying in the latter from four to six years; in the former, from twelve to sixteen years. Four out of seven fatal cases of acute rheumatism, and twelve out of eighteen of older standing, were associated with pericarditis, which was always severe and extensive; but universal adhesion was neither the constant nor even the common result of rheumatic pericarditis, and it existed in cases where the previous existence of rheumatism was altogether denied. In valvular disease there were eighteen rheumatic cases, twenty-three non-rheumatic, and twelve doubtful. The recent cases were all examples of inflammation of the mitral valve. When old and recent disease existed together, and when old disease was seen in different stages, the mitral valve generally appeared to have been first attacked, and the aortic secondarily; and hence the preponderance of double valvular lesion in rheumatic cases, seemed to be due to renewed inflammations at distinct periods. Inflammatory thickening occurred also in several cases in which there had been no rheumatism. Disease of the kidney was associated with two cases of simple recent fibrinous deposit on the valves, and three of recent pericarditis, in which no other cause was known to have been in operation. It seemed questionable how far this could be taken as a cause of great thickening of the valves, or of an adherent pericardium. Disease of each set of valves seemed to produce, in nearly equal proportions, hypertrophy and dilatation, but aortic regurgitation especially the latter; atheroma of the aorta, more commonly hypertrophy; adhesion of the pericardium, chiefly dilatation. Disease of the kidney was associated with an immense majority of the cases of hypertrophy, and similarly of all the cases of disease of the kidney; more than a third presented on post-mortem examination more or less of hypertrophy of the heart. A table was appended, in which

the post-mortem appearances were arranged, of all the cases in which the clinical history threw any light on the lesion of the heart found after death.

Case of Epilepsy treated by Tracheotomy. By W. H. Cane, Esq. [Communicated, with Observations, by Marshall Hall, M.D., F.R.S.] Dr. Marshall Hall had suggested on several occasions, and especially in a conversation with Mr. Cane, that as the attack of epileptic or other *convulsion* implied closure of the larynx, with expiratory efforts, the attack of convulsive epilepsy would be prevented by tracheotomy. Mr. Cane was summoned, on Feb. 1, 1851, to the case of a boatman, aged 24, who had become subject to violent fits of epilepsy, one of which had just occurred in so extreme a form as to leave him in a state of deep apoplectic coma and asphyxia, inspiration being performed only "by seldom and short catches, whilst the veins of the head and neck were everywhere visible and greatly distended." This state had continued nineteen hours. "Feeling convinced," Mr. Cane observes, "that the patient must shortly expire, and that the root of the evil was in the closure of the larynx, I at once proceeded to open the trachea, a matter of no small difficulty, on account of the twisted state of the neck, the engorged state of the vessels, and the constant action of the muscles. The operation of tracheotomy was performed, and the tracheal tube is kept in the trachea to the present time. The relief to the patient was immediate; the air passed into the lungs, the state of spasm subsided, with the turgid condition of the head and neck, and the patient soon recovered his sensibility. This was not the only gratifying result: although the poor man had experienced his epileptic seizures in increasing violence during seven or eight years, and recently thrice a week, he had, on April 1st, during two months, had no return of them. More recent accounts of the patient, who is now in Staffordshire, confirmed the former report; the tube is still kept in the trachea, and the epileptic seizures have not recurred.

Case of Organized Polypus of the Heart. By Thomas Bell Elcock Fletcher, M.D., Physician to the General Hospital, Birmingham. The patient in whom this morbid appearance was found, was a female, thirty-four years old, admitted under the author's care, at the General Dispensary, in October 1842, with symptoms of heart-disease of some years' duration. She had had rheumatism when eight years old, and her health had since been always feeble. Examination of the chest showed that there was considerable enlargement of the heart, and its action was violent; its beat was audible at some distance from the patient. The first sound was prolonged, but of a sharp tone, and was heard most intensely at the level, and two inches to the left side, of the left nipple. There was dulness on percussion, and bronchial respiration at the base of the left lung anteriorly; elsewhere respiration was natural. The liver appeared to be enlarged. The patient was relieved by elaterium, in various combinations, and afterwards took steel and digitalis with advantage, and in a month was dismissed from her attendance at the dispensary. Early in December she relapsed, and died in the course of a few days. The sound of the heart for the last few days was audible at four yards' distance; her friends stated they could hear it in the room below. It appeared to the author to be superficial, inducing the belief that it depended upon the doubling of an adhesion of the pericardium. After death, fluid was found in the right pleura, and in each lung a patch of hæmorrhagic deposit. No adhesions of the pericardium existed. There was considerable dilatation of all the cavities of the heart, especially on the right side. The foramen ovale admitted the point of the little finger, and about half an inch below its orifice in the left auricle, there was attached, by a narrow pedicle, a polypus, two inches long and three in circumference, which projected through the mitral orifice into the left ventricle. This polypus appeared to be covered by a membrane continuous with the endocardium, and had a cavity in its centre, the size of a small nut, containing bloody serum.

Remarks on a Peculiar Appearance observed in the Gums of Consumptive Patients. By Theophilus Thompson, M.D., F.R.S. The author, after glancing at the risk of allowing the study of auscultation to supersede attention to general symptoms, referred to the discovery communicated to the Society by the late Dr. Burton, of a blue line at the edge of the gums, as indicative of the presence of lead, and thence derived an encouragement to the examination of this part of the system, when there is reason to suspect any poisoned or morbid condition of the blood. He then presented the results of his observations in reference to this inquiry in cases of consumption, and avowed his conviction of the frequent existence in phthisical subjects of a mark at the reflected edge of the gums, deeper in colour than the adjoining surface; in some patients a mere streak on a raised border, in others, a margin more than a line in breadth, of a vermilion tint, inclining to lake: the mark being most distinct around the lower incisors, but usually observable in both jaws, and often around the molar, but modified in its situation by the form of the mouth. The author had examined some hundred cases in the course of the investigation, and gave the analysis of 102, of whom he had full records. In forty of forty-eight women, the gingival margin was present; and in fifty-four phthisical men, although in a few the line was so faint as to be open to question, there was only one in whom it could be considered decidedly absent. He had reasons for suspecting that the same condition of the system which produces this state of the gums tends also to produce clubbing of the fingers; but he considered that the change in the extremity of the fingers rarely occured till some time after the streak is manifest in the gums. Of seventy-six patients, forty-five were found to have clubbed fingers; of these forty-five, only one had gums free from the characteristic margin; yet twenty of the seventy-six had marginated gums, but no expansion of the extremities of the fingers. The author discussed the effect of various modifying influences, such as hereditary tendency, catamenial disturbances, and habits as respects cleanliness, but could not connect the presence of the symptoms in question with any of these circumstances; but he was of opinion that causes which irritate the mucous membrane tend to accelerate and increase the manifestation of the margin. He suggested this as an explanation of the more frequent absence of the line in women than in men, and dwelt on its practical importance, as indicating, in such cases, the use of refrigerants, as preliminary to the introduction of tonic remedies. The author canvassed the question whether a similar line existed in any other disease; he allowed that M. Fredericq may be correct in the opinion that certain changes in the gums occur towards the close of various chronic diseases, but he had never yet observed the peculiar margin described in this communication, without detecting other indications of consumption, although frequently only incipient. As respects prognosis in phthisis, he proposed the general rule, that cases in which the streak is observed early, or is broad or deep-coloured, tend to proceed more rapidly than those in which it was absent or slight; whilst freedom from the streak, even in the third stage, afforded encouragement in treatment. In reference to diagnosis, the author believes,—1st. That the absence of the streak in men affected with inconclusive symptoms of phthisis, may incline us to a favourable interpretation of any such suspicious indications; but that in women, rather less weight is to be attributed to this negative sign. 2nd. That the presence of the sign in women is almost conclusive evidence of the presence of the tubercular element in the blood. The paper concludes with the remark, that the symptom therein described is one of many proofs that consumption is *not exclusively a local disease, but rather a constitutional condition*, requiring for its elucidation and treatment far more than an acquaintance, however exact, with the phenomena of auscultation.

SURGICAL SOCIETY OF IRELAND.

December 7, 1850.

Mr. Trant, in the Chair.

Case of Polypus Uteri. By Dr. Banon. Dr. Banon exhibited a polypus uteri, which he had just removed from a lady, aged 74, who had suffered severely from hæmorrhage. Dr. Banon and Mr. Carte removed the tumour, by passing a needle armed with a double ligature through its centre, and tying it on either side so as to strangulate the vessels, then removing the polypus by a blunt-pointed curved bistoury. Scarcely any hæmorrhage attended the operation; and the patient was quite free from unpleasant symptoms on the fourteenth day.

Cancerous Tumour removed from the Orbit. By Dr. Jacob. Dr. Jacob exhibited a dissection of a tumour, lately removed from the orbit of a man in the City of Dublin Hospital. He had lost the eye many years ago, but suffered no pain until about a year since, when the contents of the orbit began to enlarge, and continued to increase. The tumour projected beyond the cavity so far, as to stretch the upper lid, which still covered it. Its surface was covered with a network of vessels, and was irregularly knobbed; it bled slightly when pressed or handled, and felt hard and inelastic. He suffered severely from paroxysms of intolerable pain at night, requiring opiates for its alleviation. The tumour was easily removed. A bistoury was passed under the outer canthus for about an inch, and pushed through the skin, so as to allow the lids to be separated freely, after which the blade of a common scalpel was carried round the orbit between the bone and the tumour, and through the soft parts in the bottom, so as to extricate the entire mass as far as possible. The bleeding, at first considerable, nearly ceased in a short time, and the orbit was filled with lint. There was some oozing of blood the night of the operation, and so much the following day as to require the application of fresh dressings, the patient being at the same time much prostrated; but he had since rallied.

The dissection of the tumour displayed the progress of malignant disease amongst parts of diverse character. The original structures partly retained their natural organisation in the midst of the diseased mass. The eyeball, shrunk to a mere button, as it usually is when the cornea has been destroyed and the humours of the eye allowed to escape, still appeared sound; the sclerotic being white and fibrous, and the choroid being still visible; the optic nerve, too, although shrunk and wasted, was distinct for half an inch. The muscles, however, were thickened and greatly enlarged. On one side lay a distinct hard tumour the size of a large hazel-nut, and on the other a softer, but still a firm one, evidently the lachrymal gland, four or five times its natural size. The disease was evidently carcinomatous or scirrhous, although in some parts apparently assuming somewhat the encephaloid character, and even yielding a creamy material on pressure. The small hard tumour was in part of nearly cartilaginous density, but the lachrymal gland was not much firmer than natural, although less granular. The appearances afforded little hope of escape from the extension of the specific disease; but as scirrhus in this situation may arise in the conjunctival covering of the eye, and may therefore be superficial, the operation was called for; and especially, as the poor man suffered dreadful torture from the pressure of the tumour and consequent stretching of the nerves. Dr. Jacob had seen so many tumours of the orbit of non-malignant nature, and so many recoveries after removals of very doubtful ones, that he considered himself justified in affording this man the chance which extirpation afforded; but it was only a chance.

Case of Poisoning by Chloroform. By Dr. Bagot. Dr. Bagot related the case of a young lady, to whom he had been called ten hours and a half after the administration of from a drachm and a half to two drachms of

chloroform, to allay neuralgic pains of the face. His first visit was made at half-past ten p.m. The symptoms under which she laboured were those of coma. She was lying on her left side, perfectly unconscious of all around her, her eyelids closed ; on raising the lids, the eyeballs appeared much suffused, the pupils irregular, and scarcely acted upon by light. There was considerable congestion about her face, and her head felt hot; the surface of the body and legs was cold ; the pulse was 90, thready, irregular, and intermittent. Up to seven o'clock, her friends had not found much difficulty in arousing her, although she soon relapsed into the same state. Since that hour it had been much more difficult to dispel the stupor, and it was only after many endeavours that Dr. Bagot was able to do so. When roused, however, she intelligently answered a question, but after some hesitation, as if endeavouring to collect her thoughts. She then almost immediately sunk into the same comatose state, having first said that she knew that she was dying. Two or three times during the day she had shown hysterical symptoms, crying when moved, and having the same thought of approaching dissolution before her mind. Her bowels (habitually confined) had not been moved for three days.

The treatment consisted in the admission of fresh air, strong carbonate of ammonia to her nose, an occasional sprinkle of cold water over the face, and stupes of hot water, containing an abundance of mustard, to the feet and legs. As soon as she could swallow, he gave her draughts of ether and aromatic spirits of ammonia ; and in about two hours, when the urgent symptoms were relieved, and reaction had set in, she took some strong tea, by which she was much benefited. She also had a draught containing one drop of croton oil, which affected her bowels in seven hours. As she recovered from the effects of the chloroform, the neuralgic pains returned to her face with great violence.

Next morning, she informed Dr. Bagot that she had passed a wakeful night, and had suffered much from headache, which was confined to the right temple. This pain continuing through the day, he applied two leeches to her temple, which gave immediate relief ; she was enabled for the first time to turn off her left side. She was much weakened by this illness, and fainted at her first attempt to sit up in bed, where she was obliged to remain some days.

December 21, 1850.

Dr. Jacob in the Chair.

On a Functional Affection of the Spine, liable to be mistaken for Organic Disease. By Henry Kennedy, A.B., M.R.I.A. The affection alluded to was essentially a disease of the young, being seen most frequently between twelve and twenty years of age. Dr. Kennedy had, however, met with it as early as nine years, and as late as twenty-five. He had only seen it in private practice, and it was more common amongst males than females, in the proportion of at least two to one. It consisted in a pain in the back, combined with weakness, and this was always referred to the lumbar region ; at least he had never seen it higher up. This pain commenced gradually, and might or might not be attended with the feeling of weakness ; and occasionally only the latter was complained of. On examining the spine, the patient was nearly always able to refer the suffering to a particular part ; but Dr. Kennedy had seen cases where the feeling was more diffused. It was worthy of notice, that a rough examination of the part might be made—the spine might be twisted, or percussion strongly used, and yet the patient would not complain. When left to their own feelings, they invariably preferred the recumbent posture. Walking was much less irksome than sitting, and particularly when they had no support for the back. In addition to an ordinary chair, they would use a cushion, so that it might press on the spine where they complained ; and even when reclining at full length, they often placed a cushion in the hollow of the back, so

as to cause direct pressure. Those whose business led them to stand and work at a desk, seemed pecularly liable to the affection.

Case 1. Mr. ——, a young gentleman of 18, whose employment was in an office in Dublin, where he spent six or seven hours a day, partly standing and partly sitting at a desk, began to suffer from pain in the small of the back. He was of small size, but of a highly developed nervous system, as was shown when he laboured under any common indisposition; as, for instance, a cold. The pain in the back was trifling at first, though constant; so that he was able to pursue his usual avocations for about four months; when it became so distressing that he was compelled to confine himself to a sofa the greater portion of the day, and when he did sit up, he always used a cushion between his back and the chair. On examination, nothing wrong could be detected with the part of the spine of which he complained most; which was about the third lumbar vertebra. It could be twisted, and otherwise roughly handled, without causing any inconvenience, but he could not sit without support beyond a few moments. When he had any inducement, he could go through an amount of exertion on his feet, which seemed totally incompatible with the other symptoms. His general health appeared good; his tongue clean; his appetite not impaired. He continued in this state for four months, during which time he was seen by the late Mr. Carmichael, and a variety of treatment was adopted. In two months more he had recovered so far as to be able to resume his business, and at a still later period recovered completely; nor had he since, though some years had passed, suffered from the same affection.

Case 2. A brother of the last patient, at the age of 21, began to suffer from pain in the back, attended by a feeling of weakness. He was also in an office where both standing and sitting at a desk was necessary; but it was in a country town. At first it was merely an inconvenience; by degrees, however, it became worse, so that he could scarcely go through his duties, and finally he came to Dublin for advice. He was seen by Mr. Cusack and Dr. Kennedy, and the symptoms were exactly those detailed in the last case, but not so severe. In this instance there were some signs of dyspepsia. After a certain period, not so long as in the former instance, this patient also got well, and had remained free of any suffering from his back, a period of five years having elapsed.

With regard to the *nature* of this affection, Dr. Kennedy was inclined to say—though it be anything but proved—that it arose from causes incident to the period of life at which it occured, conjoined with some obscure derangement of the general health. But this was but conjecture.

The *diagnosis* was of some moment; for the symptoms might lead one to dread the existence of serious disease; or it might be confounded with an organic disease. A young lady, while abroad, got the affection. She was advised to keep the recumbent posture, and to have issues put in. This advice was persevered in for some months, when she was brought home, and seen by Sir Philip Crampton, who at once ordered the issues to be dried, and the patient to get up, and go about. This was done, and the lady recovered, though slowly; for her general health had been injured by her long confinement. The diagnosis would, probably, turn on the presence or absence of constitutional symptoms; such as a quick pulse, night sweats, etc. In addition, even a rough examination of the spine did not cause any pain to the patient—a marked contrast between the two cases; and lastly, the situation afforded some assistance; for in the one affection it was, as far as Dr. Kennedy had seen, always in the lumbar region, and sometimes even at one side of the vertebral column; while in the other, organic disease was not probably so common here as higher up.

The *prognosis* is favourable. The patient will get well; but his recovery will occupy some time. Dr. Kennedy had seen no instance where the affection was completely got rid of under six months; and in some of the cases it was much longer. It sometimes returned after the patient had been well for

months. To say that no case could run into more serious disease, would be going farther than prudence would justify; for in truth this affection, when well-marked, was sufficiently distressing. But Dr. Kennedy had not met any case of the sort. In one instance, indeed, a patient laboured under it when she was between eleven and twelve years of age. She recovered perfectly, but about two years subsequently was attacked with caries of the cervical vertebræ, which ultimately proved fatal by the disease extending to the membranes of the brain. With this exception—and it was not a case exactly in point—he had known no fatal results in connexion with that form of spinal affection under notice.

On the subject of treatment, Dr. Kennedy had nothing very definite to offer. A considerable variety of means had been used, both local and constitutional. The former included local bleedings, dry cupping, blisters, frictions, the cold douche, and galvanism; and the latter, aperients, tonics, change of air, and relaxation from business. Of these two, the latter had in his experience proved by much the most useful. He had also seen benefit follow the application of small and repeated blisters, as also the use of a weak stream of galvanism, applied daily, or every second day, according to circumstances. The patient, too, often got great relief from wearing a stiff belt. Still the general measures were the more important. In all the severer cases, the patient must give up his business for a time; two to three months complete relaxation must be enjoined, and if the patient could change his air, so much the better. Exercise, more or less, according to circumstances, should be advised to be taken daily; not, of course, to be carried to fatigue: at the same time that the patient, while at rest, might with advantage assume the horizontal position, propped up or supported in the way most agreeable to him. Strict confinement would generally do much more harm than good. Besides relaxation from business, and change of air, the cold douche, frictions, etc., were worthy of trial. As to medicines, Dr. Kennedy had tried a number, more particularly those of the tonic class; excepting strychnine, however, from which in some cases benefit had arisen, they appeared to produce little or no effect.

Effects of Rupture of the Cicatrix of a Burn. By Dr. Bagot. Some time since, a woman brought to him a little boy, about nine years old, who had got his arm contracted by cicatrix after a burn. He (Dr. Bagot) advised the woman to take the child to an hospital. A day or two after, the boy was running along the street, when he fell. In falling, the hand was caught by some obstacle, and the cicatrix was suddenly torn. This injury was followed by a great effusion of blood. The wound was again allowed to heal without the intervention of medical aid; the cicatrix following that wound never contracted in the slightest degree, and the boy has now the perfect use of his arm.

Case of Abscess in the Anterior Wall of the Uterus. By Dr. Moss. About seven months since, Dr. Moss was sent for to see a lady, who was suddenly taken with severe cramps in the abdomen and difficulty in passing water, weak pulse, and general febrile symptoms. He directed an enema to be given speedily, with anodyne draughts afterwards, unless there was speedy relief. In the morning, he found that, though considerable relief was given, it had not been complete. He then made a vaginal examination; and, on introducing the finger, he found a tumour pressing downwards, which had dragged down the posterior part of the bladder He then got the assistance of Dr. Johnson, who found his (Dr. Moss's) diagnosis correct. He feared it was a fibrous tumour, and determined, if possible, to force the tumour back again. He did so, and it left the passage clear, and the os resumed its proper position. From that time, however, up to last week, the patient had suffered a variety of pains, all in the same region. The bowels, however, had been kept regular. Last week he was sent for suddenly to go and see the lady again. She informed him, that she had passed half a wineglassful of what,

on inspection, seemed to be healthy-looking pus, from the vagina. He found part of the tumour still existing, but softer. On using the speculum, he found the pus coming directly from the os, so that he presumed there was an abscess of an indolent character forming for some time. The patient had had considerable relief; but he rather feared the tumour was again filling, though he hoped he would be able, by making an opening, to give permanent relief.

January 11, 1851.

Dr. Beatty, and afterwards Dr. Jacob, in the Chair.

Remarkable Specimen of Colloid Degeneration springing from the Forearm. By the Secretary. Case. T. D., aged 65, was admitted into the Athy Infirmary on the 19th of December, 1850, for dysentery. He had a large tumour on his forearm of (he said) six months' growth, which never gave him pain, but, from its magnitude, caused great inconvenience. He was treated for the bowel complaint with the usual remedies, but died on the 30th of December, eleven days from his admission.

Inspection of the Body, twenty-four hours after death. The spleen and kidneys were enlarged, the latter to three times their normal size; the former weighed about three pounds. On cutting into them, they presented well-marked cerebriform matter. The liver was enlarged, but did not present any such appearance. The intestines were much congested throughout; the large intestines had ulcers in different parts, and one very large one near the head of the colon. He had never manifested any symptoms of disease of the brain or chest: the examination was therefore confined to the abdomen. The tumour occupied the anterior aspect of the forearm, extending from the bend of the elbow to the base of the metacarpal bone of the thumb, measuring in its longitudinal direction 19 inches, and in its circumference 33 inches. It weighed 25lbs. 8oz. The integument covering it was of a dusky yellow colour, traversed by numerous large and tortuous veins. It was uneven on its surface, and on its most prominent parts gave an elastic fluctuating sensation, as of a fluid in a dense cyst, much more distinct in some points than in others. The muscles of the forearm (particularly those arising from the internal condyle) were of a yellowish colour, much atrophied, and spread out in a ribbon-like manner over the surface of the tumour; their tendons formed grooves in its surface. The fingers were permanently flexed on the palm; the interspaces between the tendons forming the elastic fluctuating prominences alluded to above. The subcutaneous cellular tissue had in some places been absorbed, the true skin being intimately connected to the walls of the tumour. The arteries of the forearm, which had been previously injected, appeared to have resisted the disease. The nervous trunks generally were enlarged in size, especially the median, which was stretched and flattened in its course over the surface of the tumour. The sac was found to consist of a thick gelatinous wall, very rugged on its inner surface, from masses of the jelly-form substance protruding inwards; it was filled to distension by a dark brownish fluid, very like liquid glue or thin treacle. The disease appeared to have originated in the radius, as the central portion of the shaft of this bone was completely removed; but the rough and spiculated ends of its upper and lower extremities projected into the cyst, whilst the ulna, though flattened and slightly bent, was sound throughout. The elbow and wrist were quite free.

Microscopic Examination. A thin section of the morbid structure presented a fibrous stroma, the interspaces or loculi of which contained congregated cells of different shapes, some caudate, others fusiform, but most of them oval or round, with nuclei. Acetic acid rendered the fibrous stroma somewhat more distinct, but decidedly brought more clearly into view the nuclei and nucleoli of the cells. Some compound granular cells and fat granules were scattered in small groups, amidst a great quantity of granules and molecules. The colloid fluid presented numerous very delicate cells,

rendered transparent on the addition of acetic acid, thus exposing their nuclei; but no fibrous arrangement (though diligently sought for) was detected in this fluid part; it contained naked nuclei, and some oil-globules, with an abundance of molecular matter. The blood from the cephalic vein, microscopically examined, appeared of a glutinous nature, by which was meant a decided tendency to form tags or tails as the corpuscles glided between the glasses.

Case of Simulated Neuralgia from a common Pin, which had been swallowed, and in eight months after emerged from the surface of the body. By H. C. Field, M.D. After some remarks on the cases in which pins have been said to have been swallowed, or thrust into parts of the body, Dr. Field related the following case.

Case. Mary M., a healthy woman, aged 30, in July 1842, came to the Stillorgan Dispensary. She said her mouth had been full of pins: that she had accidentally swallowed one, which was choking. Dr. Field immediately relieved her by using a probang. In the following October, he was requested to visit her as a dispensary patient; she then told him that she was in the greatest agony in her hip-joint, extending down the limb on the same side. He immediately bled her largely from the arm, had her cupped over the seat of pain, and gave her two grains of opium. The next day, she had had some short sleep, but the pain was still very great. After exhausting every means he could think of, narcotising, mercurialising, blistering, and tonics, Dr. Field at length advised her to try an hospital. After submitting to various remedies in Steevens' Hospital, without more than temporary relief, she was advised to go into the country for change of air, being greatly emaciated. She came again, dreadfully reduced in flesh, to the country, where Dr. Field saw her, but did nothing for her; and after remaining some time at home, suffering still from what appeared to be severe neuralgia, and being much reduced, she one day felt a sudden remission of the pain, and three days after it left her. From this time she rapidly recovered her health and strength, and was soon able to leave her bed. Shortly after, she found what she called a sore pimple on the inside of her thigh, which she poulticed and plastered, but could not cure; and having quite regained her strength, after an illness of *eight months*, she walked to the dispensary. On examining the pimple, Dr. Field found in its centre a sharp point; and after a little, he extracted, by its point, a large pin. Dr. Field thought that the simulation of idiopathic disease, for so long a time by a foreign body, rendered it extremely interesting, and established the *possibility* of a common pin, after being swallowed, emerging from the surface of the body.

MISCELLANEOUS INTELLIGENCE.

Dinner at St. Bartholomew's Hospital. During last month, the President, Treasurer, and Governors, gave their Annual Dinner in the hall of the Hospital. Upwards of two hundred gentlemen were present, comprising the Almoners, many of the Governors, and Medical Officers. General Sir George Pollock honoured the governors with his presence. There were also as guests many of the distinguished foreign physicians and surgeons now on a visit to London; among whom may be mentioned Dr. Warren of Boston, U. S., Dr. Pantaleoni of Rome, Professor Jaëger of Vienna, Dr. Donders of Utrecht, and Dr. Hannover of Copenhagen.

Physiological Society of Edinburgh. A new society with this name was instituted at Edinburgh, on the 4th of June: "having for its object the investigation of the structure and functions of all organized beings, in their healthy and diseased conditions." The following gentlemen were appointed office-bearers: — President, Professor Hughes Bennett; Vice-Presidents, Mr. Zaglas and Mr. J. S. Sanderson: Secretaries, Dr. W. T.

Gairdner, and Mr. John Barlow. A society called "the Anatomical and Physiological Society" formerly existed in Edinburgh ; but was at last absorbed by the Medico-Chirurgical.

Insurance Offices and the Medical Profession. The *Medical Times* publishes the following as a correct list of the companies who do not demean themselves by seeking gratuitous advice. The fee paid by the New Equitable is *two guineas.* We believe that the great success of this and other new companies is mainly due to the energetic support which they are receiving from medical men. The older societies however are now reaping the advantage of following the good example of their youthful rivals. The subjoined list embraces most of the trustworthy insurance companies in England.

Architects—69, Lombard-street, London.
Britannia—1, Princes-street, Bank, London.
British Mutual—17, New Bridge-street, Blackfriars.
Church of England—Lothbury.
Commercial—112, Cheapside, London.
East of Scotland—1, Bank-street, Dundee.
East of England Mutual—Cheapside.
Engineers', Masonic, and Universal—345, Strand.
English and Scottish Law—12, Waterloo-place, London.
English Widows' Fund—67, Fleet-street.
European Life Insurance and Annuity Company—10, Chatham-place, Blackfriars.
General and Mining—4, Bridge-street, Blackfriars.
General Benefit—4, Farringdon-street.
Great Britain—Waterloo-place, and King William-street.
Indian and London—King William-street, and 14, Waterloo-place.
Industrial and General—2, Waterloo-place, Pall-Mall.
Kent Mutual—High-street, Rochester.
Kent Mutual Life Assurance Society—6, Old Jewry, London.
Leeds and Yorkshire—Commercial-buildings, Leeds
Legal and Commercial—73, Cheapside.
London Indisputable—31, Lombard-street.
London Mutual Life—63, Moorgate-street, City.
London and Provincial—39, Nicholas-lane.
Medical, Legal, and General—126, Strand.
Medical, Invalid, and General—25, Pall-Mall.
Mentor—2, Old Broad-street.
Metropolitan and General—27, Regent-street, Waterloo-place
Mitre—23, Pall-Mall.
National Loan Fund and Life Assurance—26, Cornhill.
National Mercantile—Poultry, Mansion-house.
New Equitable Assurance Company—450, West Strand.
North of England—11, Cheapside, London; and Old Haymarket, Sheffield.
Northern Assurance—1, Moorgate-street.
Norwich Union—Crescent, New Bridge-street.
Professional—76, Cheapside.
Prudential—14, Chatham-place.
Royal—Royal Insurance-buildings, Liverpool.
Royal Exchange—Royal Exchange.
Royal Farmers' and General—346, Strand.
Scottish Equitable—26, St. Andrew's-square, Edinburgh.
Solicitors' and General—57, Chancery-lane.
Sovereign, 5, St. James's-street.
Star, 44, Moorgate-street.
Westminster and General—27, King-street, Covent-garden.
Yorkshire—York.

Hospital Villages of Iron.—Dr. Simpson, of Edinburgh, in concluding one of his interesting Reports of the Maternity Hospital of that city, makes some important remarks on the evils of crowding the sick in hospitals, and suggests the construction of cottages or villages of iron, as a substitute for our "Hospital Palaces". We quote the passage entire.

"The convalescence of the hospital patients was often interrupted by febrile and inflammatory attacks. The house, No. 3, St. John-street, used as a hospital, was, in addition to a sunk kitchen flat, three stories in height, with two rooms in the first and second flats, and three in the third; and it was much too small for the accommodation of the patients, and of the resident house-surgeons, matron, etc. The rooms themselves were low-roofed, and very imperfectly ventilated. Various plans were attempted to improve the ventilation, but not with much success. Whenever the hospital became in any degree crowded, fevers (or weeds), with more or less abdominal tenderness, appeared among the patients; and frequently the supervention of such attacks during convalescence became so common, as to constitute the rule rather than the exception to it. Every one acquainted with hospital practice, whether obstetric, surgical, or medical, is well aware of the great liability among the patients to febrile and inflammatory attacks whenever the wards are overcrowded; and in no practice is this more visible than in midwifery. Indeed, I believe, there are few or no circumstances which would contribute more to save surgical and obstetric patients from phlebitic and other analogous disorders, than a total change in the present system of hospital practice. I have often stated and taught, that if our present medical, surgical, and obstetric hospitals were changed from being crowded palaces, with a layer of sick at each flat, into villages or cottages, with one, or at most two, patients in each room, a great saving of human life would be effected. And if the village were constructed of iron (as is sometimes now done for other purposes), instead of brick or stone, it could be taken down and rebuilt every few years; a matter apparently of much moment in hospital hygiene. Besides, the value of the material would not greatly deteriorate from use; the principal outlay would be in the first cost of it. It could be erected in any vacant space or spaces of ground, within or around a city, that chanced to be unoccupied; and, in cases of epidemics, the accommodation could always be at once and readily increased."

The Best Field for Surgical Observation. Dr. Moses Buchanan stated in 1844 (Introductory Lecture: Glasgow, 1844), that the Glasgow Royal Infirmary was the best surgical school in the world. "It will be found," he said, "to present at all times the most important gallery of acute surgical disease of any in the world." The same claim was reiterated by Dr. Easton in his Introductory Lecture, delivered on the 29th November, 1849 (and reviewed by us in our volume for 1850, p. 144). It appears, however, that the Glasgow lecturers, who had up to this date, held unchallenged the surgical supremacy of the world, are no longer to be allowed to do so. Mr. Syme, of Edinburgh, after a ten days' absence, thus addressed his class: "Gentlemen, I regret my absence for the last ten days, but I hope that the information acquired since I saw you, will conduce to the object we all have in view. I have long suspected, and am now fully satisfied, that neither Paris nor London possesses any hospital which affords so good a field for surgical observation as the Royal Infirmary of Edinburgh. The knowledge of this fact should stimulate your exertions, and prevent them from being relaxed through the vain expectation of elsewhere finding a better opportunity for practical study, while it greatly encourages me to cultivate with redoubled energy the valuable means of instruction placed within my reach." *Edinburgh Monthly Journal*, July 1851, pp. 53, 54.

Sir B. C. Brodie, Baronet, had the honorary degree of D.C.L. conferred upon him on the 3rd July, by the University of Oxford.

College of Physicians.—A Conversazione was given by the President and Fellows on Saturday, June 28, at the College, Pall-Mall East. The visitors were received by Dr. Paris, President of the College, in the Censors' room, and afterwards passed into the Library, upon the tables of which were rare books and ingenious philosophical instruments. Among the company were the Bishops of Manchester, St. Asaph, Chester, and Oxford; the Earl of Harrowby; the Earl of Rosse; Lord de Mauley; Lord Colborne; the Lord Chief-Baron; Mr. Baron Parke; Mr. Justice Coleridge; the Vice-Chancellor; M. Majendie; Professor Otto; Baron Dunckink Holmfeld; Moonshee Syed Abdoollah; Senor Don Joaquin Alfonso; Professors Daubeny, Graham, Wheatstone, Owen; Sir D. Brewster; Sir C. Fellows; Sir J. South; Sir H. Ellis; Sir H. De la Beche; Sir A. Knight, M.D.; Sir W. Newton; Sir C. Clarke, M.D.; Archdeacons Hale, Sinclair, Robinson, and Brooks; Rev. Dr. Major; Dr. R. Bright; Dr. C. Locock; Dr. R. Ferguson; Dr. Marshall Hall, etc. Refreshments upon the most liberal scale were provided. The company broke up shortly after eleven. Another conversazione will take place before the close of the season.

Pharmacy Bill. Mr. Jacob Bell of Oxford-street, recently introduced a measure into Parliament for the purpose of elevating the druggists into the rank of professional men. It was read *pro forma* a second time in the House of Commons; and was then delayed till next Session. The measure is not likely to be supported by the medical profession. As St. Alban's, the burgh for which Mr. Bell sits, may be disfranchised (for the abominable way in which the electors took bribes at the last election); and as a general election is soon expected, the bill is likely to require another guardian.

Provincial Medical and Surgical Association. The Nineteenth Anniversary Meeting of the Provincial Medical and Surgical Association will be held at Brighton, on Wednesday the 13th, and Thursday the 14th of August next. Dr. G. S. Jenks is the president elect, and the address on Surgery will be delivered by Mr. Benjamin Vallance of Brighton; that on Medicine by Dr. William King. Dr. Mantell will lecture on the Medical Topography of Sussex, with copious illustrations. The meeting is expected to be one of unusual interest and importance; and many of the élite of the profession in London are expected to attend.

New Lunatic Asylum at Colney Hatch. This new asylum for the county of Middlesex was opened on the 1st July. It is the largest asylum in Europe. The galleries have octagon ends, pierced with windows in accordance with Dr. Conolly's suggestion, in order that the patients when walking in them may escape the dreary aspect of a dead wall.

Testimonial to Dr. Laycock, of York. A handsome silver tea-service has been presented to Dr. Thomas Laycock, of York, by the Associated Licentiates Extra Urbem of the College of Physicians, with the following inscription: "Presented to Thomas Laycock, M.D., Physician to the York Dispensary, Lecturer on the Practice of Medicine in the York Medical School, etc., by his friends, the Associated Licentiates Extra Urbem of the Royal College of Physicians of London, in testimony of their very cordial esteem and regard, and in gratitude for the ability, energy, and zeal with which he has maintained their rights and interests.—Anno Domini, 1851."

APPOINTMENTS.

Hawkins, Cæsar H., Esq., Surgeon to St. George's Hospital, elected, on the 10th July (by the Council), one of the Vice-Presidents of the Royal College of Surgeons of England for the ensuing year.

Jones, Wharton, Esq., F.R.S., was recently elected to fill the triennial appointment of Professor of Physiology to the Royal Institution, vacant by the retirement of Dr. Gull, at the termination of his term of office.

Luke, James, Esq., Surgeon to the London Hospital, elected, on the 10th July (by the Council), one of the Vice-Presidents of the Royal College of Surgeons of England for the ensuing year.

South, John F., Esq., elected, on the 10th July (by the Council), President of the Royal College of Surgeons of England, in the room of Mr. Arnott, whose period of office has expired.

OBITUARY.

Emslie, Alex. L., Esq., Surgeon R.N., at Auchtermuchty, N.B., on the 9th July.

Gilbertson, Frederick, Esq., at his residence, Egham, Surrey, on the 2nd July.

Gibbes, Sir George Smith, M.D., F.R.S., at Sidmouth, on the 23rd June, aged 80. He was for many years Physician Extraordinary to Queen Charlotte; and for a lengthened period practised his profession at Bath.

James, C. H., Esq., late of the 39th Regiment, at Glasgow, on the 11th July.

Jenner, Dr. Henry, third son of the late Rev. H. Jenner, of Burbage, Wilts, and nephew of Dr. Edward Jenner, the discoverer of vaccination, at Stone, near Berkeley, on the 3rd July, of paralysis, aged 80.

Moir, D. M., Esq., Surgeon, of Musselburgh near Edinburgh, at Dumfries, of peritonitis, on the 6th July, aged 53. Mr. Moir was extensively employed in medical, surgical, and obstetric practice among a distinguished class of patients; and by his professional brethren, as well as by the public, he was deservedly held in very high estimation. His medical publications are possessed of much merit; but, we believe, are only two in number: viz., 1. *Outlines of the Ancient History of Medicine.* 12mo. Edinburgh: 1831. 2. *Practical Observations on Malignant Cholera.* 8vo. *Pamphlet.* Edinburgh: 1831. Notwithstanding the great amount and fatiguing nature of his professional duties, Mr. Moir was able, by the exercise of method, to obtain occasional hours of relaxation and leisure, many of which he devoted to literary pursuits. From 1819, to the close of his career, he was a contributor to *Blackwood's Magazine;* and his poetry, published in that miscellany with the signature of "Delta", has long since placed its author in the highest rank of British bards, and given him an European reputation. His *Mansie Waugh, the Dalkeith Tailor,* is a prose novel of singular power, and full of the richest humour; and it would have given Mr. Moir an enduring literary fame, though he had never written a verse. But it is for the sweetness, the deep pathos, and the heart-improving influence of his domestic poetry, that his name will be chiefly remembered and cherished, so long as British literature endures. No one, who is not dead to every generous impulse, can read without emotion his little volume entitled *Domestic Verses:* and we trust that there are few lovers, husbands, wives, or parents, who can peruse them, without being, not only moved to tenderness, but melted to real amendment of heart. Jeffrey well said, that "these poems are so tender and true, so sweet and natural, as to make all lower recommendations indifferent."

Pope, Edward, Esq. (in practice prior to 1815), of 1, Princes-street, Stamford-street, at his residence, on the 17th July, aged 57.

Ripley, John, Esq., Surgeon, at his residence, Whitby, Yorkshire, on the 10th July, aged 54.

Teevan, William, Esq., Surgeon, of Bryanston-square, London, on the 6th July, aged 49. He died at Treplitz in Bohemia, whither he had gone for the restoration of his health.

Wilson, Dr. James A., son of the late John Wilson, Esq., Dumfermline, N.B., at Old Calabar, Africa, in the 22nd year of his age.

ORIGINAL COMMUNICATIONS.

ILLUSTRATIONS OF THE DIFFICULTIES WHICH BESET THE DIAGNOSIS OF SOME CASES OF DISEASE.

By THOMAS POYSER, Esq., F.R.C.S.Eng.

(*Continued from p. 733 of Volume for* 1850.)

I PUBLISHED in the LONDON JOURNAL OF MEDICINE, for August 1850, some observations under the above title; and the following remarks are offered in farther elucidation of the same subject.

It has appeared to me that (in the country at least) we pay less attention to diagnosis, than to therapeutics. We are too apt to prescribe before the disease has fully developed itself; or before we know its precise nature, or the organ affected. Do we not sometimes, by a too precipitate recourse to potent medicines, interfere with the remedial efforts of nature, and not only aggravate the malady, but render its cause more obscure? The French adopt an opposite error: they more carefully investigate the cause and seat of the ailment, and then, by removing the obstacles to recovery, leave nature to perform the cure. In acute diseases, very lamentable consequences sometimes result from this timid system of therapeutics; whereas, if this "expectant method" be cautiously followed in suitable cases, much good results. Energetic remedial measures are judicious, and imperatively demanded, when the disease is acute, and its nature manifest: but, in doubtful cases, it is much safer to wait, than hastily to adopt active treatment, which may be as potent for evil as for good.

The cases subjoined may not possess much practical importance; yet, as illustrating some points of diagnosis, they may not be without some value to practitioners.

CASE II. OSSIFICATION OF THE AORTIC SEMILUNAR VALVES, WITH FATTY DEGENERATION OF THE HEART. R. H., Esq. This gentleman in early life suffered much from spasmodic asthma; but as he grew up, this disease wore off. When he was about fifty, he became subject to gout; and occasionally passed large uric acid calculi,

with severe pain, and generally a considerable discharge of blood. The hæmaturia would also sometimes recur, if he took violent exercise on horseback, or on foot, without the pain, or other symptoms of gravel. He suffered, however, much less from these affections for some years before his death; and, during the last three years of his life, he had no attack of either gout or gravel. He then became more lusty and bloated, and began to suffer from dyspnœa on walking up hill, and from occasional acute pain in the region of the bladder. He attributed the shortness of breathing to increased corpulence; and his own feelings led him to apprehend that the pain in the bladder arose from stone. The pulse was always feeble and quick; the impulse of the heart was also feeble, but the stethoscope did not indicate any other morbid condition of that organ. There was usually a puffy or œdematous swelling of the ankles and feet. These symptoms continued to increase, particularly the pain in the hypogastric region, which was occasionally so severe and long-continued, as to require large doses of opium to assuage it. For a few months before his death, Mr. H. suffered from occasional attacks of syncope; and less bodily or mental exertion brought on the paroxysms of dyspnœa. From the symptoms, as well as from stethoscopic examination, it then became evident that there was valvular disease of the heart. He was, however, never confined to the house, and followed his usual amusements and avocations to the moment of his death, which took place instantaneously, on Jan. 11th, 1851, while sitting in his library.

There existed a peculiarity in the case of Mr. R. H. which it is right to mention: viz. that if he took the smallest quantity of rice, he was immediately attacked with erythema, extending over the whole body, and accompanied with severe itching fever and swelling of the eyes, and generally continuing two or three days.

An autopsy was made thirty-six hours after death. The body was covered with a thick layer of fat. The heart was small. In the apex of the left ventricle, there was a small polypus. The aortic semilunar valves were completely ossified; and the aperture through them was so much diminished, as only to allow the end of the little finger to pass. The aorta itself was larger than usual, particularly about the arch. The coronary arteries had patches of ossific matter on them; and the muscular substance of the heart was pale, flabby, and loaded with fat. The lungs and abdominal viscera were healthy, and the bladder free from calculi, or any other morbid appearance.

Remarks. This case illustrates too truly the accuracy of Dr. Latham's remark, in the preface to his valuable *Lectures on Clinical Medicine;* that in certain diseases of the heart, "the same signs which notify their existence, declare their incurability". "What a gain," he adds, "will it be to mankind, should observation hereafter discover that the conversion of the valves of the heart, and the lining of arteries, into earthy matter or cartilage, has its sure pathological origin in certain forms of disease, in other parts or in the constitution at large, which are both obvious and curable; or in certain habits and modes of living, which can be rectified or avoided."

In this case, there can be but little doubt that when the peccant matter of the blood ceased to be eliminated from the system, through the agency of the attacks of gout or gravel, a deposit took place on

the aortic valves. It hence shows the importance of not neglecting "to rectify certain habits and modes of living", which may occasion these diseases, or by remedial measures to obviate the cause, even when the paroxysms have ceased to recur.

This case also confirms a point of diagnosis, first, I believe, adverted to by Mr. Allan Burns, in his *Treatise on the Diseases of the Heart:* that in certain affections of that organ, more especially chronic inflammation, acute pain in the hypogastric region is a common attendant, if not a pathognomic symptom. He relates some fatal cases, where the true seat of the disease was not suspected during life, the symptoms being attributed to disease of the bladder, and in one instance to disease of the uterus: yet dissection proved that these organs were quite healthy, and that the morbid condition of the heart was the sole cause of the symptoms, and of the fatal termination. In the case above narrated, the pain in the bladder was the only symptom which arrested the patient's attention, or for which he was anxious to obtain relief. As it occurred before there was any evidence of disease of the heart, and continued at intervals during the whole of its progress, I think it deserves attention, not only as a concomitant, but as a premonitory symptom, of these intractable maladies.

Case iii. Large Renal Calculi. John Brocklehurst, aged 40, the servant of a gentleman of this town, for three or four years before his death, suffered from dyspeptic symptoms, and occasional pain in the loins. He had no difficulty in micturition, nor did the urine exhibit any morbid appearance. Having tried various remedies without any relief, he was admitted into the Derbyshire Infirmary, and was several weeks under the care of the late Dr. Baker, who treated the case as one of dyspepsia. He was discharged from the infirmary without being relieved. He then consulted an irregular practitioner, who, regarding the case as one of lumbago, used heating and stimulating internal, as well as external remedies, which aggravated the symptoms. Subsequently he put himself again under my care. He was now sallow, emaciated, and the pain in the back had become more constant and severe. He had been taking the oil of turpentine and carbonate of soda in large doses. He made water freely, and without pain; but the urine was alkalescent. On examining carefully the seat of the pain, it was in the region of the kidneys, and was a little increased by pressure. At this advanced period of the disease, and from his emaciated state, the hard projecting kidneys were easily felt through the integuments. He took barley-water acidulated with muriatic acid, and opium, in such doses and at such intervals as the pain required. Under this treatment, he lived in a state of comparative comfort for about three weeks, when he sunk from exhaustion and debility.

Autopsy. Twenty-four hours after death, the body was examined Nearly the whole substance of each kidney was absorbed, and the space occupied by calculi of great magnitude. This mass of calculous matter was surrounded only by the fibrous tunic of the kidneys. One kidney contained four, the other three calculi, closely fitted together; and the whole had assumed the shape, and the ordinary size, of that organ. The calculi were composed of the earthy phosphates, confusedly cry-

stallised, and weighed altogether eight ounces and four drachms. The body was extremely emaciated, but free from any other disease.

Remarks. Many cases similar to this are on record; but I have selected it, as illustrative of the object I have in view, viz., to direct attention to a more careful diagnosis. It is not improbable, that if in the early stages of the disease, the urine had from time to time been tested, the further deposit of earthy matter might have been prevented by appropriate treatment, instead of being increased by magnesia and the other alkaline medicines, which were the remedies mainly had recourse to.

It is remarkable how large a portion of the glandular substance of the kidneys may be displaced by calculous matter, without impairing their functions, and sometimes also without occasioning much pain. In this case, till within a few weeks of the patient's death, the pain was not of a fixed character; nor did it disable him from following his usual occupation, till he was prevented doing so by exhaustion and debility.

In the Descriptive and Illustrated Catalogue of Calculi, in the Museum of the Royal College of Surgeons in London, there is an engraving of a large Calculus, of the shape and structure of those I have described. This calculus, now in the museum, weighs seven ounces and four drachms. In an original memorandum by Mr. Hunter, appended to it, it is stated, that "this calculus was taken from the pelvis of the right kidney of Mrs. ——, a natural daughter of Sir Richard Steele. She was never known to have a nephritic symptom till just before her death, when she was taken with a violent pain in her right side, near to the back, the seat of the right kidney, which appears to have thrown her into a fever, of which she died: and upon opening the body was found this stone, filling up an enlarged pelvis, and the substance of the kidney itself become so thin, as only to appear like a coat or membrane covering the stone, which gave the idea to the surgeon, that the substance of the kidney was grown into a stone."

Wirksworth, July 31, 1851.

REPORT OF A CASE OF ACUTE GLANDERS, FOLLOWED BY RECOVERY; WITH REMARKS.

By F. W. MACKENZIE, M.D.Lond., Fellow of University College; Physician to the Paddington Free Dispensary for the Diseases of Women and Children, etc.

It is unnecessary, at the present day, to adduce any additional facts or arguments to prove that Glanders is a disease which is communicable from the horse to the human species. This has been completely established by the researches of many accurate observers, and is, I believe, generally admitted by the profession at large. As, however, the recorded cases of its occurrence in man are not very numerous, from the fact, probably, that it is not readily communicated to the human race, and as consequently many points relating to the pathology of the disease are obscure, it is presumed that the report of an additional case will not be unacceptable to the profession. I therefore subjoin the particulars of one which has lately been under my care,

and have added some remarks, which have been suggested by a consideration of it.

Case. William Wilcox, a horsekeeper, aged 58, was admitted into the Paddington Infirmary, late in the evening of the 19th July. He was seen by me the following day, and appeared to be very dangerously ill. His face generally was swollen and suffused, but more especially in the submaxillary region. A large quantity of saliva was pouring from his mouth, his breath was extremely fetid and sickening, his gums were swollen, and his teeth loose,—some indeed were merely hanging from the gums. The tongue was much enlarged, and could not be protruded beyond the margin of the teeth, and it was forced upwards against the roof of the mouth by the swelling of the salivary glands below; the throat was constricted, and consequently both breathing and swallowing were difficult. His nostrils were filled with a thick glutinous secretion of an offensive odour, which was with difficulty dislodged. The patient had been very restless all night, had been constantly throwing his arms about, was alternately chilly and hot, and at times sweated profusely; he had a quick pulse, and was in a state of extreme prostration. Looking to the profuse salivation, the condition of the salivary glands, the extreme fetor of the breath, and the state of the gums and teeth, my first impression was that he had been severely salivated with mercury. It appeared, however, that he had not taken a particle of this medicine for some time, and his general symptoms were, moreover, inconsistent with this view. After a great deal of trouble, occasioned by the difficulty he had in articulating, the following history was obtained.

He had for some time past been in very destitute circumstances, in consequence of having been out of regular employment; his food had been scanty and bad, and he had been accustomed to sleep about in stables, or wherever he could get a shelter for the night. Under these circumstances, he accepted the charge of some glandered horses at Islington. He began attending to them on the 30th of June; and, at one time, had thirteen under his care, but some became so bad that they had to be sent to the knackers. In grooming them, the secretions from their mouths and nostrils were frequently blown upon his face, and the stench of the stable in which they were kept was very great. A week after he had been looking after them, he began to feel feverish and ill; his stomach in particular became disordered, and his appetite bad. He was now anxious to give up his employment, but his master pressed him to stay, and he remained for several days longer. He got progressively worse, the febrile symptoms increased, and his stomach became so much disordered that he could not retain any food; at times, he broke out into profuse cold sweats, but he had no rheumatic pains, nor had he as yet any local affection of the face, nose, or salivary glands.

On Sunday morning, July 13th, while cleaning the horses, he felt completely overpowered by the stench; and he became so ill, that he was obliged to leave the stable abruptly. He was now seized with severe headache and giddiness, and swelling of the face. Lachrymation and profuse salivation soon followed. He says that half a pint of fluid ran from his mouth in the course of an hour; his teeth became loose, and the gums painful and tumid. His tongue began to swell, his throat felt constricted, and his nostrils became filled with a thick

yellow, fetid, glutinous secretion. He had frequent rigors, succeeded by heats and cold sweats, and he felt very low and weak. He was now obliged to give up his work, and was advised to take some gin, which, together with beer, he drank from time to time, but his stomach was so irritable that very little would stay upon it. He left Islington, and came to the Iron-gate Wharf at Paddington, in the hope of getting better, but he still continued to get worse, and on the 18th July, he applied at St. Mary's Hospital for advice He received some medicine as an out-patient, but having no home to go to, he did not take it. The next day he went again, and had a blister applied below the jaw, but feeling worse towards evening, he applied for and received an order for admission into the Paddington Infirmary.

When admitted, I am told, he was in a very exhausted state; he breathed with difficulty, and could scarcely swallow some wine which was given him. The fetor from his mouth was most intolerable; he was restless, passed the night without any sleep, and was observed to throw his arms continually about.

I saw him at 2 P.M. on the following day. He was then worse than when admitted, his breathing was more difficult, and the swelling of his face had increased; this was most marked, as I have said, under the lower jaw, where it formed an enormous tumour. I have already mentioned some of his symptoms, but it may not be amiss to recapitulate the following. There was a profuse discharge of saliva running from his mouth; the tongue was tumid, and its surface covered with a white, moist fur; the gums were soft and swollen, and his teeth loose. On passing my finger under the tongue, a large elastic tumour was felt on each side of the frænum linguæ, apparently consisting of the enlarged sublingual and submaxillary glands, and the distended ducts of the latter. I made a free incision in each of these, and a great quantity of clear glairy mucus poured out, which gave the patient much relief. I was unable to examine the throat, on account of the general swelling of the parts, but from the character of the breathing, and the difficulty of swallowing, it was evidently swollen, and the isthmus faucium contracted. I could not, however, see any appearance of erosion, ulceration, or pustules. The nostrils were filled with a viscid, yellow, opaque secretion, which, as I have said, was with difficulty dislodged, on account of its tenacity. The conjunctivæ were injected, and the eyes watered profusely. The patient complained of severe headache, which was greatest over the eyes and frontal sinuses, but at times it was felt over the greater part of the head. He was very sick, could not retain food upon his stomach, and was very restless and uneasy. He stated, that he had not slept for a week. He was alternately chilly and hot, and, at times, broke out into cold sweats. His pulse was quick and weak, and he complained of great lassitude. He had no rheumatic pains, or any perceptible eruption on the skin or mucous membrane; the blister which had been applied had risen, and had a greenish, sloughy, unhealthy appearance. His bowels had twice acted during the morning, and he had made water freely.

TREATMENT. He was directed to take immediately an emetic, consisting of half a drachm of ipecacuanha, and, as soon as vomiting had ceased, to take five grains of the sesquicarbonate of ammonia in water every hour, using as little water as possible; to use frequently a gargle

of the chloride of lime, and to have wine and such nourishment as he could swallow given freely, and to take at night an opiate, consisting of twenty drops of the tincture.

July 21*st.* On visiting him in the afternoon, his appearance was in every respect improved; his face was less swollen, as was also the tongue and salivary glands. He spoke, breathed, and swallowed better. His tongue was reduced in size; he had slept comfortably during the night, and taken nourishment, such as beef-tea, freely. His pulse had fallen to 80; the skin was cool, and he had experienced no rigors during the day. He said that the emetic occasioned copious vomiting of green unhealthy matter, and that as soon as this had taken place, he felt relieved, and as if a load had been taken off him. He subsequently took the ammonia as directed. He was ordered to continue this, and to take five grains of blue pill at bed-time, as the tongue was still rather white.

July 22*nd.* Improving; the tongue was almost of its natural size, and there was very little swelling of the face or salivary glands. He spoke, breathed, and swallowed better; the breath was less fetid; the pulse was quiet; the skin cool; and the bowels open. He had slept well, and had a desire for solid food. To omit wine and beef-tea, and to have animal food, with a pint of porter daily. To continue the ammonia every four hours.

July 23*rd.* In every respect better. The swelling of the face and throat was less, as was also the discharge of saliva. He slept well, and enjoyed his food. To continue the ammonia every four hours.

July 24*th.* Better. He had slept well, and ate well; the bowels were open. The swelling of the face was now confined to the submaxillary region, and was very slight; he could breathe through his nose, and swallow without any difficulty. The tongue was clean, moist, and of its natural size; the gums were but very little swollen; the teeth were firmer; there was no fever or shivering; skin cool; pulse 72. To continue the ammonia every four hours.

July 25*th.* He was convalescing favourably.

July 28*th.* Up to this date he had been daily gaining ground. The ammonia was discontinued on the 25th, and since then he has been taking merely a nourishing diet, with a pint of porter daily. He now wished to be discharged, declaring that he never felt better in his life. He left the next day.

Diagnosis. The first question which occurs in the consideration of this case, is whether it is such as I have represented it to be, viz., one of acute glanders or not; and although the history, its mode of development, and the assemblage of symptoms, taken collectively, lead, in my opinion, to no other conclusion, yet, it must be admitted, there are points in which it differs from other cases of the disease which have been reported. Thus, in this, there was neither ecchymosis, gangrene, or pustules, observable upon the affected mucous membrane; neither was there any specific affection of the lymphatics or the cellular tissue, although such conditions are described as forming part of the disease when fully developed. If, then, these are to be regarded as essential to it, the genuineness of the present case may be doubted. But a perusal of those which have been published does not appear to me

to lead to this inference; whilst I may remark they amount to so small a number, and their history is in some respects so imperfect, that it is impossible to draw any positive conclusion from them as to the significance of particular symptoms. "Glanders", says Dr. Robert Williams, "is a disease consisting of primary fever and of local inflammation, but the local inflammation may occur independently of the fever. When the inflammation exists *per se*, the disease is termed chronic glanders; when the two are combined, it is termed acute glanders."[1] Judged by this rule, the present case must be considered as one of acute glanders, because there was both fever and local inflammation combined. The patient had indeed suffered from febrile symptoms for a week before any local inflammation declared itself, and up to the time of his admission had frequent rigors, succeeded by heats and cold sweats, and attended with lassitude and extreme prostration.

With regard again to the supervention of ecchymosis, gangrene, etc., in the pituitary membrane, it would appear from Mr. Blane's description of the disease in the horse, that the period of their occurrence varies very much in different cases. In describing chronic glanders, he says: "An increased and diseased secretion from the membrane of one or both nostrils continually flows in small or large quantities. The discharge is seldom at first perfectly purulent, but is more glairy, thick, and not unlike the white of egg, and it sometimes continues thus for a long time; at others, it soon becomes purulent, but even then there is always a degree of viscidity and glueyness in it that sticks the nostrils together as it were from its tenacity; thus differing from other pus, and which very circumstance strongly characterises the complaint. . . The disease sometimes remains long without producing ulceration; at other times, on the contrary, an ulcerating process quickly appears."[2] This quotation would show, that in the horse, inflammation of the Schneiderian membrane, attended with a discharge of a peculiar nature, viz., one possessing extreme viscidity and glueyness, is alone considered to be characteristic of the disease, and this feature was strongly marked in the present case. The patient's nostrils were filled with an offensive secretion, so adhesive, that it was only with difficulty that it could be got rid of, and it completely closed them up, so as to prevent the passage of air. But, independently of this, it appears to me, that the history of the case is alone sufficient to establish the diagnosis. The man was in good health when he undertook the care of several glandered horses; for a week he scarcely ever left the stable, and was with them, on an average, from five in the morning until eight in the evening. All this time he was necessarily breathing a very fetid and unhealthy atmosphere, and his face was often covered with the diseased secretions of the horses. At the end of a week, febrile symptoms manifest themselves, attended with great prostration; he perseveres in his employment, and in another week is attacked with headache, giddiness, and those peculiar affections of the salivary glands, mouth, and pituitary membrane, which must be considered as constituting the incipient, if not the confirmed, symptoms of glanders. This history alone, as I have re-

[1] Williams, R., M.D. Elements of Medicine, vol. ii, p. 376.
[2] Outlines of the Veterinary Art. Third Edition; p. 458.

marked, appears to be sufficient to establish the diagnosis, and I am supported in this view by an eminent authority. "It is impossible, perhaps", says Dr. Williams, "to enumerate every difficulty that may occur in the diagnosis, but when any doubt exists, an inquiry into the habits and employment of the party will probably solve the problem."[1]

Mode of Communication. Another point of interest in the case is the manner in which the disease was communicated to the patient, whether by infection—*i. e.*, through the atmosphere, or by direct contact with the diseased secretions; and in this latter case, was the surface to which they were applied abraded or entire? It was observed by Dr. Elliotson, in his valuable paper in the sixteenth volume of the *Medico-Chirurgical Transactions*, that he presumed that an abrasion of the surface to which the poison is applied is necessary for the production of the disease, because, he says, most veterinary surgeons are satisfied by experience that the matter of glanders never excites it in the horse, even if applied to the pituitary membrane of the nostrils while the surface is entire. The result of my inquiries in the present case would tend to shew that this opinion is incorrect, while it is at variance with the results of experiments which have been performed upon the lower animals. Thus we are informed that glanders has been produced by inserting the virus under the cutis with a lancet, and by rubbing it on the greasy heel of a horse. It has also been produced by inoculating the mucous membrane of the nose of the horse, or else by smearing that membrane with farcied matter. Farcied matter has also been made up into balls, and introduced into the stomach of a horse, and glanders has resulted. There can be no doubt, therefore, that the poison is absorbed both by the mucous and cutaneous tissues, and that being absorbed, it infects the blood.[2] In the present case, the patient assured me that he had no scratch or abrasion whatever of any surface upon which the morbid secretions were received; and hence the disease must have been given him either by infection, or by the application of the glanders matter to a mucous or cutaneous surface free from abrasion.

That he was favourably predisposed to take such a disease, will hereafter appear; but the manner in which the disease was communicated is important, because it tends to shew, that where a predisposition exists, it may be taken more readily than has been supposed; and that in regard to such persons the disease is as eminently contagious as others that result from morbific animal poisons. In the two first cases reported by Dr. Elliotson, in his interesting memoir, the virus was supposed to have been received through an abrasion of the cuticle; and this was also the case in the others referred to, or at least in all those in whom the mode of communication could be ascertained. This may explain a circumstance by which the present is distinguished from the majority of cases which have been related by him. I refer more particularly to the absence of specific disease of the cellular and cutaneous tissues, as well as of the lymphatic system, which would readily be accounted for if the poison were received into the system through the atmosphere, and the disease arrested before it had produced any secondary affections. Whether, however, this is

[1] Williams, R., M.D. Elements of Medicine, vol. ii, p. 391.
[2] Ibid. p. 374.

the case or not, we are justified in concluding that glanders may be communicated to man more readily than has been supposed, and in the absence of those conditions which have been considered as necessary for its production. Hence too much caution cannot be practised by those who have the charge, or are exposed to the effluvia of glandered horses, whether as regards breathing the atmosphere of their stables, or avoiding contact with their diseased secretions.

Period of Latency. I am not aware that any facts have been collected on this point, bearing upon the disease as met with in the human subject. Dr. Robert Williams observes that the poison in general has been latent from two to eight days, but he gives no facts, nor the data upon which this statement is founded. In the present case I questioned the man particularly on this point; and it appears that constitutional symptoms, viz., sickness, rigors, and fever, commenced on the seventh day after he had been taking care of the horses; and that the swelling of the face, the affection of the salivary glands, and that of the pituitary membrane, took place on the fourteenth.

Predisposing Causes. That this patient was predisposed to the disease, or rather that the state of his constitution was such as to render it susceptible to the operation of any disturbing causes which might surround it, would appear to be almost certain from a consideration of his previous history. For some time before he took charge of these horses, he had been in very destitute circumstances; badly fed, lodged, and clothed. His constitutional powers must therefore have been enfeebled, and his capability of resisting morbific influences consequently slight, and hence we may account for the ready manner in which he succumbed to the specific causes of the disease. So far, then, the case furnishes additional testimony to the truth of the doctrine, that debility, however induced, whether by want or illness, favours the extension of fever, of epidemic, and infectious diseases; and it supports the general observation that has been made in regard to glanders, that the parties who have generally contracted it have been of intemperate habits, or have had indifferent health at the time of their falling ill or contracting the disease. As this patient was exposed both to an infected atmosphere, and had also the diseased secretion applied to his face, it is difficult to say in which of the two modes it was communicated. The history of his attack would lead me to think, as I have observed, that it was most probably through the atmosphere; and there is no reason to doubt that, under certain circumstances, it may be so communicated. It is well known, for instance, that in horses the glanders often originates in this way; and all farmers are agreed that dirty, close, and ill ventilated stables, out of which the dung is seldom removed, and the situation low and damp, are fruitful sources of it. Whether the disease is thus communicable to man, has not been as clearly ascertained; for the most part, we should be justified in saying that it is not, because numbers often breathe an infected atmosphere without catching the disease. But this immunity cannot be regarded as universal, or as exempting those who are strongly predisposed to it, whether from ill health, intemperance, or destitution.

Treatment. In offering some remarks upon the treatment of the

present case, I cannot introduce the subject better than by quoting the following passage from Dr. R. Williams's philosophical work *On Morbid Poisons*. "All the remedies hitherto tried in acute glanders have failed, for only one out of fifteen has recovered, and that not from any particular treatment. Blood, when taken at the commencement, has been found buffed, and some momentary relief has been afforded, but the bleeding ought not to be repeated, as in the more advanced stages the prostration is great, and stupor quickly follows, and leech bites have become gangrenous. The coming on of typhoid symptoms has caused quina, valerian, serpentaria, ammonia, and other stimulating medicines to be exhibited, but all these experiments have failed; vomiting and purging have been likewise had recourse to, but these measures have been equally unsuccessful. In the present state of our knowledge of this disease, every experiment in treatment is warranted as the only chance of subduing a malady which has so constantly proved fatal. In the more chronic forms of the disease, the recovery of the patient has appeared rather to be owing to the excellence of his constitution, than to any powerful effect produced either by general or local treatment."[1]

In the present instance, I had no reasonable expectation of the patient recovering, nor had he, or any one who was present at the time when I first saw him; and yet in twenty-four hours he was comparatively out of danger. Now this change cannot be ascribed to any improvement in his sanitary condition consequent upon coming into hospital. For, in spite of wine and other assistance, he was worse then than when he was admitted. Hence I think that the improvement which took place must be mainly attributed to the treatment, which may be thus recapitulated in the order of sequence. 1st. An incision in each of the Whartonian ducts. 2ndly. An emetic of ipecacuanha. 3rdly. Sesquicarbonate of ammonia in water hourly, as concentrated as it could be swallowed. 4thly. An opiate at bed time, with wine and nourishment, in such quantities as the patient could be prevailed upon to take.

The incision was made in the Whartonian ducts on account of their being much distended, and from an impression that their orifices were closed from the swollen state of their parietes. It gave immediate relief to the patient, by allowing a free escape of a large quantity of pent-up saliva, and the swelling and tension of the parts were at once lessened by it. The emetic was considered to be indicated by the existence of gastric derangement throughout the progress of the case, which was manifested by a constant disposition to sickness, and the inability of the patient to retain anything upon his stomach. It was also given for the purpose of producing reaction, and rousing the constitutional powers by its operation upon the ganglionic nervous centres.

But the principal reliance was placed upon the frequent administration of the sesquicarbonate of ammonia *in a concentrated form*. This remedy, and this mode of exhibiting it, were suggested by the good effects which I had seen it produce when so given in the severe affections of the throat, which are met with in malignant scarlet-fever. It was originally recommended by Dr. Peart in such cases,

[1] Op. cit., vol. ii, p. 392.

in a work on the malignant scarlet-fever and sore throat, which he published in 1802; and its efficacy is corroborated by Mr. Wilkinson, who quotes also the testimony of Mr. Ricardo in its favour. As, however, the works in question are not very accessible to the profession, and as in the particular case under consideration, it appeared to have been most beneficial, and to have been the main cause of the patient's recovery, I shall add a few remarks upon the remedy as thus exhibited.

Ammonia is reported to have been given in glanders, but without success; and the same remark has been made with reference to its exhibition in scarlet fever: but it is not so much to the medicine, as to the method of giving it, that we are, I apprehend, to look for beneficial results. On this point, Mr. Wilkinson remarks: "It has been observed that Dr. Peart has no claim to originality in the employment of the subcarbonate of ammonia in the cure of scarlatina, Dr. Withering having used the same remedy many years before: but may there not be almost as much originality in the *manner* of exhibiting a remedy, as in the first adoption of it? Dr. Withering says, that the volatile alkali may likewise be given with advantage; but it is difficult to get a sufficient quantity of it swallowed (p. 84); and he prescribes it in the following form. ℞ Sal. absinth. ʒij, sa. vol. ammon. ʒss, aq. fontan. ʒij. M. Ft. solutio, to be put in a quart of white wine whey, and the whole to be taken in twenty-four hours; by which it appears to me that he knew little of the powers of subcarbonate of ammonia in this disease. His manner of exhibiting it would destroy its effects, or at least the effects upon which I should depend for its advantages in scarlatina."[1] These remarks appear to me to be equally applicable to the treatment of glanders with ammonia, as it is ordinarily given.

On the other hand, it was an essential part of Dr. Peart's treatment of the scarlatina, anginosa, and maligna, that it must be given in a state as strongly stimulating as it can be swallowed. His mode of exhibiting it is contained in the following passage, which is quoted from Dr. Willan. "He dissolves two drachms of the carbonate of ammonia in five ounces of water, and directs the patient to take two teaspoonfuls every two, three, or four hours, according to the urgency of the symptoms. If the difficulty of swallowing abate, and the patient wish for it, a little cold water may be added to each dose. Cold water, or toast and water, may be drank at pleasure. The above remedy was given in every form and in every stage of the scarlatina. Some," he says, "were glowing with universal efflorescence; in some the extremities were swelled; in others fetid ulcers appeared; in most the throat was swelled and inflamed, often ulcerated, and respiration almost prevented; but, in the most alarming cases, a scorching fever and raging delirium rendered the patient's situation horribly distressing. Yet, in all these variations of the disease, the volatile alkali was my specific, which I administered to between two and three hundred patients *successively and successfully*." The immediate effects of the remedy are stated to be, a diminution of heat, fever, and delirium, and a disposition to sleep. Mr. Wilkinson confirms the accuracy of these remarks; and, in regard to the *modus operandi* of the medicine,

[1] Wilkinson, J. H. Remarks on Cutaneous Diseases, pp. 19-20. Lond.: 1822.

says: "I will take the liberty to state, that I depend not upon its diuretic nor its diaphoretic qualities, but believe that it possesses the power of increasing the strength of the arterial action, at the same time that it diminishes its frequency; that it supports the vis vitæ, without increasing the heat or irritability of the system; and by such means counteracts the tendency in the scarlatina, anginosa and maligna, to ulceration and sloughing, and all the other evils which sometimes attend this dreadful disease."[1]

Mr. Wilkinson further gives the following practical illustration of the success which attended the treatment of scarlet fever in this way. "In the year 1803," he says, "I attended several cases of the scarlatina maligna with Dr. Willan and the late Dr. Hamilton. It is well known that the disease raged most fatally during that period; and we lost four of our patients out of five in one family. Never were men more puzzled to know what remedies to adopt. All which Dr. Willan has recommended in his publication were employed. Emetics, purgatives, calomel, and antimony, many other diaphoretics, opium, wine and acids, bark, blisters, decoct. contrajervæ with oxymel of squills, application of cold water, gargles of different descriptions, fumigations, etc., all without the least good effect, all without making the least sensible impression upon the disease in any of its stages. About this time, Dr. Peart published his *Practical Information on the Malignant Scarlet Fever and Sore Throat,* in which he describes the wonderful effects of the subcarbonate of ammonia, and considers it to be endowed with a specific power over that disease. Like other practitioners, he was continually lamenting the loss of his patients by that dreadful malady, till, by his own suggestion, he employed the subcarbonate of ammonia in the manner he describes; and from that moment he did not lose one patient, out of nearly three hundred. When I read this account, I immediately inquired after the character of Dr. Peart, and finding that he was most respectable both in talent and probity, and engaged in very considerable practice, I had no reason to doubt the truth of his statement, and therefore immediately adopted his remedy; and consonant with my own principle, that an effectual remedy for one genus, will, with proper management, cure all the genera of the same order, I administered it in all the following diseases—erysipelas, rubeola, scarlatina, urticara, roseola, and erythema, with all their varieties; and I am happy to be able to declare, that from that moment to the present, a space of seventeen years, I have not only never lost a patient in the above diseases, but have never had a case of the kind that has even appeared dangerous, or that has given me a moment's anxiety."

In addition to his own, he adduces the following testimony to the remedial powers of ammonia, when so given, from Mr. Ricardo, of Bow, a gentleman of great ability, and very extensive practice: "I have received your letter, requesting me to state the result of my experience of the effects of subcarbonate of ammonia in the treatment of measles, scarlatina, and erysipelas. As I employed this medicine at your suggestion, many years ago, I lament that I have not placed on record any *particular* cases, many such having been under my care; but perhaps it may be sufficient for your purpose, that I am able to

[1] Op. cit., p. 20, et seq.

declare that the exhibition of subcarbonate of ammonia in such cases has been attended, under my direction, with constant success. You know that I am situated in the neighbourhood of many schools, which I have the pleasure of attending; and during twelve or fourteen years, in which I have employed the subcarbonate of ammonia, I have not lost a single patient, of some hundreds whom I have attended in the above diseases."

I have quoted these passages at some length, not only because the plan of treatment they refer to was adopted in the case of glanders which I have reported, with very striking results, but because I believe that the principle comprehended in it is applicable to many other analogous diseases, in which it has hitherto not been tried; and, further, because I am anxious to do justice to those with whom the merit of originating it rests. It furnishes, moreover, a good illustration of the practical views which abound in the writings of our predecessors; and of the many useful facts and suggestions which are to be met with in what may be termed the indigenous medical literature of this country; and, although at the present day a preference is too often given to doctrines which have been imported, whose chief recommendation is their novelty, it would be difficult to find, in any medical records, richer or more valuable contributions, and such as are likely to be more permanently useful, than those which have been made by the zeal and persevering industry of our forefathers. I cannot doubt of the utility of this particular mode of treatment, in this and other diseases in which I have tried it; and I have less hesitation in recommending it to professional notice, as I do not lay any claim to the merit of introducing it. I would, however, observe, that there is much in the history of glanders which assimilates it to the more malignant forms of scarlet fever. Both, for instance, arise from a specific contagion; in both there is a similarity in the parts which are more especially implicated, viz., the throat, the respiratory mucous membrane, and the salivary glands; and in each there is a tendency to ulceration, sloughing, and destruction of the tissue of these parts. These circumstances furnish grounds for believing, *a priori*, that the medicine which would be best adapted for one disease, would be most curative of the other; and this conclusion, which is suggested by careful reflection, is confirmed by practical observation, so far at least as the issue of the present case is concerned.

It is unnecessary to dwell upon the other items of treatment; the use of opium was clearly indicated upon general grounds. The employment of gargles of the chlorides of lime and soda in ulcerative affections of the mouth and throat, has been long sanctioned by general experience; and there could be no doubt as to the necessity of administering wine freely, with such support as the patient was able to take.

Chester Place, Hyde Park Gardens, August 1851.

ON A NEW APPARATUS FOR FRACTURED CLAVICLE.

By HENRY LEE, Esq., F.R.C.S.Eng., Assistant-Surgeon to King's College Hospital; and Surgeon to the Lock Hospital.

THE principal use of the clavicle in man is to keep the shoulder at the requisite distance from the body, and, by affording it an unyielding support, to enable the muscles to move it, and to maintain it in position. When the clavicle is broken, the shoulder falls in, being drawn by the action of the muscles into contact with the ribs. It also falls, in obedience to the laws of gravitation, according to the position of the body. In the erect position, therefore, the shoulder will be found lower than natural, as well as to have lost something of its lateral prominence.

Different methods have been proposed for the treatment of this fracture. The most common method is the figure-of-eight bandage applied about the shoulders. This keeps the two scapulæ on the back of the chest, and prevents their anterior edges from falling forwards. Some degree of extension is made in this way, but still it rarely happens that the fractured extremities can by this means be brought into apposition; and one reason of this is, no doubt, that it affords no provision against the shoulder falling by its natural weight.

A second plan of treatment, which may, with certain modifications, be combined with the former, is that of M. Desault. This consists of a cushion, in the shape of a wedge, placed in the axilla, with the broad part upward. The thin point is prolonged so as to reach as low as the short ribs. This cushion is retained in its place by a bandage, and the arm is bound down upon it. The upper part of the cushion thus acts as a fulcrum, the part of the humerus below it as a lever, and the shoulders are by this means drawn asunder. An artificial clavicle is thus formed, while the natural one is being repaired. This apparatus is, however, very difficult to apply, and demands that the patient should be kept at rest afterwards. In a few days, even with the greatest care, the bandage will require to be readjusted, and this necessarily involves a disturbance of the fractured extremities. But the chief objection to this apparatus lies, perhaps, in the circumstance of the cushion resting upon the moveable ribs. As the extending power is always the same, and depends upon the elbow being fixed by an unyielding bandage, it follows, that any motion which is allowed at the point of support, or at the fulcrum, must necessarily be communicated to the free extremity of the lever; and, consequently, in the case before us, would tell upon the fractured portion of the clavicle.

A third plan, which has recently been adopted for fracture of the clavicle, is that which was suggested by Mr. Ellis. It consists in the adaptation of a firm cushion, in the shape of the top of a crutch, to the axilla of the affected side. This rests upon a vertical plate, which reaches nearly as low down as the crest of the ilium. The apparatus is supported and retained in its position by a band extending over the opposite shoulder. Extension is then made by using the arm as a lever, as in Desault's method of treatment; but, as in that, the cushion which forms the fulcrum is constantly liable to move with the motions of the ribs.

Messrs. Philp and Whicker, of 67, St. James' Street, have, at my request, constructed an apparatus, by means of which lateral extension can be made in cases of fractured clavicle from a fixed point. It consists of a backboard, retained in its position by two broad straps crossing over the shoulders, and by a perpendicular plate reaching to the loins, and connected with a band round the waist; a firm cushion is adapted to each axilla, and extends to the front of the shoulder-joint. To the anterior extremities of these, the straps which go over the shoulders are buckled. Each cushion is directly connected with the backboard by means of a steel bar, slightly concave forward, and capable of being extended laterally and fixed in position by means of a screw. When applied, the two cushions are separated to a convenient distance and fitted to the axillæ. The straps are drawn moderately tight over the shoulders, and the elbow of the affected side is connected with the body by means of a handkerchief or bandage. It is advisable also to support the arm in a sling; and this may be conveniently done by passing a broad band from the elbow in front and behind the arm to the opposite shoulder, below which the cushion in the axilla affords a fixed point for its attachment.

The principal advantage of this apparatus consists in its different parts being so connected and adjusted as not to move with the motions of the ribs; for as these are raised, in all their ordinary actions, simultaneously on both sides, any influence which they possess must be exercised equally in different directions; and as corresponding parts of the apparatus are placed upon the two sides of the chest, any tendency to displacement is exactly met and counteracted by a similar tendency from the opposite side. The result is, that although the cushions rest upon the ribs, they yet do not move with the ribs, but afford firm, and comparatively fixed points of support.

A second advantage of this apparatus consists in its not requiring to be readjusted; should the bandage round the body, or the sling which supports the arm become loose, they may be tightened without in any way disturbing the position of the instrument, or the fracture.

A third point of some importance is, that the arm on the opposite side to the fracture is not confined, and the patient may, in ordinary cases, be allowed to walk about as soon as the instrument is properly adjusted.

In severe fractures of the clavicle, and in such as are complicated with injury to the ribs, it may become desirable to remove all pressure from the side of the chest.[1] This may readily be accomplished by increasing the distance between the two cushions, and connecting *both* the arms with the body. Any amount of lateral extension may in this way be made without any pressure upon the ribs, and even without interfering in any degree with their actions.

---

[1] It was reported in the case of the late Sir Robert Peel, that he was quite unable to bear the pressure of the ordinary clavicle bandage upon the chest.

CASE OF COLLOID OR GELATINIFORM CANCER OF THE PERITONEUM AND COLON; WITH REMARKS.

By ROBERT HUNTER SEMPLE, M.D., and EDWARD BALLARD, M.D.

Case. Mary Hall, aged 66, an inmate of the Islington Workhouse, moderately well-formed, rather thin and pale, but not remarkably so, presented herself for medical relief on the 23rd of April, 1851. She complained of pain in the bowels, with purging, and some vomiting. She did not represent her case as a serious one, and she was not in the infirmary. The disease was considered as a common disorder of the bowels; and she was accordingly ordered to take the following: ℞ Tr. opii ʒss, mag. carb. ʒss, sulph. mag. ʒij, aq. menth. pip. ʒvj. Sumat coch. ij magna 4tis horis.

April 25. The pain in the stomach and bowels was not relieved; the tongue was furred; the skin hot and dry; purging still continued; vomiting had ceased. She was ordered to take the following: ℞ Hydr. c. cretâ, pulv. ipecac. co., āā gr. iij. Fiat pulvis 4tis horis sumendus. She improved slightly under this treatment; but, as she did not lose all the symptoms, she was ordered into the infirmary, in order that she might be seen and examined in bed.

April 28. She was now lying in bed, undressed, and the state of the abdomen was carefully examined. It was generally soft and yielding, and resonant; but, owing to the pain experienced in the manipulation, the abdominal muscles were put upon the stretch, which considerably obscured the physical symptoms. It was very evident, however, that a dulness existed below the stomach, and there was a feeling of an irregular, soft, tumefied mass in that situation. The palpation of this tumid part caused great pain, and the pain was not at all relieved, but, on the contrary, was very much increased by pressure, especially by firm pressure. There was want of appetite, furred tongue, dry and hot skin, thirst, and diarrhœa; the stools were fluid and frothy, but not fæculent; the pulse was rapid and rather full. Under these circumstances, Dr. Semple considered that, whatever the disease might ultimately prove to be, there was, at the period now described, a local inflammation of the colon, and that, although there was diarrhœa, there was nevertheless abundance of fæcal matter impacted in the intestine, which might probably be the cause of the present mischief. This opinion was founded upon the circumstance, that Dr. Semple had often observed in old persons who neglected the state of their bowels, that great fæcal accumulations often led to inflammatory conditions of the intestinal canal, and that, although in such cases diarrhœa often existed, it should not be allowed to mislead the practitioner, and to induce him to trust to astringent remedies. There was at this period no emaciation, nor any other appearance to lead to the suspicion of organic disease. She was therefore directed to remain in bed, to take liquids for her food, *and to apply eight leeches over the situation of the supposed tumour*. She was also directed to apply warm poultices after the leeches were removed.

April 30. She was decidedly relieved by the application of the leeches, which had bled well; but there was still a great degree of tenderness on

pressure, and the diarrhœa continued. The muscles of the abdomen being now less contracted, there was felt a distinct tumefaction over the course of the colon. Under the impression that there was inflammatory disease, and that, notwithstanding the diarrhœa, there was still an accumulation of fæculent matter in the intestines, the following plan was recommended. Six more leeches were directed to be applied over the region of the colon, and the leech-bites fomented as before. The following medicines were also ordered: ℞ Hydrargyri chloridi gr. ij, opii gr. $\frac{1}{3}$. Ft. pilula 6tis horis sumenda. ℞ Tincturæ catechu ʒij, aquæ menth. pip. ʒvj. Sumat cochlearia ij magna 4tis horis.

May 2. She was decidedly better: the tenderness on pressure was very much relieved; the diarrhœa was less frequent. She was directed to continue the medicines.

May 3. Her bowels had now become confined, and she was accordingly ordered to discontinue the former medicines, and to take an ounce of castor oil.

May 4. She now reported that she was very much better; the tenderness had almost disappeared; her tongue was cleaning. She stated, that during the night she had been to the water-closet and had passed, with great difficulty, some hard lumps like stones, but which unfortunately she had not preserved, and that the evacuation of these masses was attended with immediate relief. Dr. Semple therefore considered, that his conjecture as to the existence of hard fæculent masses in the intestine had been correctly formed; and he therefore, in order to evacuate any remaining portions of such matter, directed her to take an ounce of the common purging mixture, consisting of salts and senna, every four hours. (It will be seen, by reference to the *post-mortem* examination, that there was a large quantity of fæcal matter found in the intestines after death.)

May 8. The patient was still improving, and expressed herself better in all respects; she slept well at night, and had very little pain in the abdomen. She complained, however, of flatulence, acidity of the stomach, and want of appetite, and she was accordingly ordered the following: ℞ Liq. potassæ ʒij, essentiæ menth. pip. ʒss, infus. gentianæ ʒvj. Ft. mist., cujus sumat coch. ij magna 4tis horis.

May 9. She now complained of some feverish symptoms, as hot, dry skin, furred tongue, and thirst, and she was accordingly ordered to take the following febrifuge mixture. ℞ Antimon. potassio-tart. gr. j, sp. æth. nitrici ʒij, liq. amm. acet., et mist. camph., āā ʒiij. M. Ft. mist., cujus sumat coch. ij magna 4tis horis. This medicine allayed the feverish symptoms.

She now became so much better that she was able to leave her bed, and, at her own request, was allowed a mutton chop daily, with half a pint of porter, which she duly consumed; and the only medicine she took was an occasional dose of infusion of gentian, which she found to strengthen her. After the lapse of about a month, however, she again began to complain of pain in the abdomen, of sleepless nights, and of a deficiency of appetite. She was often examined carefully, and the tumefaction over the region of the colon was distinctly recognised; the tumour, however, was soft and quite moveable, and there was no nodulation apparent in any part. At this time, Dr. Semple suspected the existence of organic disease, and expressed an opinion

that the nature of the case was one of the soft forms of cancer, and, indeed, he considered it to be a tumour of medullary sarcoma. Under this impression, she was ordered to take small doses occasionally of tincture of henbane in peppermint water.

June 17. The pain was not diminished by the use of the henbane; she had sleepless nights; and her appetite, although not lost, had become capricious, and she was allowed, at her own request, to have sometimes fish, and sometimes eggs, in place of the mutton chop. In order to allay the pain, of which she continually complained, she was ordered to take twenty minims of tincture of opium every four hours in peppermint water. This produced some alleviation of the pain, and she accordingly took it every day for a considerable time. The case was now regarded as hopeless, and the symptoms of organic disease became quite apparent; the features became shrunk, there was excessive emaciation, and total loss of appetite; the pulse was rapid, and very feeble; she retained her consciousness throughout, and wished for death to release her from her sufferings. She never had any fæcal vomiting, nor was she latterly troubled with vomiting at all. She was ordered to take the opiate occasionally. She gradually sank, and died on the 29th of July.

Post-Mortem Examination of the Body, made on the 30th of July by Dr. Ballard and Dr. Semple.

Conformation. Spare; muscles pale; scarcely any subcutaneous fat.

Head. Brain quite healthy.

Chest. Pleuræ both healthy; no adhesion; lungs slightly emphysematous; a little puckering with cretaceous matter at the apex of each; heart small.

Abdomen. The tumour perceived during life was evident on handling the abdomen; it was firm, and slightly moveable, emitting a dull sound on percussion, bordered by resonance of the intestines below, and of the stomach between it and the hepatic dulness above. It extended across the abdomen, in the direction of the transverse colon, an inch below the umbilicus; and, on opening the abdomen, the parietes were found strongly adherent to it, in the middle line, over a circular extent of about two and a half inches diameter. The situation of the parts then displayed was as follows: The tumour, which turned out to be in the transverse colon, lay across the abdomen, at the level mentioned; and the stomach, which was of full size, occupied, with the liver, its natural position, a part of it lying between the tumour and the edge of the liver. The cæcum and ascending colon were not found in their usual position, but placed in a line with the transverse colon; the cæcum occupying a position in the right flank, and the extremity of the ileum crossing the iliac fossa to enter it. The small intestines were tolerably filled with flatus. The sigmoid flexure was lying altogether within the pelvis; and, with the rectum, was filled with solid fæces. With the exception of the serous covering of the liver, spleen, and stomach, every part of the peritoneum, parietal and visceral, together with its folds, was studded with minute granular elevations, which rendered the surface rough to the finger passed over it. Each granule was surrounded by a little zone of redness. At first sight, they were taken for miliary tubercles; but, on the nature of the tumour being discovered, they were subjected to closer examin-

ation, and found to consist each of a little bit of gelatinous matter, enclosed in the substance of the serous membrane: in no case were the grains found to be bilocular. There were but few on the diaphragmatic peritoneum, and at the upper part of the abdomen; but were more abundant, and placed closer, over all those parts which lay below and towards the pelvis: here, too, some were larger, and nearly of the size of small peas. The tumour consisted of the transverse arch of the colon, which was adherent above to a part of the great curvature of the stomach, and below to a part of the jejunum; and it presented externally a purple discoloured appearance. On handling it, part of its substance gave way, and a portion of the contents passed into the peritoneal cavity. The cæcum was filled with liquid fæces. On passing the finger from it into the tumefied transverse colon, the canal was found so contracted as scarcely to admit it for about six inches. It was laid open throughout, and the nature of the disease then became evident. Throughout the contracted portion, the internal surface was raised into large rugose elevations of irregular shape, but most of them with their long diameter placed transversely. The wall of the intestine was thickened to the extent of from one-eighth to half an inch. The whole rugæ and intestinal wall were filled with locular colloid cancer, which had evidently first infiltrated the mucous membrane, and then passed through the muscular coat to the serous, which in some parts it had infiltrated also; in other parts, this membrane passed unaltered over the colloid matter. Near the commencement of the descending colon, there were small isolated elevations, of the size of a pea and larger, on the mucous surface, each consisting of gelatiniform matter contained in loculi. The cell in many parts opened upon the free surface of the membrane, which here exhibited, when examined in water, a reticulated appearance. At the adherent part, the mucous membrane of the stomach presented some purple discolouration; and, on floating out the mass of disease in water, several foramina were observed, by which a probe could be passed from the stomach into the contracted part of the colon. The rest of the stomach was healthy. The liver presented the appearance known as biliary congestion: the gall-bladder contained thirty largish angular gall-stones, two of them firmly impacted in its duct. The spleen was natural. The left kidney was small, with a lobulated exterior, and felt soft and fluctuating. On section, it was found universally hollowed out into cysts, as large as a hazel nut, most of them containing a clear serous fluid; none of the natural tissues of the organ remained. The right kidney was nearly twice its natural size, and at its lower extremity presented three or four cysts, similar to those in the left; but the whole upper two-thirds was hypertrophied, soft, and watery. The ovaries were small and hard. The uterus was small, but healthy. The bladder was healthy.

Remarks. The rarity of the occurrence of colloid as compared with that of scirrhous and the encephaloid forms of cancer, and the little frequency with which cancer of the large intestine (except of the rectum, perhaps) is met with at all, give an interest to this case. Judging from the appearance of that part of the colon where the disease was in an incipient state, the infiltration commenced in the mucous membrane, and extended from this through the thickness of the wall of the intes-

tine. Along with the progress of the infiltration, a process of shortening of the canal appears to have gone on, which, as the shortening portion was fixed by adhesion, resulted in the traction from their natural position of the cæcum and ascending colon. In a case of gelatiniform cancer of the peritoneum, published by Dr. Ballard in the *Medico-Chirurgical Transactions*, the advanced result of this affection, when occurring in the serous membrane, was exhibited. The present case is of interest in connexion with that, as shewing how the disease may commence in single loculi, scattered like tubercles on the surface of the membrane. Had this patient lived, no doubt more of these granules would have become developed; they would have formed an uniform layer over the membrane, new loculi would have become developed about them, and complete infiltration, with thickening of the membrane, would, as in that case, have been the result. In this instance, the disease of the serous membrane, though plainly consecutive to that of the colon, evidently arose independently of it, and, from its appearance in so many different foci, could only be supposed to have occurred from general contamination of the nutritive system with the sort of cancerous diathesis. It may be observed further, in connexion with the case, that it occurred, as colloid cancer mostly does, in a female.

The history of the case, as recorded by Dr. Semple, though pointing to the large intestine, and especially to its transverse arch as the locality of the disease, by no means indicates its nature. Indeed, apart from a consideration of the general symptoms, we do not see how even its seat could have been discovered with any accuracy, by the amount of physical exploration employed.

There are three other points to which we desire to direct attention. One of these is the absence of any fæcal vomiting, as symptomatic of the communications between the stomach and the colon, and the absence of fæcal matter at all in the former after death. The fact was, that the communications were by foramina, which appeared to have been formed by the breaking down of cancerous loculi, which had reached through the adherent organs; and not only were the communications blocked up by gelatinous matter, but they were probably closed also by pressure of the cancerous developments bounding them. Another remark we have to make, is on the absence of the cancerous aspect so commonly observed in the cachexia which accompanies the occurrence of other forms of cancer. The same absence of sallowness was observed in the case before referred to, and would appear to place some more marked distinction than is at present recognised between colloid cancer and the other forms of the disease. Our third remark is in connexion with the fact, that colloid cancer does not kill the patient, as scirrhous and encephaloid often do, by a general effect on the blood and nutrition of the body, but may go on increasing and extending its ravages far and wide, in the part that it attacks; the patient meanwhile only suffering from the encroachment it makes upon the functions of parts, whose healthy action is more or less necessary to life. This is illustrated in the case before us. The immediate cause of death was the contracted state of the large intestine, and would have taken place in the same manner, had the cause of the contraction been inflammatory or hypertrophous, in place of being cancerous. In Dr. Ballard's case, again, no constitutional symptoms of cancer

were present, the symptoms which the patient presented being due to the pressure of the new formation upon the organs of the chest and abdomen; and the patient died as if she had been worn out with ascites, ovarian tumour, or any other disease acting in a similar manner.

CLINICAL ILLUSTRATIONS OF DISEASES OF THE NERVOUS SYSTEM.

By ROBERT HUNTER SEMPLE, M.D.

CASE OF ACUTE SUICIDAL MANIA TERMINATING FATALLY.

Case. Henry Staples, aged 23, a boot-closer, of average size and conformation; thin, spare, rather tall; rather good-looking than otherwise.

Previous History. His father had been twice insane; the first time, was upwards of twenty years ago, when he was very gloomy, melancholy, and desponding; and, according to the account which I received from his eldest son, he was in a state of insanity when the subject of the present case was conceived. About ten years ago, the father made an attempt upon his life by cutting his throat, and was accordingly taken to St. Bartholomew's Hospital, where he was kept closely watched and under restraint, and where he eventually recovered; and was now (July 1851) in a sufficiently sane state to manage his affairs. I was informed that the subject of the present case had been well brought up, and had been educated as well as, or rather better than persons in his rank of life usually are; he was by no means ignorant. His brother stated that, from his earliest youth he had exhibited symptoms of moroseness of disposition and sulkiness; but that he now attributed these peculiarities to the influence of hereditary mental disease. He was reported to have been always a very steady young man, attentive to his work, esteemed by his employers, and not at all addicted to drink, or to sexual indulgence.[1]

On Friday, July 4, 1851, an alteration was observed in his manner; he complained of unusual lowness of spirits, and began crying like a child; he had also pains in his limbs, and general uneasiness. On Sunday morning he rose from bed, and talked in a wild and incoherent manner; he also began dancing and capering about the room. Three of his acquaintances came in to see him, and proposed an excursion to Epping Forest to raise his spirits and to amuse him. It appears that they took him with them, and gave him some cold brandy and water, together with ale and ginger-beer. It does not appear that they drank much; but, when the subject of the case came home, he was furiously delirious. In consequence, a medical man was sent for, who administered some medicine, and told the relatives that he would pass some

---

[1] His brother has told me, that he used to have frequent conversations with him, and that he often complained of lowness of spirits; that, from reading some medical book, he had come to the conclusion that he had injured himself by extreme continence; and that he was continually in dread of alienation of mind.

black stools, and that, after doing so, he would be better. On Monday morning he was rather better, but in the afternoon he was seized with general trembling and crying. During the night of Monday, he made repeated attempts to strangle himself, by placing his thumbs over his throat, but these attempts were observed and frustrated by his brothers. On Tuesday he dressed himself, and went out with one of his brothers, but was evidently extremely uneasy in his mind, reproaching himself that *he had never got married*, that he had injured his health by extreme continence, and that he should become an idiot. During Tuesday night, he became worse, and was almost uncontrollable, and tried to destroy himself in whatever way he could, by using the instruments and tools employed in his trade. On Wednesday morning, at six o'clock, he was taken out into the air by his brothers, in the hope of soothing him; but, on their leaving him for only a few yards behind them, they perceived, on looking back, that he was knocking his head violently against a lamp-post. He was then brought home when his family were at breakfast, and, when unperceived for a moment, he seized a knife and drew it across his throat, but the knife was immediately secured by one of his brothers. He was then taken out again for the purpose of diverting him, to the house of one of his brothers; but while there he tried to jump out of the window, and also to strangle himself with his handkerchief; in fact, he made every attempt in his power to destroy himself. On Wednesday afternoon, he was seen by Mr. Hutchinson, one of the parish surgeons of St. Mary, Islington, and he was sent by him, on a lunatic certificate, to the Islington Infirmary, with a view to his conveyance to a lunatic asylum. He had now become so excessively violent, that it was impossible to restrain him by ordinary means, and he was carried to the workhouse in a strait jacket, and with his legs bound. The brother who furnished me with this account, stated that, so far as he knew, his head was not particularly hot, nor did he ever complain of headache, but his eyes were wild, and he asked for water; he had no sleep since Monday night, when he slept for about an hour and a half.

He was brought to the Islington Infirmary on Thursday, July 10.

When I saw him, he was in a very excited state, calling out loudly; he was confined by a strait waistcoat. His head was very hot; his skin was hot, dry, and parched; his pulse was rapid, but not very full; his tongue was dry and furred, his pupils torpid; he was very thirsty. His head was ordered to be shaved, and vinegar and water to be applied to the scalp; and eight leeches were ordered to be applied to the temples.

July 11. He was much the same; still uncontrollably violent, and necessarily confined in the strait waistcoat; head still hot; eye-balls rolling and prominent; pupils neither much contracted nor much dilated; tongue furred; bowels confined; skin hot. Although he was very violent, he nevertheless knew what was said to him, and put out his tongue when he was asked to do so; but he appeared to be in dread of something or somebody; and continually asked to be spared from some imaginary tormentor. He always addressed me by name, and begged me to relieve him from some apprehended danger; but he was so incoherent that I could not ascertain what he meant. I should mention that, except in the particular of restraint, he was treated with great

kindness. He was so exceedingly violent, that not only did he perpetually attempt to strangle himself in bed, to jump out of the window, and to kill himself by knocking his head against the wall, but he was also dangerous to others, for, although his arms and legs were confined, he bit one of his nurses very severely, and with his teeth he tore his coat in two. By my express directions, therefore, he was kept under restraint by physical means. He was ordered to take the following: ℞ Hydr. chloridi gr. iij. Fiat pilula 4tis horis sumenda. ℞ Sulph. mag. ʒss, inf. sennæ ʒvj. Ft. mist., cujus sumat coch. ij magna 4tis horis.

I ought to mention, that I was requested at this time to sign an order, for the purpose of conveying this man to a lunatic asylum, but I declined to do so for the following reasons. He was in such a state of bodily disease as to require the most careful medical treatment; and the steps necessary to be taken in the case of pauper lunatics, of conveying them for examination before a magistrate, bringing them back to the Infirmary, and subsequently conducting them for several miles to a lunatic asylum, could not, I conceived, be adopted in the present case, without imminent danger to the life of the man himself, and to the safety of others.

July 12. He was slightly better, but still very incoherent. His bowels had been freely opened, and he had passed a large quantity of very dark, almost black, stools. The head was not so hot; there was no alteration in the appearance of the pupils. He was directed to apply a large blister to the nape of the neck and between the shoulders, and to keep it open by stimulating ointment, consisting of equal parts of emplastrum lyttæ and unguentum resinæ; he was also directed to continue the purgative mixture. He continued in the same state for the next two days; the delirium still continued, which was always of an *apprehensive character*, as if he feared that something was going to befal him, and he talked almost incessantly. I took great pains to ascertain whether the case were one of delirium tremens, but I was convinced that it was not, for the head was burning hot from the commencement, the skin was always hot and dry, the tongue was white and furred and dry, not covered with a creamy mucus, and I could observe, amidst all his violence, nothing that could properly be considered a tremulous motion. I therefore directed the antiphlogistic system to be continued, the blister in the back of the neck to be kept open, and cold applications to be kept constantly to the head.

July 15. He was rather more tranquil, but still raving, apprehensive, and incoherent. Bowels confined. He was directed to take half a drachm of compound jalap powder.

July 16. On this day he suddenly became worse; he was unusually quiet; the tongue became brown, cracked, and dry; the skin hot; he had great thirst; pulse was rapid and small. He was ordered to take the following: ℞ Antimon. potassio-tart. gr. j, sp. ætheris nitrici ʒij, liq. ammoniæ acetatis, et mist. camphoræ, āā ʒiij. Ft. mist., cujus sumat coch. ij magna 4tis horis.

July 17. He was rapidly sinking; the skin cold and covered with a clammy sweat; the tongue black; the teeth covered with sordes; pulse very feeble, almost imperceptible, very rapid. He died very tranquilly on the same day.

Post-Mortem Examination, Nineteen Hours after Death. Weather warm, but not sultry or oppressive. Present: Dr. Semple, Dr. Ballard, Mr. Burford Norman. The body was that of a thin, spare man; there was no particular appearance observed exteriorly in any part. The head did not appear congested; the eyes presented no unusual appearance.

Head. The scalp was natural and not congested. The skull was thin, and in many parts it was translucent. The two sides of the skull were unsymmetrical in a very marked degree, and the skull looked as if it had been subjected to lateral pressure, which had caused its walls to be compressed unequally. As an example of this want of symmetry, it was particularly observed that the part of the skull which, according to phrenologists, is placed over the organ of destructiveness, was prominent on the left side, and depressed on the right, while the right frontal region was prominent, and the left depressed. The dura mater was normal. The arachnoid membrane, covering the dura mater, was natural; that covering the brain was of rather firm consistence, but not remarkably thickened, and not stripped off with facility, but tearing with the effort. The pia mater was congested, and its small vessels were minutely injected in a ramiform manner. The veins and sinuses of the brain were prominent, but not much congested; there was a little air in some of the veins. There were no appearances of adhesion in any part of the arachnoid membrane; and there was no pus, or coagulable lymph, anywhere discernible. On removing the brain, about an ounce and a half of serum, tinged with blood, escaped into the cranial cavity. The whole of the brain, viewed generally, presented an injected appearance, but no part was especially so more than another. The arteries and nerves were healthy. The consistence of the brain, when felt externally, was of average firmness; and, when carefully examined in all directions by dissection, it was found to be of perfectly natural consistence throughout. There were some bloody points dispersed among the white matter, but certainly not more than are seen in brains which are considered healthy. The ventricles contained hardly any fluid, and these and all the other cavities and organs of the brain were found to be perfectly healthy, although most carefully examined by myself and by the able anatomists who assisted me in the dissection.

Chest. The heart and lungs were perfectly healthy.

Abdomen. All the abdominal organs were perfectly healthy.

Remarks. The above case affords matter for numerous, though unsatisfactory, reflexions. A young man in the prime of life is seized, without any known cause, with violent delirium; the mild treatment which he received at first, tends only to increase his disorder; restraint becomes absolutely necessary in order to protect himself and others from the effects of his own violence; he is treated by mild antiphlogistic remedies, but in a few days he rapidly sinks and dies; and after death no morbid appearance of any importance can be detected by the most careful examination. It will not be uninstructive to pass over, *seriatim*, some of the leading features of this very painful case.

Causes. No cause can be assigned for this attack, except hereditary predisposition. It appears that the father had been distinctly insane upon

at least two occasions, and that he had actually been under treatment at one period for a wound in the throat, inflicted on himself while labouring under suicidal mania. It also appears that the father was insane at the time when the subject of the present case was conceived; a circumstance, if it be true, which forms an important and curious fact in the pathogeny of insanity. The only indications of derangement of intellect in Henry Staples were some traces of sulkiness and moroseness in early life; but it appears that he was well educated, did not indulge his appetites or passions, and felt a presentiment of the mental disease which was to overwhelm him.

Symptoms. The symptoms were clearly those of acute suicidal mania, and he sought to gratify his propensity for self-destruction by any means in his power. It also appeared that he laboured under subacute cerebritis, from the great heat of the head, the hot dry skin, the thirst, and rapid pulse.

Diagnosis. From *ordinary mania*, the case was distinguished by the decided symptoms of inflammatory and febrile action. From *acute phrenitis* it was distinguished by the pulse being rapid and rather full, not hard and strong; by the absence of previous vomiting and other preliminary indications; by the absence of the staring blood-shot appearance of the eyes, and of intolerance of light, which denote the sthenic form of cerebral inflammation. From *meningitis* (although the symptoms of this disease are obscure and uncertain) it was pretty well distinguished by the absence of vomiting, of irregular outline of the pupillary aperture, of strabismus, of convulsions, and of coma; many or most of which symptoms usually accompany inflammation of the cerebral membranes, and the effusion consequent upon that disease. From *delirium tremens*, to which it bore some resemblance, it was very clearly discriminated by the previous history of the case; by the character of the delirium, which in delirium tremens is busy, rambling, and talkative, but in the present case was furious, violent, mischievous, and destructive; by the state of the head and skin, which in delirium tremens are cool and remarkably moist, but in the present case were uniformly hot and dry; and by the state of the tongue, which in delirium tremens is covered with a creamy moisture, but in the present case was dry and furred.

Treatment. The treatment was entirely founded upon the above diagnosis; the absence of symptoms denoting the sthenic form of encephalitis contraindicated the adoption of copious bleedings; while the hot and dry skin, and the dry and furred tongue, precluded the use of any form of opium. A middle course was therefore pursued; eight leeches were applied to the temples in order to moderate the inflammatory action which existed; a small quantity of calomel, amounting altogether to a scruple, given in divided doses, was administered; and the bowels were kept open by simple purgatives; and, after the antiphlogistic plan had been adopted to this extent, a blister was applied and kept open in the nape of the neck. Only very light diet was allowed, and the principal drink was water.

Morbid Anatomy. The pathology of this affection is exceedingly obscure; and, although it is allowable to suppose that vascular congestion may have existed during life, but had disappeared at or after death, yet it is quite certain that no traces of inflammatory disease, or

of any other morbid action, could be anywhere discovered. I do not pretend to assert that, in cases like the present, morbid appearances do not exist, but I am sure (and I write from a rather extensive experience) that in many instances it is very difficult to find them; and it is perhaps reserved for another age, and for more accurate and refined methods of investigation, to determine the nature of those subtle changes in the structure of the human brain, which derange the operations of the intellect, and temporarily or permanently deprive man of the godlike faculty of reason.

8, Torrington Square, August 1851.

OBSERVATIONS ON THE PATHOLOGY AND TREATMENT OF PAIN, ESPECIALLY IN FIBROUS AND FIBRO-SEROUS TEXTURES.

By JAMES KILGOUR, M.D.

The three following cases may prove interesting, from the analogy which existed between certain of the symptoms common to each; and more particularly from the circumstance, that pain was a prominent feature in all of them. They are arranged in chronological order.

Case 1. Charles George, a young man, aged 26, tall, and rather muscular in form, whose occupation was that of a farm-labourer, was first seen by me on the 17th January, 1849. At that time he presented the appearance of a person labouring under organic disease; his aspect was sallow, his figure bowed, his walk feeble, and the least exertion produced breathlessness and exhaustion. He stated that he had been ill since the preceding June; that his medical attendant had treated him for fever; and that, for a short time, his urine had been bloody. These were the only antecedent facts, connected with the history of the case, which I could rely upon as authentic.

He then complained of severe palpitation and breathlessness upon exertion, or upon attempting to lie down; taking food also aggravated these feelings, and caused a sense of fulness and distension. His pulse beat, upon the average, 115 in the minute; it was not irregular in any way, but extremely excitable. There was no heat of skin; but the urine was reported to be occasionally turbid; there was some thirst, and the tongue was white and slightly furred; the bowels were rather confined. There was no swelling of the extremities, nor œdema anywhere. A very careful examination of the chest, which was well shaped, revealed nothing unusual, except that the situation of the apex of the heart was rather more to the right than common. Pressure at the epigastrium caused uneasiness, but not pain at this time.

The treatment was generally calmative, and at the same time directed towards the relief of the dyspeptic symptoms. During its continuance, he passed a large round worm, and gradually improved so far as to be capable of some exertion, and of lying down in bed. He was discharged on the 19th of February, with a hope upon my part, and a belief upon his own, that he was upon the highway to recovery. These expectations were not destined, however, to be at once realised.

During the summer, his symptoms returned; and he again applied to me, on the 2nd August, in a worse condition than I had yet seen him. All his former ailments had returned upon him with increased force; and, in addition to them, he now complained of a fixed pain, felt most under the margin of the left ribs, and towards the back, ascending the spine; also of an occasional pain of a stabbing character, which seemed to pass from the situation of the apex of the heart towards the spine, and produced much distress and alarm. There was great tenderness upon pressure at the epigastrium, extending upwards, and towards the left; there was also considerable epigastric pulsation, but no great tenseness of the recti muscles. The pulse, as before, was regular; but the heart's apex beat still more to the right than formerly, and could now be felt most distinctly nearly midway between the nipple and the left edge of the sternum, and upon the lower, instead of the upper, border of the sixth rib. The cause of this displacement was mysterious, not being affirmed by any physical sign, though repeated examinations were carefully made, with a view to its discovery. The patient also complained of being occasionally "caught" (as he expressed it) on the left side of his neck, so as to be unable to move it while the spasm lasted. Digestion was painfully performed, with much tympanitic distension of the stomach and acid eructation, and a pinching pain in the abdomen was sometimes experienced. The urine was at this time examined, and found of sp. gr. 1·009, colour pale, odour fetid, and reaction alkaline.

Leeching and other modes of medication were attempted, but without relief; and, after a short trial of these remedies, dispairing of any advantage from medical advice, the patient gave himself over, on the 20th August, to the care of nature, and, as it turned out, his *vis medicatrix* proved sufficient for the emergency. About two months subsequent to this date, I was much surprised to meet the patient in the street, walking nearly erect, and wonderfully improved in appearance. He informed me that, shortly after he had left my care, he was alarmed by coughing up a quantity of yellow matter tinged with blood. This produced, for the moment, alarming faintness, but was at the same time accompanied by great relief to the pain and palpitation. He also said that, every day since then, he had been in the habit of coughing up a certain portion of the same matter, but that latterly it had diminished in quantity, and had become thinner and nearly colourless. I requested him to call upon me, with a view to the examination of his chest, but he did not comply with my wishes.

Remarks. In the matter coughed up, we have the elucidation of a case which lasted for fourteen months, and baffled the penetration and perseverance of many medical observers. An internal inflammation, whose activity had many varying degrees of intensity at different times, and which ultimately terminated in abscess, had given rise to a majority of the various symptoms which had distressed the patient, and puzzled the physician.

It only now remains to discuss the probable situation of the tumour. In doing so, a reference must be made to the symptoms, both individually and collectively. The symptom which, by itself, is perhaps of the most importance to our present object, is the altered position of the heart; a change, which, in the circumstances, must have occurred

from mechanical causes, and which affords proof positive that a part, at least, of the disease lay within the thorax. Next, we have the pain, the most prominent feature of the malady, and which, from its seat and course, must have resided chiefly in the vagus and phrenic nerves, and also, by implication, in the accessory, as was proved by the spasm of the left sterno-mastoid muscle. Then we have the palpitation and breathlessness; the latter of which symptoms was probably caused by the disordered function of the vagus; while the former was most likely due in part to the mechanical violence done to the heart, as well as to its direct participation in the inflammatory process through the pericardium. Last, among the more important signs, we have the tympanitic distension of the stomach, and the excess of acid generated there; both being conditions which are often induced by pressure, though they may certainly arise from other causes. The abscess must have occupied a position partly, if not wholly, within the thorax; and there is a probability, from the existence of the last-mentioned symptom, that it exercised some degree of pressure upon the stomach. We may therefore conclude, with some confidence, that the septum between the thorax and abdomen was probably the seat of this inflammation and abscess; and we are the rather led to this conjecture, from the knowledge that certain parts of the diaphragm are liable to such accidents, though the pus more generally seeks an outlet at the epigastrium or umbilicus, than upwards into the cavity of the chest. Anatomical reasons also favour this view, which explains at once the affection of the heart, the stomach, and the lungs, all of which were more involved by sympathy than by direct participation in the morbid process. Should we speculate upon the cause of the primary inflammation, it would be proper to recal the incident of the passage of the worm and the bloody urine, and to mention that two or three instances are on record, of worms having made their way outwards through some of the hollow viscera, and of having excited inflammation and suppuration in their progress. Without denying the possibility of such an origin for the case in point, I am rather disinclined to allow the claims of the worm, which should otherwise have appeared in person to support them. As regards the alkalinity of the urine mentioned above, it is perhaps worthy of mention, that Dr. Beneke, of the German Hospital at Dalston, has found the urine to contain an undue proportion of phosphates in many cases of emaciation, and when pus has been formed after acute inflammation.

Case II. Jane Bufton, a widow, aged 58, was seen for the first time on the 16th January, 1850. At this period, she had been ill for four months, and had been treated for fever, upon a strict antiphlogistic plan. In person she was stout and well formed, but her countenance was sallow, and expressive of anxiety, and she stooped forward, not from weakness, but with a view to relief from pain. She stated that her complaint had begun with cough and spitting; and that at first she had little pain, which then bore the character of a stitch, and was principally confined to the left side. Subsequently, however, it became altered in situation, and took the nature of a dead aching, and finally of a tearing pain, occurring in paroxysms, which prevented her from lying down in bed. This was pretty much the state of matters

when I saw her. She represented the pain at that time as agonising, and as totally preventing continued sleep; it extended from the apex of the heart backwards to the spine, and upwards to the neck, also along the left arm, and occasionally invaded the lower extremity of the same side. A paroxysm was easily induced by cold air, mental emotion, or any cause of sudden hurry to the circulation. The pulse was full and regular, and beat 72 in the minute; palpitation was not complained of; nor was pain excited by pressure at the epigastrium. There was some cough, accompanied by a tough mucous expectoration. The appetite was indifferent, the bowels regular, and the tongue white. A careful examination of the chest, by percussion and auscultation, discovered nothing but an apparently sound condition of the heart, lungs, and their investing membranes. A great amelioration was temporarily effected in this case by the use of iron, in combination with narcotics and antispasmodics. But this improvement seemed to be only the prelude to an attack of greater severity, which occurred in the beginning of April, during the course of which the pulse rose to 90; there was pain upon pressure at the epigastrium; and there was also difficulty and pain in deglutition. A large number of leeches were applied over the cardiac region with very great relief; and, in the report of the 18th April, upon which day I ceased my attendance, it is stated that she was not free from pain, particularly at night, but could lie down; that she slept pretty well; and that her general condition was much improved. As I have not been applied to since that date, it is probable that this patient has continued pretty well up to this time.

Remarks. In this case, from the nature of the early treatment, we may presume the pain to have been of an inflammatory kind at first, as it certainly was during the last attack. But, during its middle period, this did not seem to be the case, whether we look at the symptoms or at the result of treatment. Upon what, then, did the pain depend at that time? Are we to suppose that the impression made on the nerves of the affected part, during the first inflammation, had so altered their structure, or impaired their function, as to render them incapable of conveying healthy sensations, as is sometimes the case after injuries from external violence, when the parts have apparently returned to their normal condition, but when pain is still felt in their nerves? or are we to fancy that a smouldering inflammation lurked in some of the tissues, and supplied the source of irritation? Either opinion might be maintained by argument, and would certainly afford the ground for an interesting inquiry; which, however, I must decline at present, reserving a few remarks upon pain for the end of this paper.

Case iii. Elizabeth Black, aged 48, was seen on the 17th July, 1850. She stated that she had been ill for four months. In person she was above the middle height, spare, but well formed; her complexion was sallow, and the expression of her countenance was anxious. She complained of a fixed pain of great severity, passing from the apex of the heart backwards to the spine and between the shoulders, the same being aggravated by a long breath, or by taking food into the stomach. Exertion produced breathlessness and palpitation, and there was slight cough. The pulse was 84, full and rather hard, but quite regular.

Upon examining the chest, the ribs in front of the heart were found to project a little, and the left ventricle to be somewhat hypertrophied; in other respects, the heart was normal. The lungs and pleura gave no evidence of being otherwise than natural, except at a point below the heart's apex, and a little to its left, where some resonance of voice was heard, with sibilant and creaking rhonchi at the end of expiration. Percussion, however, failed to elicit any appreciable dulness at this spot. Venesection to twelve ounces was performed with remarkable relief to the pain, which from this time occupied no prominent place among the symptoms, and was only complained of when a deep inspiration was made. A slight cough, with mucous expectoration, remained, but the resonance entirely disappeared, and the râles, which were very circumscribed, became moist instead of dry. The treatment lasted from the 17th to the 26th January, when the patient was discharged.

General Observations. The cases which I have just described, or cases analogous to them in respect of their principal symptoms, might easily have been multiplied, had it been necessary to adduce additional testimony, to prove that the seat of pain complained of in these instances is a very common one. Abernethy used to demonstrate to his dyspeptic patients, in a manner not less unpleasant than convincing, that they could not bear pressure at the epigastrium; for the frequency of pain or tenderness in this situation had not escaped the notice of that acute and experienced observer. The fact that pain does occur here so frequently, is perhaps not to be wondered at, when we reflect that, wherever the terminal distribution of nerves occurs, there we find great sensibility. This has been remarked by M. Valleix, in his treatise upon neuralgic affections; and seems to be an arrangement by which an alarm of danger may be at once communicated to the system, and the more important organs protected from its action. But nature in this, as in all her plans, has aimed rather at the accomplishment of one paramount object, than at complete perfection in all; and we can therefore easily see, that in sensibility we possess a guardian of such vigilant excitability, that, once aroused, it is often difficult, and in some cases impossible, to stifle its warning voice. It is noticeable, that in the first of the three cases recorded, the pain was certainly, and in the other two presumably, of inflammatory origin; and that the tissue principally affected was the same in each—the fibrous. Upon these points some speculative remarks may be hazarded: first, as to the modes in which nerves are primarily affected with pain; and secondly, as to the coincidence of some painful affections occurring in connexion with fibrous tissue.

Modes in which the Nerves are primarily affected with Pain. From this inquiry must be excluded the cases of pain arising from external injury, or from reflex action; because it would be premature, with our present knowledge of the action of the nerves, to attempt any explanation of their altered function during the occurrence of pain. We must therefore limit the field of our conjecture; and, with a view to practical ends, inquire how healthy nerves may take on abnormal action. For one class of cases it may suffice to say, in the mean time, that the nerves supplying tissues, in which an unhealthy process is

going on, become involved in that action; and we are prepared to expect that, in such circumstances, some change of function may occur. But, in some instances, nerves become painfully affected by certain influences not inducing appreciable structural change; and the question is, whether in these cases such influences act for the first time otherwise than in the way of inducing inflammation. By way of example, moisture and cold produce tic; but is not the first attack of that complaint always of an inflammatory nature, when the nerve was healthy prior to its exposure to the exciting cause? Again, a *materies morbi* in the blood may stand in the place of cold and moisture; and what is the result? An attack of acute rheumatism in the first instance; and, most likely, a succession of chronic attacks for the future. If this reasoning be correct, it follows that healthy structures are incapable of morbid action, which is not the general belief as to nerves. A practical deduction would also follow, that the treatment in such cases should be, to use an old-fashioned term, antiphlogistic. Pain would thus come to be considered the expression of an altered structure, rather than of an altered function; and, if we argue from the analogy of known causes of pain, such as pressure, we may presume that some obstruction to the progress of the legitimate influence of the affected nerves exists, which obstacle we can hardly imagine unconnected with a physical change. From the same premises it would follow that, in reflex pain, the nerve affected must be itself healthy; otherwise, how could it convey correctly even a wrong impression? The singularity in these cases is the point at which the morbid sensation becomes developed, and which, though not yet reduced under a fixed law, is perhaps to be explained by the general remark of M. Valleix, above alluded to, respecting the sensibility of nerves towards their extremities.

We have now to apply these observations to the cases described, and to others analogous to them, where pain at the præcordial region is a prominent symptom. We have seen that it is not excited in healthy nerves, except by mechanical means, or by some change occurring in the surrounding tissues, or by special influences producing inflammatory action; and therefore, in the absence of the first and the last of these cases, we have only to inquire, what is the tissue affected? to which the nature of the pain often affords an answer. We are then to presume, that some change is going on in one or more of the organs which adjoin the seat of the pain. We are not to believe that a functional derangement of their nerves exists, at least if the case be at all recent; but, proceeding upon the first supposition, we must endeavour to discover the kind of change which is being effected, more particularly if it be of an inflammatory nature. If this point be made out, it is of little practical import, in the outset of the treatment, whether the mischief is caused by the liver or by the stomach, or whether it is due to neither. The former organ has much to answer for in the way of exciting diaphragmatic and even pericardial inflammation; though it would seem, from some late researches of Dr. John Taylor, that a faulty condition of the kidney is even more productive of pericarditis than rheumatism itself. When, then, the great depurating organs are at fault, certain tissues become affected; this brings us to the second subject of speculation.

Connexion of certain tissues with some painful disorders. The fibrous, fibro-serous, or fibro-cellular tissues seem peculiarly obnoxious to the evil influences of bad blood and bad climate. And, as if evil communications corrupt good manners in this as in other cases, these membranes involve the neighbouring nerves in the same disturbance, the consequence of which is, that their affections are very painful, often tedious, and generally liable to recur. For it seems to be a law of nervous matter, that, if once impressed with any peculiar action, it manifests a tendency to maintain the same. This, perhaps, is only a consequence of that property in such matter to resist change, by which our characters, aptitudes, and repugnances, remain the same from the moment of their full development until their extinction.

Accepting as a fact that fibrous, fibro-serous, and fibro-cellular tissues are extremely susceptible of anormal nutrition in some shape, we may recal to mind certain neuralgic phenomena, which perhaps may be independent of any source beyond the nerve affected, but which nevertheless deserve notice, on account of their propinquity to these structures. Of this kind are sciatica, lumbago, tic, pleurodynia, certain forms of headache, of rheumatism, of gout, and also some painful affections of the abdomen occurring in the course of Bright's disease, and sometimes terminating in ascites. These complaints, for the most part, own a humoral or an atmospheric origin, or one depending upon the joint influence of both; and, as their causes are known to affect fibrous tissues in preference to any other, it is only natural to presume some connexion between them and the nerves to which the mischief is referred. I often used to reflect upon the singularity of the fact, that, in facial neuralgia, the nerve did not become affected until its emergence from its bony tunnel; but this view of the case clears up that difficulty, and is wonderfully confirmed by the kind of treatment which is found most useful in such disorders, consisting of those remedies which tend to improve the condition of the blood, with other means directed to the same end.

Of the reason why these tissues should be affected under such influences, I can offer no explanation, unless we accept as such what has been often advanced before—that a lesser vital organization possesses a smaller power of resistance. Some peculiarity connected with the circulation of these parts may, as in the case of articular cartilages, perhaps enable us to make an advance towards discovery; but, in the meantime, we must rest satisfied with the fact, or with the sequence of facts, as we know them. A knowledge of them affords us a valuable means of diagnosis and aid to treatment, besides forming the starting ground for the philosophy of the question. Of course there is a great difference in the sensibility to pain in various individuals. Hunter says that animals with fair skin and hair are more susceptible of cold, as also of pain, than the dark. This is well known in the army, where we find that the power of bearing violence committed on the body is in proportion to the darkness of the individual. The late Sir Robert Peel was a striking instance of this peculiarity; and the truth of Hunter's remark is further borne out by the fact, that many fair and scrofulous individuals have great quickness of feeling and mental susceptibility. The structure of the nervous system must thus have a strong influence in determining the character of the individual,

which at one time was judged of from the form of the head alone, as indeed it very generally is at this day. The variety of the kinds of pain which may be excited in the same nerves is also curious, yet not more so than the numerous and contrary sensations which we experience through the same medium in a state of health, and by which we are enabled to characterise the properties of bodies, and to experience a gratification of many descriptions and degrees.

In this apparent complexity of function enjoyed by the cerebro-spinal nerves, does the sympathetic or its branches take any part? Dr. Seller, of the Royal Infirmary of Edinburgh, attributes to the branches of this nerve the pain experienced in headache; and Professor Hughes Bennett states that through them the pain of colic, gall stones, etc., is experienced; and it is certain that mental emotion influences powerfully their organic action. But, after all, the question at present has no great pathological interest; for should we, by an unheard-of accuracy in diagnosis, attain to a knowledge of the particular fibres involved in a case of neuralgia, we have no treatment wherewith to follow up such a transcendental discovery. It is time, also, that this vagrant discussion should terminate, though the subject and its collateral topics are well nigh inexhaustible. Yet one more remark is necessary as bearing upon the general conclusion; which is, that in very many cases, when the nervous matter is alone involved, no pain is felt, the only visible result being a cessation or modification of its action; and yet intense pain may be excited in a nerve by its being put upon the stretch, as by a spiculum of bone, or by a tumour. In these cases, to be sure, the pain is usually very intermittent; yet all pain is more or less so, for it is not conceivable that a nerve should have the power of maintaining a continuous action for an unlimited period.

The following are the inferences at which I arrive.

I. Setting aside mechanical agency of all kinds and reflex action, pain is incurred in healthy nerves by their participating or becoming involved in abnormal processes occurring in the tissues to which they are distributed, by which, if the process be long continued or intense, some change takes place, rendering them liable to be affected with pain upon the recurrence of a small amount of the original exciting cause, and without the concurrents which accompanied their first seizure.

II. It is doubtful whether the nerve alone suffers in such secondary or succeeding attacks, or whether the surrounding tissues are likewise affected.

III. Such incidents are most frequent when the structures concerned partake of the nature of fibrous tissue.

IV. Loss of tone, or diminished power of resistance, in the parts invaded, is frequently permanent.

V. This atony is most frequently local in its origin and extent.

VI. In such instances, it may arise from change of structure, inappreciable to our means of observation.

VII. If these premises are correct, it follows that, when pain occurs in the situations referred to, and lasts for any time, the treatment should be directed to favour the subsidence of the morbid action, as well as to neutralise the exciting cause; and that, for the first indication, the abstraction of blood is probably the most effective means.

VIII. When the tissues have lost their powers of reaction, and yield at once to a depressing influence, a tonic and alterative or depurating plan of treatment is to be followed.

IX. The vigour of the treatment is generally to be proportionate to the importance of the parts or organs concerned, and to the strength of the constitution.

Here it is assumed that pain is a certain index of abnormal nutrition on the one hand, and of altered function or structure upon the other; and, as the second condition is caused by the first, we must infer that if the first be warded off or mitigated, its consequences will not follow, or only in a minor degree; and if pain be the certain index of inflammatory action in such cases, and it be proved by experience that blood-letting, local or general, has the power of assuaging that pain, we can only suppose, at least in cases where tumefaction has not occurred, that it so acts by allaying the abnormal action.

The conclusions drawn from this short train of reasoning are opposed by a remarkable statement of Dr. Dietl of Vienna, as to the efficacy of blood-letting in pneumonia, which was noticed in the *Edinburgh Monthly Journal* for January 1851, and which is to the effect that, while 85 cases treated by bleeding alone gave a mortality of 20·4 per cent., 106 by powerful doses of tartar emetic alone 20·7 per cent., 189, treated by dietetic means only, gave the diminished per-centage of 7·4. Whether this statement be free from error or from fallacy, I am not enabled to declare; but the results are curious, and appear to be in contradiction to nature itself, which seeks relief in this disease by the effusion of blood, sometimes occurring very copiously, and seldom without apparent advantage. In other complaints, the same mode of relief occurs naturally; and if the healing art is to be founded upon an observance of the laws and operations of nature, we have certainly the sanction of the highest authority for continuing the practice of blood-letting, Dr Dietl's tables to the contrary notwithstanding. If the preceding remarks be correct, it must be of the utmost consequence to preserve the nerves of the inflamed part from permanent injury; and this consideration alone, were the relief to present suffering of no account, should preserve every honest pathologist from the venal paths of a do-nothing quackery.

Halifax, July 15th, 1851.

BIBLIOGRAPHICAL RECORD

1. Letters on the Laws of Man's Nature and Development. By Henry George Atkinson, F.G.S., and Harriet Martineau. 8vo., pp. 390. London: 1851.
2. Miss Martineau and her Master. By J. Stevenson Bushnan, M.D., Physician to the Metropolitan Free Hospital. 8vo., pp. 173. London: 1851.
3. Letters to a Candid Inquirer on Animal Magnetism. By William Gregory, M.D., F.R.S.E. 8vo., pp. 528. London: 1851.
4. The Mesmeric Mania of 1851. By John Hughes Bennett, M.D., F.R.S.E., Professor of the Theory of Physic and of Clinical Medicine in the University of Edinburgh. pp. 21. Edinburgh: 1851.
5. What is Mesmerism? an Attempt to explain its Phenomena on the admitted principles of Physiological and Psychical Science. By Alexander Wood, M.D., Fellow and Member of Council of the Royal College of Physicians of Edinburgh. pp. 31. Edinburgh: 1851.

Mr. Atkinson, at the commencement of his work, cites, among other mottoes, the observation of Sir Humphrey Davy, "that the physical inquirer is seldom disposed to assert confidently on any abstruse subjects belonging to the order of natural things, and still less so on those relating to the more mysterious relations of moral events, and intellectual natures". We wish Mr. Atkinson had laid this pithy sentence rather more to heart; for more confident assertions on abstruse subjects it was never our fortune to read. We look in vain in his lucubrations for the caution and reserve so wisely inculcated by his great authority; and we lay down his book with the conviction, that he has no real knowledge of the state of mind which he praises in Sir Humphrey Davy. It is evident that the mind must have a certain grandeur and amplitude before it can perceive its own littleness, and that the mental sight must go forth out of darkness, before it can be dazzled with the light of day. Confidence in its own decisions, and in its own strength, belongs to the youth of nations and to the infancy of mind; but modesty and hesitation surround those, whose more matured intelligence has recognised the narrow boundaries of human thought.

Mr. Atkinson has no such hesitation and reserve; he passes before him the tremendous problems of existence and futurity, and, without fear, assigns to them their solutions. A mere point of earth, the veriest drop in the ocean, he cries aloud that his sight can embrace the universe, and penetrate the wonders of the watery expanse. Unable to see the vivid light before which the prophet veiled his face, he creates his idol, though the truth is on every side of him, as the Israelites made their golden calf, even while the glory of the Godhead overshadowed the Mount.

We owe this joint publication of Mr. Atkinson and Miss Martineau to the circumstance that two minds, similarly and singularly constituted, have come into contact. The mind of the lady, indeed, seems to have been subjugated by the stronger volition of her masculine coadjutor; but it would have been impossible that this should have been so thoroughly effected, had not the path been made easy by the original conformity between them in point of reasoning power, and in the marked deficiencies of their mental constitutions. Dr. Bushnan has pointed out with great force the nature of this defect. Mr. Atkinson seems to have no perception of that great class of intuitive truths, which the Scotch metaphysicians, in opposition to Locke and Hume, have in the latest time so well examined, which form the basis of the philosophy of Kant, which are discussed with wonderful precision in the pages of Cousin, but which are to be found also in what remains to us of the

wisdom of Socrates, and of the vast speculations of Plato. There is little doubt, but that this highest power of the mind, by which alone we are definitely separated from brutes, is more developed in some minds than others, and, taking the aggregate, in some nations than others. The Germans and the Scotch possess it more than either the English or the French, and it is probable, that the Greeks were more largely endowed with it than the Romans, and the Jews than any nation of the earth. Among these "necessary truths" is included the idea of "cause", as distinct altogether from the phenomena with which it may be involved. Phenomena, it is true, may first give us the idea of cause, and are, as Cousin expresses it, its chronological antecedents; but, once seized by the mind, the idea of cause becomes detached altogether from its antecedents, and is perceived to be an independent and necessary truth. Two phenomena succeeding each other may give the idea of cause; but, once given, the mind abstracts it from the narrow origin from which, as far as our minds are concerned, it sprang, and it becomes illimitable and boundless. Of such an abstraction as this, Mr. Atkinson seems perfectly unconscious; he never separates causation from the idea of causal connexion between phenomena, and it is indeed probable that he cannot rise higher than the limited, and therefore erroneous, dogma of Brown, that causation is nothing more than invariable antecedence. Besides this inherent mental defect, Mr. Atkinson unfortunately presents another, which obviously arises from defective training, viz., a deficiency of logical power. This is evident in almost every page, and is so marked, that Dr. Bushnan has often controverted his positions, by logical induction from his own premises. With this untrained reasoning faculty, Mr. Atkinson has attempted to work out problems for himself, and it is clear that his knowledge of what the reasoning powers of other men have taught us of these problems is very limited. Hence, on an original want of learning and of information, he has brought to bear a defective instrument, and the result has been a strange mixture of the commonplace and the erroneous.

We wish we could stop here, and charge Mr. Atkinson only with intellectual defects. But, we are afraid, sins yet more heinous must be imputed to him. We will give him full credit for being sincere and honest in his belief of the marvels of clairvoyance and prevision, but we deny that he has truthfully treated the subjects he proposed to himself, or rather, which Miss Martineau proposed to him. Everything which might tell against him has been avoided, to an extent which warrants us in calling it a *suppressio veri*. His treatment of Lord Bacon is an example of this. He has culled carefully from the writings of Bacon the expressions which support his views, while other passages are as carefully excluded. In this manner he ingeniously represents himself as a sort of commentator on Bacon, and represents as an unbeliever and an atheist, professing a sham religion, in deference to the ignorance and prejudices of his contemporaries, the man who has written, that he would "rather believe all the fables of the Talmud, than that this universal frame is without a mind"—the man who prayed that "from the unlocking of the gates of sense, and the kindling of greater natural light, nothing of incredulity or intellectual night might arise in our minds towards divine mysteries".

We may then assert that, from original defect of mind, from want of education, and, perhaps, even from want of moral integrity, Mr. Atkinson is the last person whose opinions on *Man's Nature and Development* we should be disposed to adopt.

Let us, however, pass to the book itself. We object to it strongly on several grounds. We might take exception to it as a mesmeric performance, and examine into the wonders so unhesitatingly asserted. Or we might condemn its tone, and the manner in which it speaks of things sacred and dear to most men, and which on this ground, if on no other, are entitled to tender and respectful treatment. But of far more consequence is it to us, to exa-

mine the conclusions arrived at in it, concerning matters of aith and usual credence. Dr. Bushnan has adopted the same view, and, in his most able analysis of Mr. Atkinson's doctrines, has passed over with little notice the mesmeric absurdities, and the offensive manner, to fix his attention on the scientific, or rather, the pseudo-scientific dogmas, proclaimed in the work. It is, however, no easy matter to collect Mr. Atkinson's opinions; they are enunciated often enough it is true, but so obscurely, and with so little method, that it requires care to understand them thoroughly. But the following summary of them is, we believe, quite correct. Mr. Atkinson believes—

"That the matter which exists in space has had no beginning, and is to have no end; that it exists from eternity to eternity; that the arrangements of the universe, in all their gigantic extent, are the result of the laws of nature; that there is no design, and no chance in the order of things; that plants and animals at particular epochs arise spontaneously, and continue for a time to exhibit the phenomena peculiar to the organised departments of nature, in obedience to certain fixed laws of matter; that mind is the action of the brain; that there is no God, no hereafter for man, no liberty of action, no sin, no responsibility; that phrenology and mesmerism afford the means by which one man may study the phenomena of another's mind as a part of nature; that distance does not prevent one man from seeing what passes in another's mind; that there is ground of hope for the improvement of the moral world in the fear inspired by mesmerism; that the inmost thoughts of any individual may be at any time subjected to the scrutiny of another; lastly, that the foretelling future events is a power which exists in nature." (*Bushnan*, p. 15.)

Mr. Atkinson's opinions being thus reduced to an intelligible form, it is at once evident, that the dogma about the eternity of matter is simply the old atheistical and material assumption, which we really hoped had disappeared for ever. It is a complete assumption, to assert that matter can never have been created, and can never be annihilated. That matter is eternal, is not a necessary and intuitive truth, and not being so, no logic can ever prove it. On the other hand, it is an intuitive truth, that, in the idea of causality, the mind sees force and power, which is independent of matter, and, though first suggested by it, is not necessarily connected with it; and it can be easily observed by any one, that this idea of force and power is an ultimate one, mysterious and obscure, as no doubt it must be to a being of finite intelligence, but still one in which the mind rests complacently, and seeks no farther; whereas, when any one speaks of matter, the mind, in virtue of its own inherent necessity, seeks beyond the matter for the force which called it into being, and which maintains it in action. It is the same necessity which led the philosopher of old to question the materialist dogma of his time with the demand,—"and Chaos, whence?" When any one speaks of the eternity of matter, the reason of each person penetrates deeper still, and asks—"but matter, whence?" It is sufficient answer to Mr. Atkinson's fundamental position that matter is eternal, to reply that such an assumption is unsatisfactory to every educated mind. Dr. Bushnan sums up his argument on this head in these eloquent terms.

"If matter be eternal, there can be no God; there is, there cannot be any existence, whether intelligent or non-intelligent, not subject to the properties and laws of matter. If matter be eternal, everything which happens, and everything which is produced, must be the result of necessity,—that is, the consequence of the operation of the original laws and properties of matter. And therefore, if matter be eternal, everything must arise out of what is strictly called chance—that is, by the sole operation of such properties and laws of matter as the circumstances of each particular case bring into play. It seems possible, that there may be individual minds so anomalously constituted, as to feel no difficulty in such views. But it is certain that such is not the natural sound constitution of the mind of man. For, if

matter be eternal, there cannot be any power in the universe ; everything which exists, and everything which occurs, must originate in the various affections of the atoms and masses which compose the material universe. Again, if matter be eternal, there cannot be any such thing as a true cause in Nature, as everything termed a cause under this assumption, can be nothing more than the expression for the law under which any event has occurred. *And therefore, under the assumption that matter is eternal, the absurd conclusion follows, that the notion of power, and the notion of cause, in the sense in which these notions are intuitively apprehended by the mind of man, are deceptions imposed upon him by the constitution of his nature.*" (*Bushnan*, p. 164.)

We have already expressed our belief that Mr. Atkinson belongs to that class of persons, happily very small, who are deficient in the power of recognising intuitive truths. This is proved by the contentment with which he rests in the assumption of the eternity of matter; but it is still more evident in the manner in which he uses the terms *cause*, *law*, *chance*, and *design*. Mr. Atkinson's second position is, as we have seen, that the arrangements of the universe are the result of the laws of nature, that is, of the action of the properties of matter which it originally and necessarily possessed. By virtue of these properties, it is supposed that matter changes, that elements unite, that organisation declares itself, that life appears, and, finally, that reason comes to light, and is able to discover how, and in obedience to what blind forces, it has been born. Now the term "*law*", as applied to reactions of matter upon itself, is evidently simply a convenient mode of saying, that phenomena assume a particular relation to each other, which relation is determined from observation. For example, we say it is a law that bodies subjected to heat shall undergo a proportionate expansion ; which is evidently merely another mode of saying that, in our experience, bodies expand when heat is applied. But as every one of these so-called "laws" expresses nothing more than the sequence of phenomena, there is nothing about it which is necessary and inevitable. The law merely implies, that, as such phenomena have assumed so often such a relation, they will probably assume it again. And the probability that they will so assume it increases with every fresh observation, which shows that they have again so assumed it. But the highest degree of evidence in favour of the constancy of such a law, is one merely of probability; and the human mind can evidently never attain to the certainty that a certain succession of phenomena is constant, since infinity alone can know that there is no possible exception. In fact, even now, many of our so-called laws are coupled with their exceptions, as in the example above given, where it is customary to say, that the expansion of water below a certain temperature, or the contraction of clay above it, are exceptions to the law that bodies expand by heat. Consequently, if Mr. Atkinson asserts that it is a law that matter shall be always active, and must always give rise to certain effects, it can at once be affirmed that this is a mere hypothesis, and that we have no right to affirm that matter cannot be perfectly quiescent. We differ here from Dr. Bushnan in believing, that in the so-called "law of gravitation", we do no more than affirm the existence of a force which attracts bodies inversely as the squares of their distances; and although the highest generalisation has been given to this law, it is evident, that, in all other similar cases, its universality and constancy must be to us a matter of probability, never of absolute certainty.

It follows, then, that when Mr. Atkinson speaks of a necessary law, that is, of an inevitable necessity that matter shall act in a certain way, he is affirming what the reason of every one rejects; since an inability to pronounce on the universality of anything is a necessary result of the very condition of finite beings. Probability, as Butler remarks, "is the very guide of life", and our so-called "laws" are merely the expression of its greatest amount. Thus, by using the term "law", we do not in the least advance

ourselves, when we seek to solve the mysteries of creation ; but, on the contrary, we impose on ourselves a word which literally means nothing, or, according to the sense in which it is taken, implies an error.

There is no doubt that, owing to a want of precision in thought and language, many persons, in speaking of "law", are in reality referring to "cause". In using the expression that a certain series of events is governed by its own law, many persons simply express their belief that such series cannot originate of itself, but must be traced back to some cause, and that the successive changes which have preceded the effect they have before them, can be indicated with more or less probability. The idea of cause is, as we have already said, intuitively suggested in all actions of matter ; and the sequence of one phenomenon to another develops in the mind both the notion of causal connexion between them, and of absolute causation in general. And, even if it should be afterwards discovered that the phenomena in question were really not connected, still the abstract idea of causation remains. But, as it is evident that the invariable sequence of phenomena, and therefore their causal relation, cannot be absolutely proved, it follows that there never can be anything more than a greater or less probability that there is such a causal relation between them, and, consequently, in the last analysis, the only permanent idea of cause is the abstract one which can be detached altogether from phenomena.

In speaking of the "eternal and immutable laws of the universe", Mr. Atkinson has therefore either been making use of meaningless terms, or he has confounded the idea of cause with law. It is, indeed, evident that he has really been impelled beyond the point at which he had endeavoured to stop, and has admitted, behind his so-called "immutable laws", some force or power calling them into action. Thus he writes—"We know nothing fundamental of nature, nor can we conceive anything of the nature of the primary cause" (p. 7). This is quite true ; but it is no less true that we must admit that there is a primary cause, and Mr. Atkinson has done so in this very passage. Yet, as Dr. Bushnan has very clearly pointed out, if we adhere strictly to Mr. Atkinson's system, "there is no room for the term cause in any other sense than is synonymous with law".

The same obscurity and uncertainty are found in Mr. Atkinson's notions of chance and design. Mr. Atkinson says there is no chance, and therefore no design, in nature. But, as Dr. Bushnan remarks, "the equivalent of the proposition, that there is no such thing as chance, is simply, that anything which happens has a cause ; while the meaning of design is, the direction of known causes in such a manner that they shall produce a previously-conceived effect. What kind of logic is this ? Every event must have a cause, therefore causes cannot be so directed as to produce a previously conceived effect ! The proposition that nothing happens by chance, does not in the least interfere with the possibility of the conception of design". (*Bushnan*, p. 70.) In fact, there is no such thing as chance, and all that men mean by the word is, as Dr. Bushnan remarks, that a chance event is one which had not a preconceived purpose. When a man uses the common expression, that it chanced so and so, he means that, independently of his volition and purpose, or of that of other people, an event occurred which was not foreseen, because the causes producing it were not recognised by him. Dr. Bushnan's illustration is a very good one : "when a person shakes the dice-box and throws sixes, no one doubts that, if he could repeat exactly the same series of acts over and over, he would throw sixes as many times, and the event is said to occur by chance ; not because it is believed that it is not produced by a definite series of efficient causes, but because any attempt to control or direct these is abandoned as impracticable" (p. 74). When Mr. Atkinson speaks of "chance excluding laws", it is simply, and by his own showing, nonsense, as laws cannot be affected by what does not exist. And further, as chance means, if it means anything, that events occur without a preconceived purpose to

be gained by them, therefore, as Mr. Atkinson states that events never occur by chance, that is, without a preconceived purpose, he actually affirms that every event has a preconceived purpose, or, in other words, occurs from design. Instead of saying, therefore, there is no chance, and therefore no design, the proper reading of Mr. Atkinson's opinion should be, there is no chance, and therefore there must be design. But if, abandoning this ground, Mr. Atkinson's meaning be taken to be that there is no design, because causes act by necessity, and results cannot be other than they are, although they cannot be foreseen, we must again repeat our assertion, that this is an unjustifiable assumption of what cannot be proved, but which is opposed by all reasoning which men can bring to bear on it. For this doctrine of necessity can only be founded on the other dogma of the self-existence of the material world, and we have already exposed the very insufficient grounds any one can have for an assumption so monstrous.

Acting upon his hypothetical positions of the eternity of matter and the necessary action of its so-called laws, Mr. Atkinson proceeds to arrange his other articles of belief in accordance with them. As everything occurs from "necessity" (that is, some blind inherent force, which is infinitely more incomprehensible to us than the intuitive conception of an infinite and omnipotent and all-intelligent cause), there can of course be nothing like freedom of action. A concurrence of atoms makes man what he is, good or evil (as we ignorantly term it), wise or ignorant, an angel or a demon. Responsibility ceases, and, with it, rewards and punishments. What we do we do, not of ourselves, but because it was originally in the nature of things that we should perform that action and no other. This shallow doctrine, propounded over and over again by those who perplex themselves with things above them, and who yet neglect the evidence which lies close at hand, needs no refutation. Within ourselves we bear the witness to the freedom of our own will; and within ourselves, also, we too often hear the judge which tells us that we have chosen the broad path, when we should have taken the narrow one. "Man's free will", says Dr. Bushnan, "cannot be established by reasoning; it is a fact in his mental constitution. . . . . All that Mr. Atkinson can set against the universal belief of men, as to the fact of their liberty of action, is the double assumption that mind is matter, and matter eternal." (pp. 77-81.)

A curious instance of the extraordinary absence of logical power in Mr. Atkinson's mind presents itself in connexion with this subject. He has, as we have seen, denied the existence of a superintending moral ruler, of freedom of action, and, consequently, of responsibility, and right and wrong. No one could then be possibly prepared for the following discovery.

"The knowledge which mesmerism gives of the influence of body on body, and, consequently, of mind on mind, will bring about a morality we have not yet dreamed of. And who shall disguise his nature and his acts from the *clairvoyant* eye of some one who is observing our actions and most secret thoughts, so that our whole character and history may be read off at any moment? Few have the faintest idea of the influence these great truths will have upon the morals of men." (*Atkinson*, p. 280.)

How, we would ask Mr. Atkinson, can actions arising from necessity be altered by the influence of the clairvoyant eye? It is evident that liberty of action is here assumed; that a man is supposed to do one thing rather than another, because he knows that his conduct is watched. And, more than this, the existence of a moral code is fully admitted; else how would the person watched know that he ought to act in one way rather than another? Pushed to their legitimate conclusion, Mr. Atkinson's *clairvoyant* superintendence and control necessarily implies free will and conscience, and, consequently, the idea of rewards and punishments, and of a future life. Let Mr. Atkinson take his own premises, as implied in the above passage, and argue them on the model of Butler's *Analogy of Religion*, and he cannot

logically halt anywhere on the road, but must abandon materialism, necessity, and atheism.

We do not think it worth while to proceed further in this direction. Why should we, indeed, be called upon to go over this beaten ground of materialism and necessity, as if it had never been advanced, and never refuted? We do not find that Mr. Atkinson has discovered any new facts; but rather that he has put together, feebly and incoherently, what, in the hands of others, have been more cogent and forcible arguments.

We have chosen the above line of argument, first, because it deals most directly and completely with what is most dangerous in Mr. Atkinson's teaching; and, secondly, because it is the one Dr. Bushnan has followed. But it is a peculiarity in Mr. Atkinson's creed, that it can be refuted in various ways. We have adopted one way, but we might with equal ease have adopted another. We might have shewn, not the metaphysical absurdities of Mr. Atkinson's dogmas, but the utter want of harmony between them and truths for which we can advance evidence. We might insist on the phenomena of mind, and show how inconsistent these are with materialist doctrines. Or, from the recesses of our moral nature, we might have called forth facts, which cannot in any way be harmonized with non-volition and necessity. Or, passing externally, we might have arrayed against this materialist and atheist the truths clothed in the divine light of Revelation. In any case, Mr. Atkinson could have been as easily silenced as he has been by Dr. Bushnan, in the line of argument chosen by him. But it is unnecessary; nor should we have wasted even the space we have upon him, were it not that his book has been endorsed by one, whose name, unhappily, may prevent it from being utterly still-born.

We do not think it worth while to follow Mr. Atkinson into the mesmeric portion of his book; but we cannot resist giving the following excellent exposure, by Dr. Bushnan, of the inconceivable inconsistencies and absurdities which pervade this portion of it. Mr. Atkinson holds, as we need scarcely say, that there is no such thing as mind; that what we call mind, is a manifestation of the properties of matter. As we write these lines, we do so, according to Mr. Atkinson, because a certain chemical change in the brain gives us certain ideas, and a certain volition (if we can use the term) to express them; and this chemical change is produced inevitably and necessarily from the action of the laws of matter. But Mr. Atkinson believes that there are persons, in the mesmeric state or not, who can foretell future events. Therefore, as future events will be the results of certain future material changes, without which they could not occur; and as the act of thought in the brain of the person prophesying arises from *present* physical changes in his brain, if any one can foretell *future* events, it can only be by the same changes occurring in his brain which are hereafter to occur in the matter, by the changes of which are to be produced the results foretold. That is to say, A, foretelling an action of B's (which action is to be produced by a change in B's brain), must undergo at the time the same series of changes which B is to undergo at some future time, and these changes must occur in the same matter. But, as the matter producing the action of B, exists only in B, it is impossible that A, not being possessed of B's matter, can foresee the changes which are to occur in B, by the action of the matter proper to B. In other words, if A can foretell a future mental act of B, A must possess B's brain, and set it to work before it works for B himself. The whole thing is reduced to an absurdity; and nothing can more strikingly show Mr. Atkinson's deficiency of reasoning power, than the fact that he did not foresee the inevitable collision between his materialism and his mesmerism. But let us hear Dr. Bushnan on this point, for he exposes the nonsense of the thing most clearly.

"Mr. Atkinson says, that men can predict future events independently of mesmerism; that some men, in their ordinary state of life, can predict future events. What does this amount to? How does this admission accord with

his dogma that there is nothing in the universe, that there is nothing in the inorganic or organic world, but matter worked into its several forms, in accordance with the laws of physics and chemistry? According to his dogma, life is nothing but organism, and organism is nothing but the dust of the earth, which, under the operation of physical conditions—that is, under the operation of physical conditions of so rare concurrence, that in the present system of things, that concurrence seems to have taken place but once for each species of animals—has assorted itself in the nice proportions required for the peculiar structures of the existing animal kingdom. Mr. Atkinson does not perceive any difficulty in the supposition, that the thinking organism of man's brain should be produced by the mere affinities of the elementary substances which enter into its composition, and that the operation of external impressions made upon it, through the nerves, should determine it to various processes of thought, desire, emotion, and action on things without, through the muscular system. All these, according to him, are so many chemical changes, wrought on the elementary particles composing the brain by physical influences extending to it from without; and we so far agree with him, as to believe that a chemical change does occur in some part of the brain, as often as any such exertion of its function takes place. But when he says that the chemical change, which has just occurred in one man's brain, can be sympathised with in another man's brain, at a distance, even in an opposite quarter of the globe; or that such a chemical change in the brain of one individual, shall prefigure, in an intelligible form, the result of nice chemical changes which are to take place, during months or years, in the brains of thousands of individuals, bound neither to it nor to each other, by any tie acknowledged in the laws of chemistry; then we affirm that his conclusion holds nothing in common with his premises. Mr. Atkinson cites the fulfilment of various predictions, for the purpose of showing, according to our interpretation of his views, that the chemical action of the brain, in one individual, can intelligibly represent the results of the nicest and most complex kinds of chemical action in the brains of thousands of persons, during a succession of years. To prove that we are not trifling with the reader, we must be allowed to quote a passage, already cited: 'What are the instincts of animals, and the mind of man, but a result of chemical action or material process?' (p. 257.) But to return to the chemical process in one brain, which embodies intelligibly the sum of the like actions in thousands of brains, during a succession of years, Mr. Atkinson cites several predictions, afterwards accomplished, from the life of Joan of Arc: among others, the following. On the 1st of March, 1430, Joan made the following predictions: 'Before seven years are past, the English will abandon a larger prize than they have done before Orleans, and will lose everything in France. They will experience the severest loss they have ever felt in France; and this will be by a great victory, which God will bestow on the French.' Mr. Atkinson then enters into particulars, to show that this prediction was literally fulfilled; the great victory referred to being at the distance of twenty, if not of twenty-two years from the date of the prediction. Let the reader only cast one passing glance on the monstrous absurdity, which the author's mode of viewing this subject brings upon him—a few chemical changes in the brain of one individual representing, in an intelligible form, the results of thousands of forms of chemical changes thereafter to take place in the brains of millions of Frenchmen and Englishmen, during twenty years. Does Mr. Atkinson say what he refers to is simply a matter of fact? It is not our business at present to dispute his fact; we grant him the full benefit of it. But we are entitled to ask him to reconcile his so-called fact with the dogma as to the chemical character of mind, which runs through his book." (pp. 148-51.)

Dr. Bushnan then proceeds to show that, however he twist his argument,

Mr. Atkinson cannot avoid being impaled on one or other horn of a dilemma, and thus concludes:

"It is plainly altogether impossible to reconcile the idea of thought being the result of chemical action, with any kind of prediction, beyond what directly flows from a principle which includes the prediction. And this rule extends to all the forms of clairvoyance, or Mr. Atkinson must make his election, and either give up clairvoyance, or confess that there is something more in the operations of the human mind, than what is analogous to chemical or any other kind of material action." (p. 152.)

We shall not waste further space on Mr. Atkinson; and, in parting with him and his misguided associate, we shall only express the hope, that the universal condemnation and refutation their doctrines have received, may lead them to consider once more the momentous questions they have so rashly discussed. To say that their doctrines strike at the basis of all religion, is saying little; they strike away from under our feet all moral restraints, all reverence, all hope, all love; they would sap alike the virtue of individuals, and the integrity of states; and, if it were possible that they could ever be universally received, they would make this earth a very hell, seething in the impurities of a world, from which the divine traces of the Deity had been withdrawn.

Dr. Bushnan's analysis and refutation is a most well-timed one. It is excellently done, and will, we hope, prevent Mr. Atkinson from again parading his crude ideas on the public. Dr. Bushnan's style is easy, his facts logically arranged, and his conclusions inevitable. The only possible addition we could have wished, would have been a chapter devoted expressly to consider the obscurity of Mr. Atkinson's language, and his constant inconsistencies. As to the obscurity of language, it surpasses all credence; there are many sentences of which it is impossible to make sense; and how Miss Martineau, who has hitherto had the reputation of ability, could have accepted them, without asking what they meant, we cannot conceive. But perhaps Dr. Bushnan conceived, that Mr. Atkinson's vagueness and inaccuracy in the use of terms is sufficiently exhibited in the analysis of his opinions.

We do not wish to pay Dr. Gregory a compliment, when we say that we turn with pleasure from Mr. Atkinson to him. Completely as we differ from Dr. Gregory, to get back from Mr. Atkinson's speculations to simple mesmerism, seems by comparison returning into the region of common sense. Unfortunately, this is only by comparison; and, if Dr. Gregory's work is not so atrociously absurd as Mr. Atkinson's, this is owing merely to the infinitely narrower scope of the subjects treated of. Dr. Gregory's book is a large treatise on mesmerism, written with the fervour of a convert, and with the vigour of a man whose scientific reputation depends on the affirmation of his position. We have no intention of entering fully into it, for we have no wish to entangle ourselves at present in the thorny paths of mesmerism; but it is worth while to discover, if we can, how far Dr. Gregory's general arguments and method of regarding evidence tell in his favour.

The first letter is occupied with the consideration of what Dr. Gregory terms the "objections to animal magnetism". In few words, the gist of the chapter is, that we are not to reject "facts alleged on respectable testimony, because they appear absurd, incredible, or, in a vague sense, impossible"; and that "time will overcome the strongest prejudices", as has been seen in the establishment of the doctrines of the circulation of the blood, of vaccination, of the movements of the earth round the sun, etc. This is an argument which has been repeated over and over again by the advocates of mesmerism, as of almost every novelty; and Dr. Gregory, and others in the same position, are constantly pleased to assert that the "great truths" of mesmerism are now in the same position as were the "great truths" of astronomy, of geography, and of physiology, at the time of their first promulgation; and

that the parts of Galileo, Harvey, Jenner, and Columbus, are now enacted by the modest advocates of mesmerism, phrenology, and homœopathy. This line of argument has been so often made use of, that it is worth while to see exactly what it is worth.

When Dr. Gregory asserts that we are not to reject alleged facts (which are not clearly impossible), because they appear inconsistent with our previous experience, he is most perfectly in the right. But when any new fact is presented to the mind, the process appears to be this: The mind, seizing the new fact, compares it with other facts previously known, and, according to its greater or less knowledge of other facts, and its amount of logical power, determines the greater or less amount of probability of the alleged fact. Supposing that the evidence brought forth to support the facts is accordant with those previously known, or, not being accordant, is sufficient to counterbalance them, then the mind receives the new teaching without hesitation. All that the mind can do, or can be called upon to do, is to exercise its logical power fairly, in examining into the evidence for, and the position of, the facts. If a fact is presented, which may be in reality a great truth, yet is quite discordant with facts previously known, and the evidence of which is not such as to set aside these discordant facts, the mind logically can do nothing but refuse to admit the new truth. Thus, when Copernicus promulgated his hypothesis (for at the time it was no more) that the earth revolved round the sun, it seemed so inconsistent with what appeared to be facts, and was so little supported by arguments, especially by such arguments as could be apprehended by the generality of minds, that it was rejected by the whole world. And, logically, it was impossible that this should be otherwise; for, if this great truth had been at once welcomed by acclamation, it is evident that this could not have been the result of a proper action of mind, but would have been simply a belief without cause. Or, to take an example nearer home, English medical men have been much blamed for not immediately assenting to the doctrine of vaccination; but there is no doubt that the assent was given quite as soon as it logically ought to have been. In fact, when we look back with indignation on the men who opposed what were afterwards recognised as great truths, we do them injustice; they were often more reasonable than the advocates of the novel proposition.

When the alleged facts of clairvoyance are brought forward, would Dr. Gregory have us receive them at once? Would he not admit that the world must ponder them, must compare them with what it previously knew; must, in fact, judge them by the standard which each man possesses in his own knowledge and logical powers? Dr. Gregory will of course agree to this; but he will answer, that the facts in favour of clairvoyance, if known, are weighty enough to warrant its reception. Here we join issue, and do not hesitate to affirm that, when they are weighty enough, they will receive immediate assent. For we have no doubt that the verdict of the general body of thinkers is always given at the proper time, and that great truths never remain unacknowledged, when the evidence is logically sufficient.

We believe, then (Dr. Gregory may call this reasoning in a circle, but it is not), that the general incredulity of which he complains, proves, not that the alleged facts of clairvoyance are unknown, or foolishly rejected, but that, to the great body of thinkers of this country, they do not present themselves as truths. Dr. Gregory may say that this is no argument against their abstract truth, any more than the very reasonable incredulity of the time was an argument against vaccination. Indirectly, however, it is a very strong argument against clairvoyance; for, if the arguments for a truth are easily accessible to the multitude, there is no reason why they should not be at once received. The arguments for the Copernican theory were abstruse, and not easily appreciated, and the theory made slow progress; vaccination was supported by facts more easily ascertained, and its truth was early recognised; the effects of ether could be seen by every one, and ether and chloroform met

with immediate adoption. In a century after the death of Copernicus, all Europe believed that the earth moved and not the sun; before his death, Harvey was praised and honoured by the greatest medical corporate body in this country, the College of Physicians; in very few years, Jenner received a grant and public thanks from the House of Commons; in a few weeks, Simpson was hailed with the unanimous approbation of the profession, for the application of chloroform. If Dr. Gregory insists on instituting a parallel between these great truths and mesmerism, we cannot allow him to stop half way. He asserts that Copernicus was contemned; that Harvey was ridiculed; and that mesmerism in its turn is neglected for a time. But he should go on, and compare the length of time which the comparatively abstruse arguments for the Copernican theory and for the circulation of the blood took to establish themselves, with the length of time during which the easily apprehended so-called facts of clairvoyance have been unavailingly paraded before the world. It is now more than sixty years since Mesmer appeared before the French Academy, to prove the truth of that which even now has no firm footing among scientific men. Is it more difficult, then, to bring before us the facts of mesmerism, than the abstruse mathematical arguments of Copernicus, or the physiological ones of Harvey? On the contrary, there are abundance of mesmerisers, no lack of subjects, no difficulty in the perception of the phenomena; and yet, by the mesmerists' own shewing, they are, after sixty years, as neglected and unappreciated as were Copernicus, Galileo, and Harvey, at the first promulgation of their doctrines. We should advise Dr. Gregory to abandon his parallel, as, even taken in his own way, it tells more against than for him.

But we will turn the argument in another direction. When a novel doctrine is propounded, the proofs of which are so abstruse and peculiar, as to be unappreciable by the public generally (which is not the case with clairvoyance[1]), the uninitiated can only receive it on faith. Such faith can only be given, when it is felt that the character and logical powers of the professor of the new truth are such as to command our adhesion. Every one believes that the world goes round the sun, although not one person in ten thousand knows the demonstration of the fact. Supposing that from some cause we could not examine clairvoyance for ourselves, but had to depend on testimony; we should require, before believing the facts stated, to be satisfied that the mesmerist who had produced them was an honest man, and was also so logically constituted, as to warrant his having tested the facts in the way the public generally would test them, were they able to examine them for themselves. Thus Dr. Gregory has written a book, containing a certain number of facts about clairvoyance. These facts do not accord with our honest experience; we cannot logically receive them; but, supposing we had no experience on the subject, our next step would be, to endeavour to ascertain Dr. Gregory's logical capacity. To do this thoroughly, we should have to go systematically through his book; but, as our space does not permit this, we will take a single instance. At p. 243, we find the following statement:

"It has lately been stated by M. Allix, on the authority of M. Benoit in Paris, and of another discoverer (also I believe a Frenchman, who is now in America), both of whom, during the last ten years, have been employed in working out the discovery, which they had severally and independently made, although they are now associated to work it out, that this magnetic sympathy is remarkably developed in snails; that these animals, after having once been in communication or in contact, continue ever after to sympathise, no matter at what distance they may be. And it has been proposed to found

[1] We use the term clairvoyance in preference to mesmerism, because it implies a particular series of alleged phenomena, which we are certain have no existence; whereas some of what are absurdly called mesmeric phenomena are real.

on this fact a mode of communication between distant places. . . . . It would appear that every letter has a snail belonging to it in Paris; while in America each letter has also a snail, sympathetic with that of the same letter in Paris, the two snails of each letter having been at some period, and by some process, brought into full sympathy, and then separated and marked. When a word is to be spelled in Paris, the snail belonging to the first letter is brought by some galvanic apparatus into a state of disturbance, with which his fellow in America sympathises. But this requires to be ascertained, which is done by approaching in America, to all the snails successively, a testing apparatus, not described, which, however, includes a snail. On the approach of this, the snail whose fellow in Paris has been acted upon, exhibits some symptom which is not exhibited by any other, and the corresponding letter is noted down."

Dr. Gregory states that this at first appeared very ridiculous, but that when he recollected all "that he had seen of sympathy in men, all that was known about sympathy in the lower animals, . . . he perceived that the only difficulty lay in admitting the fact of the extraordinary sympathy between snails. Now I know nothing," continues Dr. Gregory, "about the habits of snails; and surely I am not entitled to reject facts thus attested, without some investigation into them. I cannot say that the alleged sympathy is impossible." (p. 245.)

We venture to assert, that there is not one of our readers, who will not consider that the utter want of parallel facts to this one (that is to say, its unusual nature), the opposing facts which immediately rise up in opposition to it, the deficiency of evidence which is brought forward to support it, render it impossible that any sound-judging person should place this alleged fact anywhere but on the very borders of incredibility, in the region of the highest improbability. It is clearly not impossible, but neither are hundreds of assertions which we hear daily, and which yet we feel that we may without hesitation consider as infinitely improbable. What, then, can we think of the judgment and logical powers of the man, who can allude to this improbable assertion in the following terms:

"It will certainly be very remarkable, if a snail telegraph should come into action, which, in spite of the proverbial slowness of the animal concerned, should rival in rapidity the electric telegraph, and surpass it in security; inasmuch as there are no wires to be cut by an enemy, besides being infinitely less costly, since no solid tangible means of communication are required, and all that is needed is the apparatus at either end of the line, and the properly prepared snails." (p. 246.)

We have selected this instance of facile and illogical belief, because it is the most striking we can find in the book; but the same want of judgment and discrimination pervades every page, and warrants us in asserting, that even were we at all doubtful of the error of Dr. Gregory's facts, his manner of testifying to them is so unfortunate, as to deprive us of the power of being duly impressed by them.

We need not trouble ourselves to go further into an analysis of Dr. Gregory's mental peculiarities; one specimen will suffice for all. We shall only say that Dr. Gregory must pardon us, if, admitting as we do most fully his sincerity, we must entertain the strongest doubts of his power of determining the different degrees of probability, or, in other words, of distinguishing truth from error.

The pamphlets of Drs. Hughes Bennett and Wood relate to the same subject, viz. the curious experiments which have been lately exhibited, under the absurd name of electro-biology. We believe these experiments will be of great use in opening the eyes of the public to the real source of what is true, in the phenomena which the mesmerists have so erroneously attempted to bind up into a system, and to explain by a crazy hypothesis. This curious subjugation of one mind by another, and the power of direction which the stronger mind can by suggestion give to the weaker, has been long known to medical men.

The experiments of Dr. Darling and Mr. Lewis have proved that the facility of impression, which we had thought had been the characteristic of the mind of the middle ages rather than our own, still exists among us to a great extent. Drs. Bennett and Wood's papers are very interesting; and, with Mr. Braid's papers and works, are well worthy the study of those who are interested in the remarkable mental phenomena, which the older physicians classified under the term "ecstacy".

DIGITALINE. RAPPORTS DE MM. RAYER, SOUBEIRAN et BOUILLAUD. pp. 55. Paris, Martinet: 1851.

The first of these Reports to the Académie Nationale de Médecine, relates to the chemical and pharmaceutical properties of digitaline; the second to its physiological and therapeutical action. The works on which these Reports are founded are upon digitalis, and are written by MM. Quevenne and Homolle, who, in the preamble of the memoir which forms the subject of the first Report, use the following language: "The capital point in the chemical and therapeutical history of digitalis, the extraction of the active principle of this plant, having been attained by us, we should have confined our researches to obtaining this result, and should have been satisfied with the sanction which the Society of Pharmacy had given to this first effort, by decreeing to the memoir presented by one of us the prize proposed for the extraction of digitaline. But a great number of persons, although admitting the importance of the discovery of this principle, presented to our notice some objections, which were more or less serious. Thus, for example, what were the other bodies which accompanied the digitaline in the plant? Are there not some among them which contribute to the reputed sedative or diuretic actions of digitalis? Or rather, does digitaline by itself represent these two properties? Others inquired whether this principle always offered the desired degree of identity, and if the physician could always rely in his practice upon a sufficient degree of fixity of constitution? Some even went so far as to say that, while acknowledging that digitaline exhibited indeed the properties of the plant, they would not dare to run the risk of employing a substance of such powerful properties, in the fear of its eventual inexact administration. On the other hand, every one asked himself whether digitaline, a principle which is amorphous, or of a doubtful crystallisation, was really a pure product, or if it were not possible to disengage it from some body retained in combination, and to obtain it afterwards with new and better defined properties? Familiarised more than others with the question, we were the first to feel the value of several of these objections; to ask ourselves, for example, if there were not some of the other principles of the plant, which, alone or by themselves, might possess an action worthy of interest on the animal economy. We therefore resumed our work, stimulated by our first success, led almost irresistibly by the desire of completing our first discovery, and governed by the wish of not introducing any other than a well-studied medicine into therapeutics." The reporters then proceed to state that the first memoir is divided into two parts, one relating only to digitaline, and the other devoted to all the other principles found in digitalis. The first of these is stated by the authors as being alone of practical interest; and they add that it is to it only that they desire to draw the attention of the Academy. The reporters, however, enumerate in a foot-note the other principles besides digitaline which are found in digitalis. These are: 1. *Digitalose;* 2. *Digitalin;* 3. *Digitalide;* 4. *Digitalic acid;* 5. *Antirrhinic acid;* 6. *Digitaleic acid;* 7. *Tannic acid;* 8. *Starch;* 9. *Sugar;* 10. *Pectine;* 11. *An azotised albuminoid matter;* 12 *An orange-red crystallisable colouring matter;* 13. *Chlorophyll;* 14. *A volatile oil.*

MM. Homolle and Quevenne examine, in as many separate paragraphs,

I. *The Purification of Digitaline, and its Chemical Properties.* II. *The Test of Digitaline.* III. *The best form of administering Digitaline in Medicine.*

To purify crude digitaline, authors have treated it with ether slightly alcoholised, which takes up digitaline. But this liquor dissolves also the *digitalose*, and leaves the *digitaline*. To separate the former from the digitaline, the solution is submitted to evaporation, and the residue is treated with alcohol at 60°, which dissolves the digitaline and eliminates the digitalose. Evaporated at a gentle heat, this solution by weak alcohol gives finally *pure* digitaline, or at least retaining very little of the two bodies just indicated, which cannot be completely isolated from it; so great, according to the authors, is the obstinacy with which digitaline retains the last traces of these substances. These able experimenters vainly made numerous attempts to crystallise the digitaline so obtained, and to procure it in a purer state than the specimen formerly described by one of them. When this purification is accomplished, the digitaline presents itself under the form of scaly striæ, or of masses of a straw-yellow colour, of a resinoid aspect, more or less transparent, easily crushed, and then forming a yellowish pale powder. When once isolated, the digitaline is unalterable in the air; it possesses a slight aromatic odour of a peculiar nature, and a very marked bitterness.

Digitaline is soluble in small quantity in the serum of the blood, without producing in it any apparent change. The proportion dissolved appears to be the same as in water. It is dissolved also in filtered gastric juice. Digitaline exerts no action upon litmus. It is dissolved also in small quantity in water; and in all proportions in weak or concentrated alcohol. *The characteristic and distinctive property of digitaline is, to be coloured of an emerald green by concentrated hydrochloric acid, forming a turbid solution.* Digitaline belongs to the class of immediate neutral principles; it combines neither with acids (the tannic excepted) nor with alkalis.

To be assured of the *identity* or of the *quality* of digitaline, an important and capital point in a therapeutical view, MM. Homolle and Quevenne have paid attention to the different degrees of bitterness of this substance; for they state that its degree of bitterness is incontestably a measure of its degree of energy. To succeed in this test, the following plan is to be adopted: "One centigramme of digitaline is dissolved in two grammes of alcohol, and the mixture is progressively diluted with water, until the complete disappearance of the bitter taste. If the digitaline is good, this quantity will require the employment of two *litres* of water." This method of appreciating the intensity of the taste of bodies, employed already by other observers, to judge of the richness of certain medicinal preparations, has been considered by MM. Homolle and Quevenne as proper for enabling them to obtain digitaline always identical with itself. This test is the more indispensable, because, in conforming rigorously to the mode of preparation just described, no one can be certain of having always the same product. Digitaline, except in its action on the animal economy, does not possess, unfortunately, any essential property by which we can positively recognise its purity. It does not crystallise, and does not form any crystallisable combinations; we can therefore never affirm that it has been obtained sufficiently pure, or that it has not been mixed. Let the person who prepares digitaline, therefore, be well acquainted with the fact, that this product does not offer any suitable proofs of its purity, except inasmuch as, subject to the experiment of dilution, it gives the same result as a *type* of acknowledged purity. Let the physician be also warned that digitaline does not constitute a medicine of such a certain identity that he should neglect a great degree of prudence in its use; a prudence which, besides, is demanded by the extreme activity of this new therapeutic agent.

MM. Homolle and Quevenne having thus succeeded in obtaining digitaline in the state which they call *identical*, it remained for them to determine what was the pharmaceutic form for giving it, under the quadruple relation of

safety, convenience, good preservation, and *easy administration.* The solution of this problem was the more important, because the product under consideration possesses a very great degree of activity, so that it ought to be administered only in milligrammes, or, in fact, in an *infinitesimal* dose. Among the different pharmaceutical forms considered by MM. Homolle and Quevenne, the pilular form is that to which they have given the preference. "The variety," say these authors, "which appears to us the best, is that of little sugar-plums, in which the active matter is enveloped in a layer of sugar, so that the patient, by reason of their very small size, can swallow them easily, without mastication, and therefore without any other perception than that of the sugar which covers them." These sugar-plums are called granules by the authors, and each contains a milligramme of digitaline; and it appears that this mode of administration preserves the powers of the drug to a period of which MM. Homolle and Quevenne have not yet ascertained the limit.

In concluding the analysis of the first memoir of MM. Homolle and Quevenne, the reporters think themselves justified in declaring that the researches of those authors deserve to be placed among the discoveries of medical science, and, as a testimony of the approbation of the Académie, they recommend the memoir for publication.

II. The Second Report is upon the Physiological and Therapeutical action of Digitaline, and is founded upon a second paper communicated by MM. Homolle and Quevenne upon that subject. These gentlemen propose to establish, "that digitaline is the only active principle of digitalis; that it presents all its physiological and therapeutical properties, and that the constancy of its effects, as well as its unchangeableness, give it an incontestable advantage over the pharmaceutical preparations of digitalis." In order to give to the Académie a just account of the labours of MM. Homolle and Quevenne, the reporters divide their analysis into three parts. The first is devoted to a rapid sketch of the opinions expressed upon the properties of digitalis: the second relates to the examination of the researches made by the authors of the memoir on the properties of digitaline: and the third contains the account of the experiments instituted by the commission.

1. This part of the report does not require a detailed examination, as it presents no novelty, except, perhaps, the analogy drawn by the reporter between the effects of digitalis and those of *retained bile,* as observed in jaundice. The reporter states, that he has observed for eighteen years the effects of this *animal digitalis,* as he somewhat fancifully terms it, and that it invariably retards the pulse, except in those cases where jaundice is accompanied by inflammation and fever.

2. This part contains an account of a series of physiological and pathological experiments on the properties of digitaline, compared with those of the other preparations of digitalis. One of the authors made a series of experiments on himself, and his exemplary exactness in recording the results is warmly eulogised by the reporters. From the analysis of the first six trials, undertaken in the course of the years 1842, 1843, 1847, 1848, 1850, it results that the *medium* of the diminution in number of the pulsations of the heart and arteries has been about four pulsations *during,* and four *after,* the administration of the medicine. Experiments made on two dogs proved that, in one, the pulse was lowered from 59 to 51, and in the other, from 87 to 69, by the administration of minute doses of digitaline. As to the comparative efficacy of the preparations of digitalis hitherto employed, and of digitaline, MM. Homolle and Quevenne leave this point to be finally determined by clinical experience; but they think that their own observations, and the works published up to the present time, lead to the belief that the question will be resolved in favour of digitaline; and they quote the authority of MM. Hervieux, Strohl, and Sandras, who have all employed the digitaline in their practice with the

most happy results. M. Hervieux states, that one of the circumstances which plead most in favour of digitaline, is the facility of apportioning the dose; for, while this can be done in the case of the preparations of digitalis only by a very rough approximation, it can be accomplished in the case of digitaline with a mathematical rigour. M. Sandras declares, that he has never met with the inconveniences attributed to digitalis, while he has employed digitaline; the latter has appeared to him to be easy to take, and easy for the patient to bear; its effect has been perfectly fixed and regular, according to the doses in which he prescribed it. Some clinical observations made by MM. Homolle and Quevenne are then related, but we cannot say either that the cases seem to be well chosen, or the results accurately noted; and the indiscriminate manner in which the digitaline was prescribed, is not to be commended. In the first case, for instance, there was a "puerperal affection", but we are not told what was its nature; in the second, there was an "affection of the heart", and a "profound disturbance of the circulation"; in the third case, there was hypertrophy of the heart, with "lesion of the orifices"; in the fourth case, there was "profound perturbation of the cardiac circulation"; all these terms are far too vague for the present advanced state of science. Again, the digitaline was given in the seventh case for cyanosis, from persistence of the foramen ovale; and in the sixth, it was given in large doses for anasarca with albuminous urine. In our humble opinion, neither of these diseases would justify the use of digitalis in any form.

The following statement by the authors is of extreme importance, and completely accounts for the frequent uncertainty which attends the employment of digitalis in medical practice. "We have been able", say MM. Homolle and Quevenne, "to ascertain, when we have procured our specimens of digitalis, that, in the quantity which existed in 1847 on the Place de Paris, there was about a fourth part well dried, a fourth of middling quality, and half which was badly dried and manifestly bad. It is evident that this last and considerable fraction was not thrown away; and, as digitalis has only a medical use, we are obliged to admit that it has been consumed by the sick."

3. In this portion, one of the reporters (we believe M. Bouillaud) records his own clinical experience of the effects of digitaline, which he has given to 150 or 200 patients, of different age and sex. The cases in which it was administered were simple nervous diseases of the heart, but principally chronic organic affections of this organ; and a few were well-ascertained cases of intermittent fever. In all these, with the exception of three, there was a more or less considerable retardation of the pulsations of the heart and arteries; and in the three exceptions, the frequency of the pulse was maintained by a febrile phlegmasia. In several cases, also, where the acceleration of the pulsations of the heart was accompanied by irregularities and intermissions, with disorder and disturbance of its natural rhythm, digitaline not only calmed the palpitations, but it also regulated the disordered action of the organ. In intermittent fever also, the reporter has found digitaline of equal importance with digitalis, which latter he has been in the habit of prescribing with advantage in this disease, although he does not by any means assert that it is superior, or even equal, to quina as an antiperiodic and febrifuge. The commission does not decide in the present communication upon the question of the superiority of digitaline over the other preparations of digitalis, but leaves it for future investigation: and they conclude their very excellent report by a well-deserved tribute of praise to MM. Homolle and Quevenne, for their investigations on the preparation and properties of digitaline.

HAND-BOOK OF NATURAL PHILOSOPHY AND ASTRONOMY. By DIONYSIUS LARDNER, D.C.L., formerly Professor of Natural Philosophy and Astronomy in University College, London. *First Course:* Mechanics—Hydrostatics—Hydraulics—Pneumatics—Sound—Optics. pp. 819. London, 1851.

This is one of the best elementary treatises on Natural Philosophy which we have ever read; and to those who wish to obtain a knowledge of this important branch of science without wading through a multitude of huge volumes, we cordially recommend its perusal. The author is favourably known to the public by his numerous contributions to physical science, and the present work is well calculated to sustain his high reputation. While advocating the necessity of at least some knowledge of natural philosophy for all the educated classes of society, we would especially recommend that it should not be neglected by the members of our own profession; and although we admit that the student's time is pretty well occupied by sciences immediately connected with his future pursuits, yet there are periods of his pupilage, and leisure hours in practice, when works like the present may be read with pleasure and advantage. To the physiological student, an acquaintance with natural philosophy is indispensable; for although we do not agree with some learned authorities that the principle of life is a galvanic battery, or with others that the pulsations of the heart are produced by a series of chemical combinations and decompositions, yet we cannot but see that many of the functions of the human body are performed by means of laws exactly similar to those which act upon inanimate matter. Thus, whatever may be the origin of nervous influence or of muscular power, there can be no doubt that the limbs with their muscles form nothing more nor less than a series of levers—that the circulation of the blood is regulated by the laws of hydraulics—that the faculties of hearing and speaking, with all their attendant enjoyments, are closely connected with the principles of acoustics—that the beautiful mechanism of the eye is merely a series of membranes and humours for the reflection, refraction, transmission and absorption of the luminous rays—and that its defects may be remedied by the use of instruments constructed upon optical principles. We are happy to observe, that Dr. Lardner omits no opportunity of directing attention to the relation of physics to the mechanism of the human body; and, although his acquaintance with anatomy and physiology is not conspicuous, yet his occasional references to those subjects are particularly welcome to the medical reader, and exhibit the versatile and varied talents of the author.

HISTOIRE DE LA VACCINATION EN TURQUIE, EN GRÈCE, ET AUX INDES ORIENTALES. Par JEAN DE CARRO, Docteur en Médecine. pp. 116. Vienne: 1804.

GERMAN TRANSLATION of the above work, with Additions and Annotations. By FRIEDRICH GOTTHILF FRIESE, M.D. pp. 175. Breslau: 1804.

This is a highly interesting account of the introduction of Vaccination into the east of Europe, and Asia, for which the inhabitants of those countries are indebted to the philanthropic and persevering zeal of DR. DE CARRO. It will be remembered, that we published, in our account of the proceedings of the Jenner Monument Committee, at p. 682 of our number for July, a letter from Dr. de Carro, to which was appended a brief statement of the services which he had rendered in the dissemination of vaccination in foreign countries. The interest attached to the subject will, we trust, form a sufficient apology—if any be needed—for our thus noticing a work published nearly half a century ago.

The introduction of vaccination into Turkey appears to have arisen from a conversation between Dr. de Carro and the father and mother of Lady Elgin, wife of the British Ambassador at Constantinople. In December 1800,

Lord Elgin communicated to Dr. de Carro the news of the first successful attempt at vaccination in Turkey, on the person of his infant son ; and from the matter taken from the child, several other persons were vaccinated. Under the encouragement and direction of Lord Elgin, Dr. W. Scott, Dr. Hesse, etc., vaccination made progress ; although it was retarded in a measure by the prejudices of the inhabitants, and other causes, so that the matter often became exhausted, and fresh supplies had to be obtained from Dr. de Carro in Austria, and from England.

In March 1802, Lord and Lady Elgin, with Dr. Scott, visited Greece and the Archipelago ; and on the 7th November in that year, Dr. Scott wrote to Dr. de Carro, that vaccination had been commenced in Athens, and that upwards of eighty persons of all ages had been submitted to the operation in that city. The British consul at Salonica was supplied with vaccine matter for the use of M. La Font, a French physician practising in that place. This matter, supplied by Lord Elgin, at first failed : but, on a supply being received by M. La Font from Dr. de Carro, the success was most encouraging. "All the inhabitants of that town adopted vaccination with a zeal worthy of the most enlightened people : Turks, Armenians, Greeks, and Franks, all had recourse to this preservative. In a word, on March 3, 1803, six months after commencing the practice, M. La Font had vaccinated above 600 persons ; and the number had risen to 1132 on June 3, in the same year. The inhabitants of neighbouring towns are also desirous of enjoying the benefit ; he has received a pressing invitation from the inhabitants of Larissa in Thessaly ; but, as his occupations do not permit him to leave Salonica, he has deputed pupils to vaccinate in any place in which the inhabitants may desire it." (pp. 14, 15.) Under the care of Dr. Moreschi, and other physicians, vaccination became general in Greece.

In the mean time, great sensation had been produced in Asia by the news of the introduction of vaccination into Constantinople : and Lord Elgin thus wrote to Sir A. Paget, ambassador extraordinary at Vienna, in January 1802: "They write to me so often from Bassora, the East Indies, and Ceylon, for vaccine matter, that I beg you will immediately engage Dr. de Carro to send me some by all the couriers, until I desire him to desist. That which I have sent has produced no effect." A supply was sent to Bassora and Bagdad ; and thence vaccination rapidly extended over Asia. The accounts furnished from time to time to Dr. de Carro, by the British consuls and residents in Bagdad and other Eastern cities, must have been most encouraging to his energetic zeal ; but we regret that we cannot reproduce them at greater length.

Interspersed in the work are various pathological observations on the relation of cow-pox to the grease in horses, on its efficacy as a preventative of the plague, on the mode of preservation of vaccine matter, etc. There is also a copy of a *procès-verbal*, signed by Dr. A. B. Auban of Constantinople, and some of his colleagues, attesting the presence of cow-pox in certain small villages near Constantinople, in which the inhabitants, after becoming infected by it, remained free from the small-pox and from plague.

Since the time when this work was written, vaccination has become an everyday occurrence throughout the civilised world ; and, though it may not have met with all the success which some of its more sanguine promoters perhaps anticipated, the amount of benefit conferred by the discovery of Jenner is too great to be particularised. The committee now engaged in promoting the erection of a monument to Jenner are engaged in a worthy task—that of enabling the whole civilised world to display a tangible memorial of their gratitude to the memory of one of their greatest benefactors. We heartily wish them success in their endeavours.

As to the venerable author of the work before us, we can imagine with what satisfaction he must regard the success which has attended his endea-

vours, commenced upwards of half a century ago, to disseminate the blessings of vaccination. Titles and honourable marks of distinction have been, even up to his old age, conferred on him ; yet we doubt not that he values before all these the appellation of "*the friend and first apostle of Jenner*". Of himself, as the introducer of vaccination into the continent of Europe, he may say—

"Exegi monumentum ære perennius."

In concluding, let us express the sincere hope, that Dr. de Carro may long live in health and vigour; and that he may speedily see the completion of the London monument to Edward Jenner.

On Diseases of the Mucous Membrane of the Throat, and their Treatment by Topical Medication. By William R. Wagstaff, M.A., M.D., etc. pp. 183. London: 1851.

In this treatise, attention is drawn in a special manner to the effects of morbid action in the muciparous glands, and to those conditions of the mucous membrane which impair its organic function. A classification of these diseases is adopted, which has direct reference to the tissue supposed to be primarily affected by the morbific influences. As there is nothing, either in the pathology or the symptoms described, which need detain us, we shall address ourselves at once to those parts of Dr. Wagstaff's treatise in which he proposes "topical medication" as a substitute for "those general remedies, which are so carefully dwelt on by most writers". "Unless some manifest disease", observes Dr. Wagstaff, "appears to have affected all parts of the system, as is often the case in influenza, no general remedial measures of any moment will be required ; the disease, being a local one, will need little beside local treatment for its removal". (p. 41.)

We would perfectly agree with Dr. Wagstaff that, provided a disease be indeed a local one, it will require little more than a local remedy. But the whole progress of modern science seems to point out, that we can no more study with advantage the diseases of separate parts, unconnected with the general system, than our forefathers could learn their anatomy correctly with the nerves and arteries spread out before them upon a board. All the blood in the body is continually passing through the lungs, and may communicate to them conditions, the result of influences which it has received in any part of the body ; and how often these may give rise to symptoms similar to those of "acute catarrh", derived only from strictly local causes, we have yet to learn. The remedial measure upon which Dr. Wagstaff relies with the greatest confidence, "is the application of a powerful astringent directly to the affected portion of the mucous membrane, or as near to the diseased part as our present knowledge and mechanical appliances will enable us to make it". (p. 43.)

The first case related by Dr. Wagstaff of the efficacy of this treatment is quoted from Sir C. Bell, and is not calculated to confirm our notions of the local origin of the diseases of these parts. It is the case of a young woman, who had extensive ulceration of the glottis, which was followed by long-continued inflammation of the throat, and accompanied by a harsh, sawing sound, and with much difficulty in breathing. On attempting to swallow a little broth, much of it went into the wind-pipe, and she had a great struggle in recovering. (p. 45.) In this case, Sir C. Bell found that the irritation was much relieved by the application of the nitrate of silver ; and we do not doubt the propriety of this mode of treatment, but we believe that there are few well-informed physicians, or surgeons, in the present day, who would not have directed their principal attention to the previous history of the case, and endeavoured to ascertain what vice of constitution, or taint in the system, had been the original cause of the ulceration, and have treated the patient accordingly.

The instrument employed by Dr. Wagstaff for the topical medication is "a whalebone probang, to the end of which a small rounded piece of fine sponge is attached. The method of employing this is, to convey the end of a spatula to the lingual base of the epiglottis, then, by pressing the tongue firmly down and drawing it forward, the laryngeal surface of the epiglottis may be exposed; when this organ is brought fairly in view, the great difficulty of the operation is overcome; for it only remains to direct the patient to inspire gently, and to pass the sponge of the probang to the posterior surface of the epiglottis, and, by a rapid motion, to press it *downward* and *forward* in order to introduce it into the larynx." (p. 52,)

The substances employed are the perchlor. hydrarg., the bicyanid. hydrarg., the nitras hydrarg., the nitras potass., the sulphas cupri, and the nitras argent. Of all these, that to which Dr. Wagstaff gives the decided preference is the nitrate of silver, on account of "its rapid action, its efficacy, and its harmlessness". A solution of twenty grains of the salt to an ounce of distilled water, is recommended in the milder cases; and this may be increased, according to circumstances, to sixty or even to eighty grains.

The efficacy of nitrate of silver has lately been extolled for many different affections, and its use has been particularly recommended for diseases of internal cavities. We cannot help thinking, that much of its mysterious virtue would disappear, if its effects were accurately and honestly observed on the surface of the body. When there is difficulty in applying it, and where its results are not readily observed, the curative virtues attributed to it are rather startling. The diseases of the ears, eyes, and nose, of the urethra and uterus, all in turn yield a willing obedience to its magic influence.

In making these observations, we by no means wish to disparage the use of nitrate of silver as a valuable adjunct in the treatment of diseases of these parts; but we would caution our readers against adopting favorite opinions of its "specific" virtues, which in practice would not be realised.

The First Step in Chemistry. By Robert Galloway, F.C.S., Lecturer on Chemistry in Putney College. pp. 91. London: 1851.

This is a very well-written little volume, and will be of use in introducing the study of chemistry into schools, as a part of the education of youth. It is divided into ten chapters, which comprise many of the fundamental laws of the science, and it contains numerous exercises, dispersed among the chapters, to be performed by the student, and calculated to fix in his mind the principles of the foregoing explanations. It has often been to us a matter of surprise, that the subject of chemistry has not yet been adopted at boys' schools; one reason for this may be, that the books written on this science are too difficult for beginners. The work now before us is calculated to supply this defect; and deeply impressed as we are with the importance of teaching chemistry to the youth of this country, in which the science has already made, and is still making, such brilliant progress, we heartily commend this unpretending and useful work to the heads of scholastic establishments, and to others who are anxious to initiate their pupils into the principles of a most fascinating and most useful branch of human knowledge.

On Gout; its History, its Causes, and its Cure. By Wm. Gairdner, M.D. *Second Edition.* pp. 300. London: 1851.

Dr. Gairdner has availed himself of the demand for a second edition, to improve and amplify his excellent treatise.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

ANATOMY AND PHYSIOLOGY.

PROFESSOR SIMPSON ON VITAL CONTRACTIONS IN THE UMBILICAL ARTERIES AND VEINS.

Up to a late period, some physiologists doubted entirely whether the larger arteries of the human body could be made to contract at individual points by stimulants applied to those points. Few or no satisfactory experiments have yet been published, shewing that the veins possess the property of contracting locally under local stimuli. But, in the umbilical cord, the medical practitioner may have daily an opportunity of repeating experiments, which prove both of these important physiological facts: viz. the contraction both of the tubes of arteries, and of the tubes of veins, under local stimuli applied to them.

For some time past, Dr. SIMPSON has pointed out to his pupils the following facts, regarding the contractility of the umbilical veins and arteries.

1. After the child is born, the cord (whether tied or not) is generally seen to become contracted at different points, in consequence of the local contraction at those points of the vessels included within it. In fact, its vessels are thrown, by the irritation of the external atmosphere, and in consequence of their partially empty condition, into tubes consisting of a series of dilatations and contractions, like the peristaltic contractions of the intestine; but with this difference, that the contractions of the vessels are permanent.

2. By pinching a portion of the cord, immediately after the birth of the child, between the nails of the thumb and finger, contractions of the vessels of the cord will be seen to occur at the point irritated. And if this mechanical irritation is confined to individual vessels, as to one of the arteries, or to the vein, the effect is equally marked.

3. If the sheath of the cord be slit up by a pair of scissors or a knife, with any of its vessels or arteries exposed, the same experiment may be repeated upon the exposed individual vessels with similar effect: viz., that the mechanical pinching of them will be followed, in the course of a short time, by a gradual but very marked contraction in the irritated part.

4. Similar local contractions of these vessels occur, under the local application to them of irritating chemical substances, or of electricity.

5. These contractions do not instantly follow the application of the stimulant, but a short time intervenes before the effect is seen, and the contraction is permanent.

6. When the experiment is made upon the human umbilical cord, or upon that of the lower animals, when the circulation is still going on in the vessels of the cord, the irritated vessel will sometimes almost entirely close its tube under such local irritation.

7. These simple experiments, illustrative of the contractility and irritability of the coats of the veins and arteries, are the more remarkable as seen in the umbilical veins and arteries, in consequence of anatomists not being able to detect any nerves in the umbilical cord; although probably elementary nervous tissue may exist in some form in it. For if it did not exist, then we would have irritability in these vessels existing without nervous influence. Dr. Simpson proposed the investigation of the existence of nerve in any form in the umbilical cord and its vessels, as an interesting microscopical study, in reference to the physiological question of the dependence or independence of the contractility of vessels on the presence of nerves. [*Monthly Journal of Medical Science*, May 1851.]

PRACTICE OF MEDICINE AND PATHOLOGY.

PROFESSOR CHRISTISON ON THE TREATMENT OF ASCITES AND OTHER FORMS OF DROPSY BY DIURETICS EXTERNALLY APPLIED.

In the *Edinburgh Monthly Journal* for October 1850, Dr. CHRISTISON makes the following remarks:

"Some years ago, a short paper appeared in a French periodical, on the treatment of ascites by means of digitalis and squill applied outwardly in the form of liniment; and three cases were given, illustrating the diuretic and curative effects of this treatment, after failure by means of diuretics administered in the usual way, as well as by powerful purgatives. At the time, I had under my charge a boy, ten years of age, who had laboured under simple ascites—that is, without any œdema, even in the limbs—for a period of five or six months, during which the effusion had slowly and steadily increased, notwithstanding the employment of brisk purgatives, various powerful diuretics, and mercurial action. There was great difficulty in referring this affection to any particular organic disease; but, on the whole, a previous chronic peritonitis was suspected to be the cause. When he came under my care, purgatives and diuretics internally were again tried, and especially digitalis and squill, but with no better success than before. On the contrary, the enlargement and tension of the belly became gradually very great, so that the boy was confined in a great measure to bed. The French suggestion came therefore most opportunely. A mixture of equal parts of tincture of digitalis, tincture of squill, and tincture of soap, was rubbed freely and diligently into the skin of the belly morning and evening. At an early period,—so early, if I do not mistake, as the beginning of the third day,—the urine began for the first time to increase; by and by a copious flow was established; the ascites quickly subsided, and in about fourteen days entirely disappeared; the boy at the same time gained flesh and strength under the use of simple bitters and chalybeates, and, ere long, his health was completely restored. When I last heard of him, four or five years afterwards, he continued well and strong.

"The same treatment was tried afterwards in several cases more or less similar to this, but for a time with invariable disappointment. In all, however, the more ordinary measures had previously been exhausted to no purpose; and, in most of them, decided organic disease of some abdominal organ was ascertained to be the cause of the effusion. At length the following remarkable case revived the hopes excited by the first experiment. A boy, about nine years of age, had been affected with enlargement of the liver and ascites for nearly a twelvemonth. Dr. James Duncan, his medical attendant, had employed all the most serviceable remedies, but to very little purpose. Mercury, iodine, purgatives, diuretics, both vegetable and mineral, had been faithfully given, occasionally with partial effect, but not with any satisfactory amendment. At length the ascitical distension became enormous, the integuments acquired a glistening translucent appearance, the respiration was impeded, and the tightness of the skin prevented the nature and extent of the disease of the liver from being ascertained. But there was no œdema, even in the limbs. In this state I saw him for the first time. Before resorting to the temporary expedient of tapping, it was proposed to make trial of the diuretic liniment; but the integuments were so irritable, that the method by friction could not be persevered with. Dr. Duncan, however, proposed to substitute a strong infusion of digitalis, four times the pharmaceutic strength, and to apply it continuously by linen cloths covered with oil-silk to impede evaporation. In a few days, diuresis set in; and a profuse flow of urine quickly removed the whole dropsical effusion. The liver was soon felt to be greatly enlarged, lobulated, and rugose; which dis-

ease, it need scarcely be added, proved fatal a few months afterwards. But it is remarkable that the ascites never returned.

"I have often used the same method since, both in simple ascites, and likewise where that affection formed a prominent part of a more general dropsy. The issue has of course been variable, and more frequently unfavourable than successful. But, on the whole, the results of my own observation, and the experience of others in Edinburgh, who have also tried the practice, lead to the conclusion, that digitalis not unfrequently succeeds in this way, when not only it, but likewise all other diuretics taken internally, as well as the purgative method of cure, prove of no avail. It has likewise been tried with success in a few cases of obstinate excessive œdema of the limbs, in connexion with general anarsaca and Bright's disease of the kidneys, after diaphoretics, purgatives, and diuretics internally, had failed to give relief. The late invention of the texture called 'Spongio-piline' has facilitated the application of the treatment. A large sheet of spongio-piline, soaked moderately with a strong infusion of digitalis, made with one ounce of powdered leaves to twenty-four ounces of boiling water, may be applied to the whole abdomen, or to each limb, and worn constantly, without any material inconvenience to the patient."

NARCISSUS PSEUDO-NARCISSUS IN EPILEPSY.

None of the plants of the narcissus tribe are, in this country, employed in medicine; but in France, the leaves and flowers of the N. pseudo-narcissus have a considerable reputation, especially in hooping-cough and other spasmodic affections.

In the *Journal de Médecine et de Chirurgie* for May 1851, it is stated that Dr. Pichot has recently celebrated the virtues of this plant in epilepsy. He gave it to a man of twenty-three, who had been subject to epileptic attacks for four months. Each fit lasted for from one to four hours; and terminated by general convulsions and cries. He was bled from the arm; and afterwards, sulphate of quinine, with extract of valerian, were administered without result. On the 22nd of September, the first dose of the N. pseudo-narcissus was administered; and from that time, for fifteen days, three decigrammes were given twice a day. After this time, he discontinued the medicine for a week, when the dose was increased; and, towards the end of the month, he was taking four daily doses of three decigrammes. Up to the 2nd November he had had no more fits; he only experienced some transient sensations of giddiness; but on this account it was thought right to advise the continuance of a remedy, to which, there seemed no reason to doubt, his amelioration ought to be ascribed.

TETANUS TREATED BY FRICTIONS WITH CHLOROFORM AND WITH ETHER.

Dr. Morisseau relates the following case in the *Union Médicale* for June 21, 1851.

About eighteen months ago, he had as a patient in hospital a man, aged above forty, who was suffering from traumatic tetanus. When seen by Dr. Morisseau, the patient had permanent contraction of the muscles of the jaw, chest, abdomen, and back, with convulsive movements every hour. Four grammes of chloroform were ordered to be rubbed immediately on the surface of the body; and this was repeated three times in the day. In the evening, the patient was put into an acidulated vapour bath. The next morning, the patient had perspired copiously; and he had slept, which he had not done since he was first attacked. Some spoonfuls of liquid had been swallowed; the muscles were less tense, and the convulsions were less frequent and of shorter duration. Twenty grammes of chloroform were ordered to be rubbed in during the day—a third part each time. The treatment was continued

during five days; the perspiration continued; and, on the sixth day, there was nothing remaining but some general languor and great weakness, from which the patient soon recovered under proper diet and exercise.

Dr. Morisseau does not hence infer that chloroform is entirely preferable to quinine in tetanus. Both may be good in certain cases—perhaps in all; but we may be permitted to prefer the shortest and most certain remedy. He would, in other similar cases, again use chloroform, sometimes giving quinine at the same time.

Dr. ARAN has appended the following note to the communication of which the above is an abstract.

The case related by M. Morisseau is, as far as we know, the first in which friction with chloroform has been successfully employed in tetanus. The good effects which it has been shewn to possess in combating cholera cramps, painful contractions, choreic spasms, etc., would lead one to expect something from it in tetanus. Frictions with sulphuric ether have already been used in this disease, as appears from the following case, related by M. TIBALDI in a recent number of the *Gazetta Medica Lombarda.*

A labourer, aged 28, was attacked with tetanus, two days after lying on the damp ground, while in a state of perspiration. When first seen by M. Tibaldi, he was in a state of well-marked tetanus. In pursuance of the treatment generally adopted in that country in tetanus, he was bled eight several times during five days, sometimes to as much as twenty ounces; and above a hundred leeches were applied to the painful parts. On the sixth day, the state of the patient being still severe, M. Tibaldi had the loins rubbed twice with sulphuric ether; the patient was bled a ninth time, and took half a grain of acetate of morphia. The frictions put a stop to the spasmodic twitchings of which the patient complained. The next day, he was again bled; and an ounce of ether was rubbed over the back and neck. On the third day, the patient could sit up; and, in about ten days, he was convalescent.

DOES THE FREQUENCY OF ANAL FISTULA IN PHTHISICAL PATIENTS SUGGEST ANY THERAPEUTIC IMITATION OF A SIMILAR DRAIN?

It is well known, that fistula in ano is often met with in phthisical patients; and it is also pretty generally admitted, that the pulmonary disease is accelerated by the cure of the local malady. From these considerations, M. BORSON suggests that benefit may be derived in phthisis by artificially establishing an emunctory in the neighbourhood of the anus. He recently made an experiment of this kind upon a man in the second stage of phthisis at the Hôtel Dieu of Chambery. The symptoms are said to have been much relieved; but he left the hospital too soon for the results to be reported in a satisfactory manner. [*Journal de Méd. et de Chirurgie,* May 1851.]

INVOLUNTARY EXCRETIONS OF THE INSANE, TREATED BY STRYCHNIA.

M. GIRARD, physician to the lunatic asylum at Auxerre, mentioned, at the meeting of the Académie de Médecine, on June 10, that he had employed sulphate of strychnia as a remedy for involuntary evacuations in the insane. Two centigrammes (about gr. $\frac{1}{3}$) are mixed with 30 grammes (463 grains) of simple syrup. The daily dose of this compound is at first five grammes, gradually increased, sometimes to as much as thirty or forty grammes. M. Girard has not observed cerebral congestion to be produced in any case, when the medicine was carefully given. In three cases, he pushed the dose to a hundred grammes; and then some convulsive movements were produced, which readily disappeared when the medicine was discontinued and warm baths were used. [*Gazette Médicale de Paris,* June 14, 1851.]

TREATMENT OF ACUTE RHEUMATISM BY CROTON OIL.

During the last five years, Dr. G. L. Upshur, of Philadelphia, U.S., has treated eleven cases of acute rheumatism with croton oil, with the most satisfactory results. The patients were purged daily, or every second day, according to the severity of the disease, until the inflammatory symptoms were completely subdued. He says, in the *Philadelphia Medical Examiner* for October 1850:—

Of croton oil as a purgative in acute rheumatism, I am prepared to speak in the highest terms. Cathartics have always stood in the front rank of remedies in this disease, but I am disposed to believe that the efficacy of croton oil does not depend entirely upon its cathartic properties. It possesses a power over the disease beyond these, and apparently not depending on them; for other cathartics, which act as powerfully and as promptly, producing similar watery stools, do not bring a like amount of relief to the patient. I do not say that it is a specific, for I am not a believer in the doctrine of specifics in medicine; I merely desire to state, that, after a fair trial, in a number of cases accurately observed, where there was scarcely a possibility of falling into error, I believe that the croton oil is the best single remedy in the treatment of acute rheumatism. I speak not of chronic rheumatism, nor of that which results from a syphilitic taint, but of the acute inflammatory affection. In all the eleven cases, in which it was given, its beneficial attempt was palpably evident.

Dr. W. A. Thom, to whom I am indebted for the first hint in regard to the value of croton oil in this disease, informed me, about two years ago, that he had used it in several severe cases, and uniformly with success. [*Charleston Medical Journal*, March 1851.]

SURGERY.

FRACTURE OF THE ANTERIOR PORTION OF THE OS CALCIS.

Dr. Ruschenberger, Surgeon U.S. Navy, records the following case in the *Philadelphia Medical Examiner* for May 1851, p. 289.

Case. On the 24th Nov. 1850, Lieutenant W. (aged 32, athletic, weighing 190 lbs.), while in a paroxysm of mental aberration, leaped from the wall enclosing the U.S. Naval Hospital at New York, at a point where it is fifteen feet high, and alighted on his soles, on the hard gravel-paved side walk of the street. At the time, he was in his slippers. At first, he was insensible. When he recovered from that state, he said to Dr. R. that he felt as if "all the bones of his feet were crushed". Both ankles and feet were contused. Distinct crepitus was heard on moving the left foot. Below the malleolus externus, and a little anterior to the axis of the fibula, was a projection caused by a fragment of bone, estimated to be about a cubic inch in size, which was seized between the thumb and fingers, and moved easily, but not extensively, beneath the skin. Moving this fragment caused distinct crepitus and severe pain. The toes and metatarsus could be turned inwards, on a plane with the sole, almost to a right angle, owing to a partial separation of the metatarsal from the tarsal bones. There was nothing abnormal observed in the motions of the astragalus upon the tibia. There was no displacement of the posterior extremity of the os calcis; but the patient stated subsequently, that, when his consciousness returned, he found the heel bone drawn up out of place. There was no fracture of the tibia or fibula. Pressure posterior to the cuboid shewed an unusual yielding space in that region. Cold water dressings were applied to the feet and ankle; and a fourth of a grain of the meconate of morphia was administered on the 30th, the sixth day after the accident, the left ankle and foot were carefully examined. The anterior and external portion of the os calcis, which articulates with the os cuboides, was fractured and separated; the fragment lying below, and pro-

jecting externally beyond the malleolar process of the fibula. Firm steady pressure by the thumbs, directed forward and inward, reduced it, the fragment suddenly slipping into place. A roller was turned firmly around the foot, and over a compress placed upon the fractured portion. The entire leg and foot were then encased in felt, previously softened, and the whole dressing retained in place by a roller. On the 2nd December, "although unable to bear either foot in a pendent or vertical position without discomfort and pain", he was conveyed home at his own earnest request; and Dr. Ruschenberger "has been told that he is not lame".

Remarks. Dr. R. says: "The accident was probably caused by the sole of the foot coming in violent contact with some inequality, such as a small pebble, opposite to the anterior extremity of the os calcis.

"About a week after this fracture, a boy of seventeen years of age, weighing probably less than a hundred pounds, attempted to desert, and leaped the wall at the same point. In his case there was severe contusion and sprains of both ankles, but no fracture. He was able to limp away nearly a half mile." (p. 291.)

DISLOCATION OF THE OS SCAPHOIDES.

Dislocations of the bones of the foot are rare, in consequence of the great strength of the ligaments by which they are bound together, and the very limited motion of which they are capable. The following case is therefore possessed of some interest: it is reported by Dr. Norris, of the Pennsylvania Hospital, in the *Pennsylvania Medical Examiner* for May 1851, p. 303.

Case. The patient, a large, pale, sickly man, was brought to the hospital on the 13th Feb. 1850. While in the delirium of fever, he had leaped from a window about twenty feet high, alighting on the ball of the foot. There was a very marked prominence on the upper surface of the foot, immediately posterior to the articulation of the first metatarsal bone; and the man complained of pain on attempting any movement of the foot. The integument was tense, but there was no external wound. An assistant having been directed to secure the leg, reduction was effected by placing the left hand on the foot, immediately in advance of the leg, while the right hand firmly grasped the extremity of the metatarsal bones, at the same time that the thumb was pressing back the prominent bone. Strong traction having been made, the bone suddenly yielded, slipped into its place with a snap, the patient screamed with pain, and the deformity at once disappeared. A figure-of-8 roller was applied over the foot, and the man closely watched. At the end of twelve hours, this was removed; but as there was no increase of swelling, it was reapplied. The man remained several weeks under treatment for his fever. On his dismissal, he was able, with a cane, to walk without difficulty.

CASE OF GLOSSITIS.

The following case, by Dr. C. T. Quintard, of Roswell, Georgiana, U.S., is quoted by the *Boston Medical and Surgical Journal* from the *Southern Medical and Surgical Journal.*

Case. On September 23, Dr. Quintard was called in consultation to see J. F., a wagoner, aged 28, who had been ill four days. Six weeks before, a dentist, in attempting to extract one of the larger molars on the right side, had broken off the crown, and left the root. For ten days a continuous pain was felt; it then became intermittent until the 12th instant, when it ceased. On the evening of the 19th, the pain returned; the patient applied a few drops of oil of cloves, and went to sleep. In the morning, the pain became severe, and the tongue was slightly swollen. During the 20th, he complained of pain in the back, and general *malaise.* In the evening, Dr. P. visited the

patient, prescribed a cathartic, and applied a blister about the anterior part of the neck.

Sept. 20*th*. The tongue, sub-lingual, and sub-maxillary glands, were much swollen; pain severe; the masseter muscles were rigid, particularly the right.

Sept. 22d. The patient was unable to articulate; tongue protruded between the lips, tense, red, and painful to the touch; breathing laborious; brow bathed in perspiration; surface in other places hot; pulse 100, and full; saliva flowing profusely. He had passed a restless night, with constant pain. He had had no dejection since the operation of the cathartic given on the 19th. He was bled to 25 oz.; a large dose of Epsom salts was administered, and a poultice of hops and meal applied to the neck. He was much relieved by the bleeding, and was able, after some effort, to swallow the salts. 6 P.M. Breathing easier; tongue not so painful; salts had operated well. The pulse being about the same as before, twenty-five ounces more blood were drawn, together with six or eight ounces by cups under the clavicles. At 9 o'clock, there was a free discharge of fetid pus from an abscess at the base of the tongue.

Sept. 23*d*. The patient was sitting up, quite cheerful. No pain; tongue not so much swollen, nor much lessened. The finger could not be passed back to the base of the tongue. Chicken-broth was ordered. In the evening, the discharge had ceased, but was renewed by using a probe.

Sept. 24*th*. The patient slept well till towards morning, when there was a recurrence of pain. The right side of the tongue was now more swollen than the left; and as there was evidently another abscess forming, and the pulse was again full and frequent, half a grain of tartar emetic was given every two hours. 5 P.M. He had taken but two doses of the tartar emetic, which acted freely on the bowels, as well as producing the desired effect. At 2 o'clock, the second abscess discharged much offensive pus. A cup of strong green tea, and half a grain of morphia, were ordered to be taken at 8 o'clock.

Sept. 25*th*. The patient was convalescent.

Among the causes which predispose to glossitis, are reckoned compression of the jugular veins (Stahl); ptyalism (Slegel, Frank, Hosack); rubbing the head with mercurial ointment, small pox, etc. (Trincavalleus). Among the occasional causes, are wounds, laceration, and contusions of the tongue; the application of emetic to the organ, burns; while the most frequent is the action of acrid or acro-narcotic substances on the tongue. Such effects have been produced by the juice of the daphne mezereon, by tobacco leaves, and by the sting of wasps, bees, and other insects. Dupont relates a case of a young man who, for a wager, took two bites of a toad, and was speedily attacked with severe glossitis. [Vide *British and Foreign Medico-Chirurgical Review*, July 1850, p. 54.]

The treatment of this disease is generally simple, consisting of venesection, scarification of the tongue, or incisions made parallel to the raphe, the introduction of ice into the mouth, and, if the patient can swallow, the administration of cathartics or laxatives. Emetics are highly commended by Dupont, Ruggi, Wettingius, and others, in the earlier stages.

OBSTETRICS.

PARTIAL PARALYSIS IN THE LATTER MONTHS OF PREGNANCY.

At a meeting of the Edinburgh Obstetrical Society, Dr. GRAHAM WEIR shortly detailed the history of two cases of paralysis of the sensitive nerves of the fingers, coming on in the latter months of pregnancy. In the first, the disease came on gradually at the ninth month; the fore-finger and thumb of the right hand were the parts affected. So complete was the palsy, that the patient was unable to feel a needle between the fingers. Immediately after delivery, sensation returned, and had continued perfect ever since. In the second case, the disease came on about the eighth month of pregnancy; the

parts affected were the thumb and two first fingers. The peculiarity in this case was, that sensation was not absent, but perverted. A needle placed between the fingers felt by the patient as if it were (to use her own words) of the thickness of a common fire-poker. In this case, recovery was not so immediate as in the former. After delivery, she suffered intense intermittent pain in the middle finger, the paroxysms being synchronous with the after-pains. This state lasted for four days; it then gradually subsided, and she became able to use the hand as formerly.

Several similar cases were mentioned by other members of the Society. [*Monthly Journal of Medical Science*, May 1851.]

PROFESSOR SIMPSON ON FISSURING AND LACERATION OF THE STRUCTURES OF THE PERINEUM AND CERVIX UTERI IN NATURAL LABOUR.

As the result of a long series of observations, Dr. Simpson has drawn the following conclusions:—

I. Fissuring and laceration of the cervix uteri and perineum are not, as is generally conceived, rare lesions during labour; on the contrary, they are very common occurrences; especially in primiparous labours.

II. These lesions are not, as has been often alleged, necessarily the result of mismanagement, but they occur constantly in practice, despite every modification of management; and in cases also in which no kind of management has been adopted.

III. Evidence of the great frequency of laceration of the anterior structures of the perineum is furnished by,—1. Almost every careful autopsy of women after delivery, whether assisted or not assisted during their labour; 2. By the contracted or shortened state in which the perineum is almost always found, when vaginal examinations are made for uterine disease in women who have borne a family; and, 3. By the fissuring or laceration itself being usually traceable (under careful tactile examination), particularly in first labours, when that examination is instituted in the interval of pain, immediately before the passage of the child's head, or after its birth.

IV. Lacerations of the perineum may be often felt beginning in the form of slight roughish rents or fissures upon the mucous surface of the perineum, and these may extend either backwards or forwards; and if they extend forwards, they at last run over the edge of the perineum, and along its cutaneous surface; the mucous and cutaneous structures of the perineum being thus sometimes lacerated, while its middle, cellular, and fascial tissues are comparatively entire, or at least not so deeply and extensively injured.

V. The proper management and support of the perineum no doubt modifies and diminishes this form of perineal lesion; but it fails far more frequently than is generally supposed in entirely preventing it.

VI. The evidence of the frequency of fissuring of the os and of the lower or vaginal portion of the cervix uteri is the same in character, and consists principally—1. In the frequency with which slight laceration of the edges of the os, and of the mucous and middle coat of the cervix, is detected in autopsies after natural labours, and particularly with first children; and, 2. In the permanent marks of its previous occurrence, as exhibited in those cicatrices and irregularities of the cervix uteri, which anatomists have long empirically, but correctly, laid down as proofs that they, in whose bodies they are found, have been previously mothers.

VII. Fissures and lacerations of the vaginal portion of the cervix uteri not unfrequently occur to a very considerable extent, in cases in which the tissues of the cervix have been rendered rigid by previous inflammation, by carcinoma, or by other morbid causes; and, in such cases, this fissuring or laceration, if limited to the lower or vaginal portion of the cervix, seems to be accompanied with little or no danger. MATERIA MEDICA AND PHARMACY.

MERCURIAL INHALATION BY SMOKING CHEROOTS AND CIGARETTES.

The inhalation of various medicines along with the smoke of cigars or cheroots, has been more than once recommended in this JOURNAL. In prescribing the method, the physician must take care that the patient be clearly told that the smoke is to be drawn into the lungs ; and the mode of doing this must be properly explained to him.

MR. J. H. RICHARDS, of Philadelphia, writes as follows in the *Medical Examiner* for June 1851 —"I have been informed by a gentleman of intelligence, who has resided for a long time in China and Manilla, that mercury, which is there regarded as a specific in the severe forms of hepatic disorder incident to the climate (and leading to its employment to an extent that would be considered extravagant by Europeans), is constantly exhibited in the following novel and peculiar manner. The black oxide is introduced into the Manilla cheroots, and, being inhaled, is thus presented in the form of vapour to the most absorbent surface in the body. The only difficulty is the inability of the physician to regulate the amount of effect. By intelligence on the part of the patient, however, this is obviated ; whereas its advantages are such as to obtain for it the preference in many cases over the ordinary method. *It certainly is a speedy plan of producing salivation.* I mention this fact, as it is interesting in itself, and may suggest other applications of the same principle." (p. 369.)

Would this plan be admissible in pneumonia ? Perhaps not. In syphilis, iritis, peritonitis, etc., we would urge upon our readers to make trial of this method of inhalation. Nothing can be simpler than the manufacture of mercurial cigarettes with the little machine in common use by smokers ; mingling the proper quantity of the black oxide, with some light and easily smoked tobacco. It may happen, however, that the nicotine is objectionable. In such cases, then, we would recommend the tobacco to be freed from this principle by maceration in acidulated water. It is right to state, that the smoking of mercurialised cigars is by no means, as Mr. Richards supposes, a novelty in the practice of medicine. The following formula was given many years ago by Bernard :—"*Cigarettes Mercurielles.* Bichloride of mercury, 4 centigrammes ; extract of opium, 2 centigrammes ; tobacco deprived of its nicotine, 2 grammes. Deprive the tobacco leaves of their nicotine by several macerations in acidulated water, wash them in fresh spring water, then dry them, and cut them up for making into paper cigarettes." These cigarettes are recommended *(L'Officine, par Dorvault)* in syphilitic ulcerations of the throat, mouth, and nose.

SAFETY OF ACETATE OF LEAD AS A MEDICINE.

MR. W. SWEETING, in the *Provincial Medical and Surgical Journal*, June 11, 1851, combats, as a vulgar prejudice, the assertion that acetate of lead is an active acrid poison. He expresses his belief, that no well-authenticated case is on record, wherein death has followed the administration of it, and he alludes to several cases recorded by Dr. Christison and Professor Taylor, in which as much as an ounce, and even an ounce and a half, were swallowed, and yet all the patients recovered. Mr. Sweeting then describes some cases of uterine hæmorrhage, bloody diarrhœa, etc., in which it has proved of the utmost value as a sedative astringent, given in five-grain doses, for many consecutive hours. One patient took as much as 576 grains of the acetate in sixteen consecutive days. Van Swieten gave sixty grains daily for ten days, and Mr. Daniel ten grains three times a-day, without any unpleasant effect, except a slight colic after the fourth dose. The largest dose given by

Mr. Sweeting was twenty grains; and in his experience of this medicine for fourteen years, he has never met in a single instance the ill effects usually ascribed to it. Being extremely liable to decomposition, acetate of lead should always be given *simply dissolved in distilled water*. These decompositions may have been the occasion of much mischief; and hence even opium is inadmissible. Care should also be taken to have the acetate very pure. In allusion to a fatal case, occurring in the person of a child, who took in small divided doses continuously given in the space of *nine weeks, thirty-three grains*, Mr. S. suggests the inquiry, whether minute doses may not have a tendency to accumulate in the system and produce its specific effects, whilst larger ones are carried out readily, and he adds,— "I more than half suspect that where acetate of lead, internally administered, has occasioned dangerous symptoms, the preparation has not been free from oxidation. It is the *oxide* which is injurious, and which, mixed with the cider in Devonshire, gave a cognomen to the colic prevalent in that county. The same obtains in painters' colic, from swallowing, owing to neglect of ablution, particles of litharge and red lead."

LIEBIG'S BEEF-TEA AND EXTRACTUM CARNIS.

Dr. William Beneke in the *Lancet* of January 4, 1851, strongly recommends—and, we think, for very sufficient reasons—Liebig's Beef-tea, when the patient requires to have administered, in small bulk, a good animal nitrogenous food. He quotes the following formula for preparing it, as given by Liebig :—"One pound of lean beef, free of fat, and separated from the bones, in the finely chopped state in which it is used for beef sausages, or mince-meat, is uniformly mixed with its own weight of cold water, slowly heated to boiling, and the liquid, after boiling briskly for a minute or two, is strained through a towel, from the coagulated albumen and fibrine, now become hard and horny. Thus we obtain an equal weight of the most aromatic soup of such strength, as cannot be obtained even by boiling for hours from a piece of flesh. When mixed with salt, and the other usual additions by which soup is usually seasoned, and tinged somewhat darker, by means of roasted onions or burnt sugar, it forms the very best soup which can in any way be prepared from one pound of flesh."

When beef-tea prepared in this way is evaporated in a water-bath, and cooled afterwards, it forms a brownish yellow extract, to which has been given the name of Extractum Carnis. In accurately following the above-described method of preparing the beef-tea, the quantity obtained out of six pounds of meat may be evaporated to three ounces, and those three ounces, after having cooled, form the "extractum carnis". One ounce of extractum carnis is therefore equal to thirty-two ounces of meat, whence it can easily be calculated how much of it is required for providing a patient daily with the constituent parts of three, four, five, six, or more ounces of meat. Dr. Beneke desires to see the extractum carnis introduced into the Pharmacopœia; and he mentions, on the authority of Dr. Von Breslau of Munich, that it is to be received into the *Pharmacopœia Bavariæ*. It is stated not to undergo any change for years, when kept in air-tight porcelain vessels.

REPORTS OF SOCIETIES.

SURGICAL SOCIETY OF IRELAND.

January 25, 1851.

Dr. Jacob in the Chair.

Case of Warty Ulceration of the Lower Extremity successfully treated. By Dr. Stapleton. M. W., labourer, aged 60, was admitted into Jervis Street Hospital, April 29, 1850, for extensive ulceration of the right leg, which he said had been pronounced incurable by several surgeons. Many years ago, whilst working in a quarry, his shin had been cut by the falling of a piece of stone. It was long before it healed, and remained healed but for a short period, when it again broke out, and continued gradually getting worse to the present time. The ulcer now measured upwards of three inches and a half in length, and seven inches and a half in breadth. Its centre seemed deeply excavated, but was not so in reality. It was covered with a dirty-yellowish substance, through which, on the inner side of the leg, there appeared several whitish warty eminences. There was a copious, thin, and very offensive discharge from its surface. The superior margin of the ulcer resembled that of a chronic ulcer of long standing. The inferior margin was surrounded by a wall of warty structure, in the widest part one inch and a half, and was fined down to an almost single wart on either side. A probe did not pass deeply by pressure on the ulcerated surface, nor through the warts on the lower margin. The patient's health was much impaired, his complexion was sallow, his appetite bad, and his sleep disturbed. The ulcer was treated by rest and position of the limb; its surface was covered with lint steeped in lotions, varied as its appearance required; strips of bandages were then applied, after the manner of a many-tailed bandage, and over all was a roller kept moistened by water. The ulcer was healed on the sixty-eighth day. The warts had now entirely disappeared. The constitutional treatment was mercurial and tonic.

Observations on a peculiar type of nervous fever, characterized by a functional excitement of the cerebro-spinal nervous centres. By Dr. McDowell. This fever is especially characterized by the existence of symptoms which denote a *functional excitement of the cerebral and spinal nervous centres*, especially of the latter. In most instances it attacks the young, having been met with in a large proportion of cases between the ages of twelve and eighteen. In no instance did the disease occur after the age of twenty-six, and, as far as was observed, one sex is not more predisposed to its influences than another. Dr. McDowell first met with cases of this affection in the latter part of the year 1846, the year in which cerebro-spinal arachnitis (or rather meningitis) appeared in this country epidemically to a limited extent; and he had little doubt but that some examples of this peculiar fever occurring at that period were regarded as cases of meningitis.

Between the symptoms which attend this *functional* affection of the spinal cord, and those which usher in inflammation of its membraneous coverings, there will constantly be found the strongest resemblance. When the one affection is unusually prevalent, there is a more than ordinary tendency to the development of the other. In 1846, when inflammations of the membranes of the spinal cord were frequent, and in many instances terminated fatally, it was observed, that the symptoms of excitement of the spinal cord frequently became developed in the progress of cases of ordinary continued fever, without in any way tending to produce an unfavourable result; and again, during the last few months, since fever complicated by the functional

affection of the medulla spinalis has become epidemic, there have been more cases of acute meningitis and myelitis than usual. It is therefore probable, that the epidemic influences which produce the one affection, have a tendency to induce the development of the other.

Since the year 1846, Dr. McDowell had been accustomed to meet with a few occasional examples of the disease, but during the last six months it had much increased.

In the *mode of invasion* of this disease, there is little variety to be observed. It is invariably ushered in by the usual symptoms of fever of varying intensity, but generally accompanied by more than the usual amount of *gastric irritability;* sometimes the vomiting is very distressing, and occasionally, but in a few instances only, the disease has been accompanied from the outset by marked depression and prostration of the vital powers, which amounted in one case to collapse, like that of cholera, and further resembled that disease in being attended by watery stools and vomiting of a whitish serous-like fluid. About the third or fourth day, in the majority of instances, a pecular group of symptoms become developed, which stamp this affection as different from any of the more ordinary forms of fever. These symptoms, which depend upon a *functional excitement* or *erethism* of the brain and spinal cord, may be thus enumerated.

1. *Exalted sensibility* of the cutaneous surface generally, but most highly developed in the integuments of the head, back of the neck, abdomen, and calves of the legs. 2. Severe *pains* shooting throughout different parts of the body, and most generally referred to the region of the spine, occiput, shoulders, loins, and lower limbs. 3. *Tenderness on pressure* over some portion *of the spinal column.* Sometimes the whole spine is intolerant of pressure, but more generally isolated points alone are thus acutely sensitive. The cervical portion of the column seems to be the one most generally thus affected. 4. *Rigidity of the muscles of the nape of the neck*, especially of the sterno-mastoid and trapezius muscles, which limits the motion of flexion of the head, and in some instances completely prevents it. Sometimes the erector muscles of the spine are similarly excited. 5. In many of these cases, there is *the peculiar expression of trismus*, particularly in the upper half of the face, the forehead being thrown into transverse wrinkles, and the eyes having the characteristic peering expression of that affection. 6. This fever is very often accompanied by *headache*, which is *referred to the occipital region;* or when more diffused, is most keenly felt in the posterior region of the head. 7. There is always present more or less of *epigastric tenderness*, sometimes the whole of the abdomen is intolerant of pressure, but this belongs in all probability to the augmented sensibility of the surface generally, and has its seat in the integument. This symptom, by its undue prominence, may give rise to the suspicion that peritonitis exists, and so mislead the practitioner. This is illustrated by one of the cases to be presently mentioned.

In none of these cases were there any indications of congestion of the intestinal or bronchial mucous membranes, but very often a short hacking cough with hurried breathing has been present, resembling that with which practitioners are familiar in cases of hysteria, and to be referred to the same source—viz., to functional excitement of the spinal cord.

In addition, there are the symptoms of ordinary continued fever, a pungently hot skin, and a greatly accelerated circulation, the pulse ranging from 120 to 140 (in one case mounting up to 150), *but without the secretions being much vitiated*, the tongue continuing moist, the bowels acting naturally, and the urine not being sensibly altered in any of its qualities. In some cases there has been slight delirium at night, but in all of them there was observed an *irritability of disposition* and an amount of *anxiety* and of *restlessness* quite disproportional to the other symptoms, but which plainly indicated a peculiar disturbance of the sensorium.

As to the *duration* of the disease, it was observed in a large number of the cases that convalescence occurred on the eighth day. In others the disease lasted for ten days, and in a few instances only was convalescence longer postponed. In some the occurrence of perspiration marked the crisis of the disease. In one case jaundice proved critical, whilst in the greater number no marked crisis occurred, but a rapid subsidence of the disturbance of the nervous centres preceded by a short interval the disappearance of fever.

In no one instance did this fever terminate fatally.

In some cases, the fever was of a low adynamic character, and in these a tardy convalescence resulted, and in one instance cancrum oris supervened, but the child ultimately recovered.

Relapses did not belong to this type of fever, in which it was contrasted with a bilious form of fever latterly very prevalent, in which relapses were extremely common.

Lastly, instead of constituting a distinct type of fever, the symptoms of spinal irritation were observed to occur in the course of maculated typhus or of bilious relapsing fever.

The following cases, which are very briefly described, will illustrate many of the preceding remarks :—

Case I. Jane Fox, aged 22, admitted August 10th (ill two days), labouring under the symptoms of ordinary continued fever. Two days subsequently (the fourth of her illness), she complained of severe pains all over her body, aggravated either by pressure or by motion. The seat of this *exalted sensibility* was the skin; the head was rigid; the muscles of the neck hard and contracted; the head could be but very slightly flexed, and the attempt gave great pain; there was a constant pain in the occipital region, and a diffused tenderness of the scalp; the nape of the neck and the calves of the legs were especially tender to the touch.

13th *(fifth day)*. Patient is almost unable to move from extreme "soreness all over her"; she is even unwilling to allow herself to be touched by the nurse; there is much pain in the back complained of; pulse 130; tongue moist and furred.

14th. Diminution of all these symptoms. 16th (*eighth day*). Convalescent.

In the next case, the disease began with great violence, and presented at first many of the symptoms of cholera.

Case II. Anne Collins, aged 9, admitted August 9th into Dr. Corrigan's ward: *ill twenty-four hours.* On admission, there was frequent vomiting and purging; the discharges from the bowels were thin and serous, and collapse very quickly supervened. Counter-irritation, external warmth, and stimulants were freely employed. The vomiting and purging ceased, and the *third day* reaction was fully established, and slight fever was present. On the *fifth day* exalted sensibility of the surface was present; the legs were especially tender to the touch; the head was rigid, and could not be bent; and the trapezius and sternomastoid muscles were contracted and tender; the little patient was peevish, restless, and irritable to the greatest degree; the pulse was extremely rapid, and the surface of the body very hot. *Eighth day*, convalescent.

In this case, extreme debility remained, with remarkable pallor of the face; and, after a few days, gangrenous sloughing of the gums occurred. The disease, however, was arrested before the cheek became implicated; and, after a tedious illness, the child ultimately recovered.

Case III. Michael Maguire, aged 15, admitted Sept 18th. On admission, there was much fever present, although the boy was only ill a *few hours.* On the *third day*, frequent vomiting was present, with excessive tenderness of the epigastrium. There was complaint made of severe pain in the occiput and in the nape of the neck, the muscles of which were rigidly contracted. The patient complained of flying pains all over him, and there was tenderness to the touch of the nape and of the *right* leg. The face had much of

the aspect of tetanus. There was a singular amount of anxiety and of despondency present. The breathing was hurried and hysterical.

Fifth day. There was little or no improvement; the scalp was very tender to the touch, and the face still wore the tetanoid expression; there had been little sleep, with delirium, but there was no intolerance of light. The circulation was greatly hurried, and the skin was very hot; but the tongue was moist, and the bowels acted naturally.

Sixth day. The patient had slept well, and was better in every respect.

Eighth day. Skin cool and perspiring; no pains anywhere; convalescent.

Case iv. Anne Gahan, aged 24, admitted October 2nd; her illness began with shiverings, followed after two days by vomiting and shooting pains throughout the body. The day of admission was the sixth of her illness; there was much fever present; the skin was pungently hot, and the pulse beat 130 in the minute. There was great pain in the shoulders, back of the head, and spine, aggravated by the least motion; the head was stiff, and the muscles of the nape rigid. The patient screamed loudly when the least pressure was made over the dorsal vertebræ. The legs also were acutely sensitive when touched. The upper part of the face presented the appearances of trismus, the forehead was wrinkled transversely, and the eyes were more than half closed. There was no delirium or subsultus tendinum. The tongue was moist and furred. The slightest pressure on the epigastrium was intolerable, and the abdomen generally was tender when pressed on.

Seventh day. The pain was more localized in the occipital region, but the patient felt much relieved and could move more freely; the pulse was reduced to 100. The conjunctivæ were yellowish, and the epigastrium was yet tender.

Eighth day. Pulse 80; patient is deeply jaundiced, but feels quite free from pain, and there is no longer any over-sensitiveness of the surface; debility.

Ninth day. Convalescence established; recovered rapidly.

Case v. In this case the excessive sensibility of the abdomen with fever caused peritonitis to be suspected. Rose Clinton, aged 8, admitted November 20th; ill three days; for five days after admission the symptoms of mild continued fever were present. On the eighth day of her illness (Nov. 25th) she complained greatly of pain in her abdomen, the surface of which was extremely intolerant of pressure. She lay on her back, and was unwilling to move or to allow herself to be moved. The pulse was 122 and small, and much fever was present. The clinical clerk on duty suspecting peritonitis, leeched the abdomen, and administered mercury. On the next day (the ninth of her illness) the true nature of the case was manifest, for the signs of spinal irritation had become fully developed. There was pain in the back of the head and neck. Rigidity of the trapezius and sterno-mastoid muscles with consequent inability to flex the head fully. There was also "exalted sensibility" of the cutaneous surface generally to a remarkable extent. The abdomen was still tender, but no longer predominantly so. Her face was expressive of pain and suffering.

Thirteenth day. Convalescence established.

Case vi. J. Gallagher, aged 14, admitted Nov. 2nd; ill four days. He attributed his illness to over fatigue from excessive walking. When admitted he laboured under fever with excitement of the spinal nervous centre. The pulse was 120; the skin was pungently hot; the epigastrium was extremely tender; there was excessive "soreness" of the cutaneous surface, especially of the legs; the muscles of the nucha were rigid, preventing the head from being flexed; the face bore the expression of trismus in a marked degree; the breathing was very hurried, and the patient had a short frequent ringing cough, unaccompanied by any expectoration. Careful examination failed to discover any evidences of thoracic disease.

Seventh day. There was a critical perspiration; from that period convalescence was established.

The following were Dr. M'Dowell's conclusions.

1. That there is a type of fever characterized and accompanied by a functional affection of the cerebro-spinal nervous system.

2. That the predominance of "spinal irritation" distinguishes this affection from the ordinary forms of fever in which "cerebral symptoms" are of more common occurrence.

3. That the symptoms which denote excitement of the spinal cord are the following :—morbid exaltation of the cutaneous sensibility—pains along the course of the spinal nerves—spinal tenderness—rigidity of the muscles of the nape of the neck—the expression of trismus—neuralgic headache, and headache chiefly referred to the occipital region—gastric irritation, and sometimes irritation of the pulmonic branches of the vagus nerve.

4. That these symptoms present the strongest contrast to those of typhus, in which we generally meet with a tendency to stupor, listlessness, deafness, and other evidences of blunted sensibility.

5. That the disease hitherto has proved mild, tending to recovery on or about the eighth day ; that relapses do not occur; and that typhoid symptoms never are observed.

6. That instead of constituting a distinct type of fever, these signs of spinal irritation may occur in the progress of other fevers, and without tending to an unfavourable result.

7. That this affection is liable to be confounded with hysteria, peritonitis, gastritis, or gastric fever, or with cerebro-spinal meningitis.

8. That the combined symptoms of headache and epigastric tenderness which in other fevers are best treated by local depletion over the stomach, will in these cases be most effectually relieved by the application of leeches to the posterior region of the head; and for this reason, that in the type of fever under consideration, the gastric irritability and epigastric tenderness depend upon a functional lesion of innervation, whilst in other instances it is the brain which sympathizes with a deranged gastro-intestinal mucous membrane.

Observations on the Statistics of Venereal Sores in the 57th Regiment. By A. C. Gordon, M.D. During the year, from 1st April 1849, to 31st March 1850, the regiment having been very much detached, the average strength at head quarters was only 408 ; yet out of this number the aggregate period during which such of the men as were affected with local venereal sores were in hospital amounted to 1210 days, making a loss to the state on this account of work equal in value to £65 10*s.* 3*d.* The sick list on account of venereal diseases was *below* rather than *above* the general average throughout Ireland ; but supposing, that for every 500 soldiers there is a loss to the state, in consequence of the prevalence of local venereal sores, of the work of 1210 days, then as the army in Ireland amounts, at the very smallest computation, to 24,000 men, we have an annual cost to the state of £3,120 on account of this one form of disease.

During the year ending 31st March 1850, the following numbers were treated on account of venereal diseases in the head-quarter hospital out of an average strength of 408—viz. :

Species of Venereal Disease.	Number admitted.	No. of days in hospital.	Amount of Soldiers' pay.
			£ *s.* *d.*
Syphilis primitiva	53	1210	65 : 10 : 3
——— consecutiva	13	462	25 : 5 : 11
Ulcers on penis non-syphilitic	2	43	2 : 3 : 7
Bubo simplex	10	281	15 : 4 : 5
Gonnorrhœa	32	481	26 : 1 : 1
Hernia humoralis	3	42	2 : 5 : 7
Total	113	2519	136 : 10 : 9

The forms of venereal ulcers that had been observed to prevail since the return of the regiment from foreign service, on 13th Sept. 1846, to 31st March 1850, may be reduced to six.

Of these, the first, or "Hunterian chancre", is a round excavated ulcer with hard base, edges a little prominent, and I would add, its interior having, when closely examined, a somewhat reticulated or honey-combed appearance. The second is a superficial ulcer without hardness, with elevated edges, whitish or reddish surface, and no appearance of granulations. The third is also a superficial ulcer, destitute of hardness, but its centre is considerably elevated—generally of a bright red colour, and fungous appearance. The fourth is mere excoriations of the glans and prepuce, attended by more or less purulent discharge. The fifth is the phagedenic sore, having a corroding appearance, without hardness or granulation, and increasing rapidly in size. The sixth is the sloughing ulcer, which first commences in a small black spot, after which sloughing extends from this point to an indefinite depth below the surface.

There are cases in which the local ulcer assumes so anomalous an appearance as to render it a difficult matter to refer it with precision to either of the above classes; while again, it not unfrequently happens that one and the same ulcer may, during its continuance, manifest in succession the more essential characters of two or more of those just described.

The total number of admissions on account of the various forms of venereal ulcer, now briefly described, were, during the entire period, as follows :—viz., 55 of No. 1; 106 of No. 2; 20 of No. 3; 20 of No. 4; 11 of No. 5; 3 of No. 6; and 27 not definitely described; making in all an aggregate of 242 cases.

The greatest number of admissions took place during the first half year that the regiment was at home; 79 having occurred between the 13th of September 1846, and the 31st of March 1847, out of an average strength of 715. During the following year, on the contrary, the ratio of admissions was smaller than in any other corresponding period; 56 cases only having occurred in an average strength of 818. In the two succeeding years, the admissions on account of primary sores were, respectively, 54 and 53, in an average strength of 408.

Different forms of ulcer seemed to prevail at different stations occupied by the regiment previous to its arrival in Dublin; thus, during the few days that it was quartered at Chatham, three cases came under observation, and of these one was a *Hunterian* and one a *phagedenic* sore, the third being a simple superficial sore, such as is characterized as No. 2. At Canterbury and Dover, the first form of ulcer (Hunterian) constituted a little more than one-fifth of the admissions; at Windsor and Hull, about one-twelfth; while at Enniskillen, during the two years that the regiment remained there, this form of ulcer formed, in the first, one-third of the admissions; and in the second, one-fourth.

Of the 242 cases of primary sores that came under observation during the period referred to, 192 were treated without the constitutional employment of mercury; and of this number, six were followed by "secondaries", while of fifty cases in the treatment of which mercury was administered constitutionally, *secondaries* occurred in four. The only forms of primary ulcers that were followed by constitutional or secondary symptoms, were the first, or Hunterian, the second, or superficial, and the fifth, or phagedenic. Of the four cases of Hunterian chancre that were followed by secondaries, three had been treated without mercury, and one with mercury. Of the three first mentioned, the form of secondary affection was, in the first, "a vesicular eruption, and nocturnal pains in the limbs"; in the second, "red spots upon the skin, intermixed with small tubercles"; and in the third, which was complicated with phymosis, "condylomata" supervened. In the fourth case, which in the first instance had been treated with mercury, the secondary affection consisted in "aphthous sores in the mouth, and eruption", although of what precise nature did not distinctly appear.

Of the three cases of the second form of ulcer that were followed by "secondaries", all had been treated for the primary affection without mercury; one of these was complicated with gonorrhœa, and there was at the same time an incipient bubo in the left groin, which however terminated in resolution. In this instance, the particular secondary affection that supervened, was "a squamous eruption". The other two were uncomplicated, and in them the secondary affection was also "squamous eruption" in one; in the other, there was an eruption, but of what particular character is not stated.

On the three cases of phagedenic ulcer that were followed by "secondaries", mercury had previously been employed constitutionally in the treatment; and the characters of the secondary affection varied in all. Thus, in the first case, which was uncomplicated, the secondary disease was a "squamous eruption". In the second, which was also uncomplicated, the secondary disease consisted in "superficial ulcers of the tonsils, and a *pustular* eruption"; and in the third, the patient had shortly before been treated (without mercury) for an Hunterian chancre, which appears to have healed without any complication. On his readmission with phagenedic sore, there was an incipient bubo in the left groin, which however did not suppurate. Mercury was employed constitutionally, and the secondary disease that followed was "a *papular* eruption, and enlargement of the cervical glands."

In none of the cases where the local sores were subsequently followed by "secondaries", did suppurative bubo occur; for in the two cases complicated with enlargement of the inguinal glands, the inflammation terminated in resolution.

Of the 242 cases of local ulcer, treated in the regimental hospital, buboes occurred in 68; and of this number, the complication was in the right groin in 22; in the left, in 33; in both sides, in 7; and in 6 cases, the precise side affected is not stated. Of the 192 cases treated without mercury, buboes occurred in 53; being in the proportion of 3·62; and 6, as has already been stated, were followed by "secondaries", being 1 in 32. Of the 50 treated with mercury, bubo occurred in 15, or 1 in $3\frac{1}{3}$; and "secondaries" supervened in 4; being 1 in $12\frac{1}{2}$. The average number of days that the 10 cases of constitutional symptoms were in hospital was 24; the most obstinate one having been 55, and the slightest only 3.

March 8, 1851.

Dr. Jacob in the Chair.

Case of Secondary Cancerous and Encephaloid Disease. By Mr. Banon. Case. On the 19th of May, 1849, P. F., labourer, aged 40, was admitted into hospital. He had a cancerous wart on the under lip on the right side, presenting the characters of this disease in an early stage. He first observed it a few weeks previously, and attributed it to smoking. His general health was good, and the glands in the infra-maxillary region and elsewhere were not enlarged; it was hence considered to be a case favourable for operation. In seven days afterwards the man was discharged apparently cured, and with a very healthy-looking cicatrix.

In January following (a period of about eight months) there was, *for the first time*, observable a small hard swelling at the angle of the jaw on the right side; and the patient was again admitted to hospital on the 31st of January, 1850.

The swelling increased, and an abscess soon formed, which at first discharged healthy pus, but in a little time gave rise to a deep unhealthy-looking excavation. For a time the disease would appear to be arrested, but would soon break out with renewed violence. The ulcerative process, combined with sloughing, at length destroyed most of the soft parts on the right side of the neck. An immense cavity existed, at the bottom of which the great vessels of the neck could be distinctly seen. The danger of a fatal and

sudden hæmorrhage was now imminent, but in a little time small granulations sprung up, by which the denuded vessels were covered, and the danger of hæmorrhage obviated. An excessively copious ichorous discharge took place constantly, and the patient's strength rapidly gave way. He, however, very seldom complained of pain. He became much attenuated, and died on the 21st of last September. About a month previous to his death, a tumour showed itself in the opposite side of the neck, which was evidently soft cancer or medullary sarcoma. The submaxillary and part of the parotid glands were at this time completely dissected, and laid bare by the ulceration. Their function was nevertheless carried on without impairment. The *straw-coloured skin* mentioned by French authors was at this period well marked in the case of the patient.

Remarks. It was worthy of remark, that the disease should have remained so long quiescent. From the time of the operation in May 1849, until January 1850, no sign of a return of the disease could be observed; and if we look on this as a second occurrence of cancer, we must suppose that the poison had been conveyed from the cancerous wart to one of the submaxillary glands previous to the operation, and there remained latent for eight months. We should, in even the most favourable cases of carcinoma of the lip, as well as elsewhere, make a most guarded prognosis as to the curative effects of operations. The disease may have originated a second time in the submaxillary region, and the last affection may have had no direct connexion with the first. The occurrence of the cerebriform cancer in the opposite side of the neck in the latter stage, was a remarkable evidence of the close connexion between the different forms of cancer. No examination of the internal organs could be made.

March 22, 1851.

Mr. Trant in the Chair.

Case of Punctured Wound in the Abdomen: Recovery. By H. C. Field, M.D.

Case. On the 22nd of November, a gentleman, while sitting at dinner, in a fit of irritation, exclaimed that he was tired of his life, and immediately stabbed himself with a carving knife. On entering his room, Dr. Field perceived the floor covered with blood, and the patient extended on a sofa in a corner of it, apparently lifeless. He could not feel any pulse. He immediately obliged him, with great difficulty, to swallow some brandy. Blood was flowing profusely from a wound in his abdomen, to the left side of, and near to, the umbilicus. The blood, which was of a dark colour, flowed freely in one continued stream, so as to threaten immediate death. Having failed to suppress the hæmorrhage by firm compress and bandage, Dr. Field introduced to the bottom of the wound a dossil of lint, the end being kept outside, and applied firmly over it a graduated compress and a broad bandage. This arrested the further flow of blood, and a cordial draught, with forty drops of laudanum, was then administered. A feeble tremulous pulse at the wrist could now be felt, but the patient appeared in a sort of faint. He was bathed in a cold sweat, his extremities lay still and motionless, he vomited at intervals, and his urine and bloody fæces passed unconsciously, and his respiration was slow and laboured. In this state he remained for seven hours. About this time the vital powers showed a disposition to reaction. He expressed, in a few broken accents, the general uneasiness, and complained of pain and numbness in the lower extremities, particularly in the left; this, with restlessness, disturbed him during the remainder of the night, which was passed without any sleep, notwithstanding an anodyne.

Nov. 23rd. A medical attendant remained with him during the night. There was no recurrence of hæmorrhage; he still appeared in a state of extreme debility, and felt great nausea, which occasionally increased to hic-

cough and vomiting; he also complained of numbness and pain, extending down the left limb to the foot; there was slight tenderness about the wound on pressure; pulse 120, feeble, and irregular. To relieve the state of the stomach, as well as to allay the general irritability, and ensure perfect rest, Dr. Field directed the saline effervescing mixture every four hours, with fifteen drops of laudanum, also fomentations to the abdomen. *Evening.* He still complained of pain and numbness in the thigh and leg; the abdomen was more tender; there was thirst; pulse 110 and feeble; tongue white and furred; skin hot and dry. He was ordered to continue the draughts at longer intervals, also the use of ice, and the fomentations every four hours.

Nov. 24th. He had some quiet and refreshing sleep during the night, and felt himself relieved; had had two stools, each containing a large quantity of dark clotted *blood;* pain and numbness in the left limb not so troublesome; abdomen tender on pressure. Ordered the fomentations to be repeated.

Nov. 25th. He had several evacuations, each containing a quantity of clotted blood; fever much less; pulse 90; tongue foul; pain and numbness in the extremity still distressed him; there was no pain about the wound; the dressings came away, when a quantity of *fæculent* matter, mixed with blood and some pus, was discharged.

Nov. 27th. The wound discharged healthy pus unmixed with fæculent matter; he was free from fever.

Dec. 8th. He attempted to stand, but the left leg yielded beneath his weight.

Jan. 2nd. His health and strength was considerably improved; for some time the left extremity was nearly paralytic, though frequently attacked with paroxysms of pain and numbness.

Peculiar Injury of the Ankle-Joint. By Dr. Power. The patient, aged 28, a sweep, was admitted under his care into Jervis-street Hospital, on the 12th of November, 1850, suffering from a recent injury to his left lower limb. The foot was rotated considerably inwards; the outer edge of the foot was directed outwards and downwards, so that when the patient attempted to stand, this part of the foot pressed against the ground. The inner edge of the foot looked upwards and inwards. The dorsum looked upwards and outwards; and the sole of the foot looked obliquely towards the foot of the opposite side. The *external malleolus* was more prominent than natural; and instead of the ordinary well-marked sulcus underneath it, there existed a firm ridge of bone, which accompanied the motions of the foot, and disappeared when the latter was restored to its natural condition. The measurement from the lowest point of the external malleolus to the outer edge of the foot, was half an inch greater than in the natural position. The internal malleolus appeared buried in an angle formed between the foot and leg; still it could be distinctly felt. The inner edge of the foot appeared drawn up towards this malleolus, and these were nearer to each other by half an inch than the ordinary position of the limb. In a word, the foot presented very much the appearance of ordinary "*talipes varus*". The toes were rather more elevated than usual. The circumference of the limb, corresponding to the two malleoli, was found to be fully one inch more than the opposite side, or than the same limb when the patient left the hospital. A good deal of serous effusion was present both in the foot and leg. The finger could be made to sink into a longitudinal groove between the tibia and fibula. The latter bone could be traced in its entire length, without any solution of continuity; no crepitus whatever could be detected. By flexing the leg upon the thigh, and then with one hand laying hold of the heel, whilst with the other he grasped the anterior part of the foot, and by drawing the foot downwards from the leg, rotating it outwards at the same time, Dr. Power restored the foot to its natural position with the greatest ease; and this movement was attended with very little pain to the patient. When the foot was so

replaced, it was clearly ascertained that there existed no fracture of the tibia in any portion of its length.

The patient related the following history of the manner in which the accident was produced. He stated that he had been in company with some persons of his own calling, that they were intoxicated, and had quarrelled. One of them laid hold upon the patient's leg, placed the inside of it in front of his own knee, and then with both hands tried to break it, as he would "a stick or a turf".

This was an accident the reverse of that described by Mr. Pott, unaccompanied by any fracture whatsoever. Dr. Field considered the case an example of *diastasis*, or separation between the tibia and fibula at their inferior articulation. The forcible rotation of the foot inwards (whilst at the same moment the inner malleolus was forcibly pressed against by the knee of the person inflicting the injury) would be most likely to be accompanied by such a displacement outwards of the astragalus as that, in following the motions of the foot, the external surface of this bone would be made to press against the corresponding articulating surface of the fibula with considerable force. The violence being still continued, the fibula must either give way, or the external lateral ligament be torn ; but, as has been already stated, the fibula remained entire; the great probability was, therefore, that the external lateral ligament was ruptured, and not only so, but from the fact of the fibula being separated from the tibia, either the strong interosseous structure connecting these bones inferiorly must have been ruptured also, or a small portion of either of them must have been broken off. But of the existence of any such fracture there was no evidence. Hence the interosseous structures inferiorly must have been torn, and in this manner the fibula became disconnected from the tibia. The mortice for the reception of the astragalus thus became widened, and this latter bone could be moved with comparative freedom in its socket. It was more than probable that this same violent turning of the foot inwards forcibly stretched the peroneus brevis and longus ; and these muscles being thus prevented from exerting their contractile powers, the foot was left to the uncontrolled action of the muscles at the inside of the leg, thus giving the peculiar direction to the sole of the foot. By proper manipulation, the foot was easily reduced to its natural position, but when left to itself it was drawn back again to the abnormal condition.

The apparatus applied was that recommended by Dupuytren for fracture of the lower extremity of the fibula, instead with the splint applied to the outside of the leg. The thick extremity of the pad was made to rest against the lower part of the external malleolus. The upper portion of the splint and pad having been secured to the leg by the circular bandage, the luxation was reduced ; and the foot having been rotated outwards, so that the external edge was firmly drawn towards the splint, it was made fast in this situation.

The patient continued in hospital till the 13th of December, being a period of one month. At this date he left the hospital, but was not able to move about without suffering and insecurity. He was readmitted therefore upon the 19th of December, and again subjected to the same mode of treatment. On the 7th of January following, he was discharged cured, and continued to enjoy the free and perfect use of the limb.

Case of Polypus Uteri. By R. Johns, M.D. This was a specimen of the channelled polypus, described by Dr. Oldham, at an early stage of development. Dr. Johns differed from Dr. Oldham, who described the channels as being placed on the internal surface of the polypus. He believed that these cavities belonged more to the external than the internal surface of the polypus. The patient was a lady, aged 39. Dr. Johns removed the polypus by ligature and excision ; and the patient had continued well.

New Instrument for Cupping the Uterus. By T. R. Mitchell, M.D Two instruments were employed : the one, an exhausting syringe with a cup

at its extremity to hold the blood (this instrument is about fourteen inches long, and is furnished with a tube to admit the air into the cup at will, and by that means to overcome the exhaustion, a matter of much moment, as in the application of the instrument it is occasionally necessary to remove it before the exhaustion has ceased); the other instrument is a scarificator, of the same length, having three lancets set on a revolving pin, capable of being set and discharged at the distal end of the instrument. Both instruments are straight, and are something less than the circumference of a shilling in diameter, to permit their passage through a speculum. The patient having been brought before a good light, and placed upon her left side, the speculum is introduced, and the neck of the uterus brought into view, all adhering mucus being previously removed, the exhausting syringe is applied and the part made tumid by exhaustion; the scarificator is then used, and if a large quantity of blood is required, the incisions may be crossed. This is effected without any pain to the patient; the exhausting syringe can then be used as often as necessary, and as much blood taken away as the operator may wish; no dressing of any kind is required.

PROVINCIAL MEDICAL AND SURGICAL ASSOCIATION.

The Nineteenth Anniversary Meeting was held at Brighton, on Wednesday the 13th, and Thursday the 14th of August, 1851. The following gentlemen were present. We regret we have not had materials for the compilation of a complete list. Above three hundred members were present.

Alford—R. U. West, Esq.
Arundel—Silas Stedman, M.D.
Aylesbury—Robert Ceely, Esq.
Basingstoke—Thomas Workman, Esq.
Bath. J. S. Bartrum, Esq.; W. Church, Esq.; W. Davies, M.D.; Edw. Hodges, M.D.; G. Norman, Esq.; John Soden, Esq.; Thomas Stokes, Esq.; James Tunstall, M.D.
Bexhill—F. Wallis, Esq.
Birmingham—G. B. Knowles, Esq.; J. Wickenden, Esq.
Brentford—G. Cooper, Esq.
Brighton—J. C. Burrows, Esq.; Charles Carpenter, Esq.; C. W. Crowdy, M.D.; H. Davies, M.D.; Richard Dill, M.D.; G. Drummond, Esq.; J. C. Franz, M.D.; T. B. Horne, Esq.; G. S. Jenks, M.D; R. H. Kemp, Esq.; W. King, M.D.; George King, Esq.; John Lawrence, Esq.; G. Lowdell, Esq.; J. M'Whinnie, M.D.; James Oldham, Esq.; E. L. Ormerod, M.D.; G. E. Pocock, Esq.; George Royde, Esq.; R. Rugg, Esq.; S. K. J. Scott, Esq.; B. T. Seabrook, Esq.; T. H. Starr, M.D.; B. Vallance, Esq.; Wm. Wilton, Esq.; T. B. Winter, Esq.
Bristol—C. J. Fox, M.D.
Brockton—Joseph Hickman, Esq.
Callington—John Kempthorne, Esq.
Cambridge—G. M. Humphry, Esq.
Canterbury—James Reid, Esq.
Cheltenham—A. H. Hull, Esq.; J. D. Hull, Esq.; Thomas Smith, M.D.
Chichester—Allen Duke, M.D.; J. M'Carogher, M.D.; N. Tyacke, M.D.
Chester—J. Edwards, M.D.
Chiswick—Harrington Tuke, Esq.
Clifton—John Colthurst, Esq.
Cowfold—Thomas Gravely, Esq.
Crawley—Thomas Smith, Esq.
Croydon—G. Bottomley, Esq.; W. Chalmers, M.D.; C. Lashman, Esq.; E. Westall, Esq.
Cuckfield—T. S. Byass, Esq.
Dover—George Soulby, M.D.
Farnham—W. Newnham, Esq.
Great Grimsby—Thomas Bell, Esq.
Guildford—A. Napper, Esq.; James Stedman, Esq.
Hailsham—J. M. Cunningham, M.D.
Hanwell—John Conolly, M.D.
Hartfield—William Wallis, M.D.
Hastings—W. A. Greenhill, M.D.
Hayes, Middlesex—W. Conolly, M.D.
Hereford—J. B. Lye, M.D.
High Wycombe—William Rose, Esq.
Hillingdon—A. Stilwell, Esq.
Hull—F. R. Horner, M.D.; J. A. Locking, Esq.; Edward Wallis, Esq.
Hurtspierpoint—H. M. Holman, M.D.; R. Weeks, Esq.
Leeds—R. G. Mayne, M.D.
Leicester—Thomas Paget, Esq.
Lewes—Henry Moon, M.D.
Lindfield—J. H. Bull, Esq.
London—William Baly, M.D.; J. M. Beane, Esq. (Peckham); Jno. Bowling, Esq. (Hammersmith); T. L. Blundell, M.D.; I. B. Brown, Esq.; George Burrows, M.D.; John Rose Cormack, M.D. (Putney); Edwards Crisp, M.D.; Mark Dewsnap, Esq. (Hammersmith);

S. Hare, Esq.; William Harvey, Esq.; Thomas Hodgkin, M.D.; Joseph Hodgson, Esq.; C. F. J. Lord, Esq. (Hampstead); Henry Oldham, M.D.; John Propert, Esq.; A. Shaw, Esq.; Francis Sibson, M.D.; T. H. Silvester, M.D. (Clapham); John Snow, M.D.; T. Taplin, Esq.; Theophilus Thompson, M.D.; Joseph Toynbee, Esq.; W. H. Walker, Esq.; Charles West, M.D.; Charles J. B. Williams, M.D.; Forbes Winslow, M.D.; James Yearsley, Esq.

Long Sutton—Henry Ewen, Esq.
Maidstone—William Addison, M.D.
Manchester—John Bridecook, Esq.; S. Crompton, Esq.; John Hatton, Esq.; Edmund Lyon, M.D.; T. Radford, M.D.
Melton—John Kirkman, M.D.
Needham Market—J. Bedingfield, M.D.
Newhaven—John Noakes, Esq.
Northampton—Arch. Robinson, M.D.
Norwich—W. H. Ranking, M.D.
Norwood—W. Street, Esq.
Oswestry—Peploe Cartwright, Esq.
Pocklington—Thomas Hornby, Esq.
Reading—Charles Cowan, M.D.
Reigate—P. Martin, Esq.; John Steele, Esq.
Rochford—John Grabham, Esq.
Romsey—J. R. Beddome, Esq.
St. Asaph—O. Roberts, M.D.
St. Leonard-on-Sea—P. Blakiston, M.D.
Sevenoaks—George Kelson, Esq.; J. L. Worship, Esq.
Southam—H. L. Smith, Esq.
Southampton—O. W. Williams, M.D.
Southwold—Robert Wake, M.D.
Spalding—E. Morris, M.D.
Steyning—R. A. Frew, Esq.
Stockport—G. Downs, Esq.; J. Rayner, Esq.; George Turner, M.D.
Stowmarket—C. R. Bree, Esq.
Stratford-on-Avon—T. Thompson, M.D.
Sunbury—J. S. Soden, Esq.
Taunton—F. H. Woodforde, M.D.
Thrapston—J. G. Leete, Esq.
Timsbury—J. Crang, Esq.
Torquay—J. J. Field, M.D.; C. Radclyffe Hall, M.D.; C. B. Nankivell, M.D.
Totnes—John Derry, Esq.
Tring—Edward Pope, Esq.
Tunbridge Wells—W. H. Cook, Esq.; R. R. Gream, Esq.; G. Moore, M.D.; G. Moore, Jun., Esq.
Uxbridge—James Stilwell, Esq.
Warminster—G. Vicary, Esq.
Week St. Mary—J. K. Tuke, Esq.
West Coker—Charles Penny, Esq.
Westerham—C. M. Thompson, Esq.
Winchelsea—R. C. N. Davies, Esq.
Wingham—F. H. Sankey, Esq.
Worcester—H. D. Carden, Esq.; Sir Charles Hastings, M.D.; Jonas Malden, M.D.; George A. Sheppard, Esq.; J. P Sheppard, Esq.
Worlingworth—E. B. Rector, Esq.
Worthing—Henry Collet, Esq.
York—Thomas Simpson, M.D.; Caleb Williams, Esq.

First General Meeting.

Wednesday, August 13th, 1851.

Sir Charles Hastings moved that Dr. Horner, of Hull, take the chair.

Dr. Horner: I resume the chair but for the purpose of inducting thereto my successor, Dr. Jenks, and I congratulate the Association that their choice has fallen upon one whose experience and ability so well befit him for the office. I think, gentlemen, that we have much cause for satisfaction at our present position; let us not, however, I beseech you, therefore be content—be satisfied—with where we now are, for we know that these are days of progress, of onward movement, of discovery. To put forth only exertions which we have been in the habit of putting forth, would really be to retrograde in the great intellectual march. There is greater cause than ever for exertion; and as the eagle is fabled to fix its piercing gaze on the sun, and thitherward unswervingly to cleave his course, so let the light of knowledge, the good of mankind, and the advancement of science, be as it were the shining beacons of our course. With an eye that is single, and a purpose that is determined, be our course like the eagle's—onward—right on. There is one subject to which I will only cursorily allude; it is one, however, on which I have strong personal feeling, and which I cannot in my office of retiring President, refrain from just alluding to—I mean the sad bereavement which we have sustained in the death of Dr. Mackness. He was my sincere and my valued friend. But a week before his death, he wrote me expressing his congratulations at the thought of reading an address before you in this room, on this day. Here is the audience; but where is the lecturer? *Sub cespite jacet.* I say this does give us a reason for now doing our

duty in that state of life to which we have been called. If we are willing to exert ourselves for the benefit of our fellow-men, and for the great objects of the Association, now is the time that we should do it. Such a painful event also naturally awakens in the mind other feelings, of a far more important nature. The words of Young occur to my mind as most applicable:

> "Whose grave prescribes the best? A friend's.
> And yet, from a friend's grave how soon we disengage!
> E'en to the dearest, as his marble cold.
> Why are friends ravished from us? 'Tis
> To bind, by soft affection's ties, the human heart
> To thoughts of death, which reason, too supine,
> Or misemployed, ne'er fastens there.
> And yet nor reason, nor affection, nor both combined,
> Can break us from the witchcrafts of this world!
> The inexorable hour,—how near at hand!
> The inexorable hour,—how soon forgot!
> Nay, to forget it, the chief aim of life,
> Tho' well to ponder it is life's dire end."

We have now specific duties before us; and whether I look at the magnificent arrangements which have been made for you, or whether I look to the high character of our medical friends at Brighton, or whether I look at our Association, now in all the vigour of its nineteenth year, I am sure I can safely foretell a most happy, and a most prosperous meeting.

Dr. Jenks, amid hearty applause, then took the President's chair, and said: Gentlemen,—When I look round upon this assembly, composed of members of a learned and scientific profession, many of whom by the force of intellectual zeal and power have risen to distinction in the highest walks of literature and science, as well as in the various branches of medicine and surgery, and consider that I have been nominated to preside over so distinguished a body, I feel deeply sensible, I assure you, of the great honour conferred on me; but unaccustomed as I am to fill so high an office, I hardly know in what terms I can make my acknowledgements acceptable. I must entreat you, therefore, to receive my best thanks as kindly and favourably, as I tender them cordially and gratefully.

In entering upon my office, gentlemen, believe me, I have no little mistrust of my ability, through inexperience, to fulfil the duties thereof in a manner adequate to my own ideas, much less equal to the expectations of such an audience. I must, therefore, crave a larger share than usual of that indulgence and support which you always readily accord to your Presidents. I know well, on looking at the names and qualifications of those gentlemen who have already filled this chair, that there is no lack of admirable and excellent examples to all who may come after; but this very excellence it is, which augments the difficulties of their successors. In all posts of honour men are excited to do their best. There is a not unbecoming pride in doing more than was expected of us, and not less than others would have done; but with such an array of distinguished predecessors before me, in all humility and sincerity, I regard the latter hope as unattainable. I must be content to follow, *haud passibus æquis*, those eminent persons who, with so much dignity and ability, have conducted the deliberations of these meetings on former occasions, and shall think myself well rewarded if I succeed in imitating their example to your satisfaction; if not, I feel persuaded you are generous enough to accept the intention favourably, and to think there may be even some merit in the earnestness of my endeavours.

We are now met to celebrate the nineteenth anniversary of the Provincial Medical and Surgical Association, and the numbers assembled here this day abundantly testify to the continued prosperity and importance of the Society. Great have been the benefits conferred on its members, in the diffusion of knowledge, in the union of thoughts and interests, in the interchange of

kindly offices—and, I think I may add, that faithfully and extensively has the General Association been seconded in this good work by the local branches.

It was happily and wisely determined, by the honoured founder of this Institution, to collect his widely scattered associates, year by year, into one place, where minds overwrought by the cares, anxieties, and Sisyphean labours of a busy harassing profession, might forget awhile their ever-recurring toil, and indulge freely in well-intentioned and dignified sentiments and communion, by which manners are improved, character is exalted, mutual esteem generated, and good fellowship established and strengthened. Besides the cultivation of the social virtues, we gather other fruits from these meetings. We learn the advantage of combination and concert for the advancement of professional objects, and for public ends. The difficult and much vexed questions of medical reform, the unrestricted sale of poisons, the state of health of the people, together with the legislative measures needful for their improvement, have occupied your time, and been maturely and deliberately considered.

Deputations from the Provincial Medical and Surgical Association have been received by those in authority with marked respect, and listened to with becoming attention. The resolutions formed at your meetings have taken effect, your reports been approved, and your suggestions upon legislative improvements adopted. In proof of these remarks, we may refer with satisfaction to the spirit of conciliation manifested by the Council of the College of Surgeons in their recent concessions; to the Sale of Arsenic Regulation Bill, and to the impulse given to sanitary improvements all over the country.

Furthermore, as an important auxiliary to your proceedings, you have a well-established, most ably conducted, and excellent *Journal*, which registers your deeds, publishes original essays, treasures up valuable facts, and is at once a channel for mutual correspondence, impartial criticism, and useful intelligence. The volume of "Transactions", published yearly, I may say, without fear of contradiction, deserves a place in every medical library in the kingdom.

But neither are social advantages, nor science, nor medical polity, exclusively the objects sought for and obtained on these occasions. From the bosom of these meetings there emanated that excellent and charitable idea of a "Benevolent Fund", for the relief of distressed and decayed members of the profession, and the widows and orphans of those deceased. In this beneficent cause, I might be pardoned for addressing you at the length it deserves—but I forbear. At the proper time, this subject will come before you, adorned with the moving eloquence and urged with the fervent zeal which have distinguished its able advocate, the Treasurer and Secretary, upon all former occasions. To him belongs the task, *magnum munus atque onus*, of appealing to you in behalf of our poorer brethren, and well persuaded am I that he will not do so in vain. Suffer me merely to remind you, that poverty is an evil bringing in its train so much trouble, peril, and misery, that while every man should strive to avoid it, he ought at the same time to help, as far as he is able, those whom the gripe of necessity has reduced to destitution. Indeed this can hardly be considered a duty that we can do or leave undone as we list, for many are they who stand in utmost need of our bounty. And shall the reproach be cast upon us that we do not readily assist one another? Upon us! the members of a profession, of whom it was said by Dr. Johnson, that "every man has found among them great liberality and dignity of sentiment, very prompt effusion of beneficence, and willingness to exert a lucrative art, where there is no hope of lucre".

If we look heedfully at the condition of many of our poorer brethren, especially in the rural districts—over-worked, badly remunerated, cruelly oppressed by hard task-masters, or perchance ruined by the reckless competition of interlopers, we shall see abundant necessity for a Benevolent Fund.

Much of this evil is to be attributed to the adverse administration of the Poor Laws. It would have given me great pleasure if I could have announced any improvement in the relative position of medical union officers and their oppressors—the guardians of the poor, as they are called; but I am sorry to say that the Committee of the Convention of Poor-Law Medical Officers have suspended their meetings through want of support. After a statement of their difficulties and proceedings, they conclude their report by urging "the Poor-Law Medical Officers and the profession in general to consider how much the redress which is sought, and for which so large a sacrifice of money, exertion, and time, has been made by some of their brethren, is within their voluntary grasp; but that it can never be hoped for so long as the degrading and ill-paid appointments are not merely accepted, but made the objects of eager competition."

Alas! how long will this spirit of rashness on the one hand, and supineness on the other, disturb our counsels, and cast reproach upon our very name and calling. Let it be remembered that, by this ruinous competition for Poor-Law appointments, the real thrift and progress of the profession are seriously injured; that, by undertaking more than they can perform, medical officers share the guilt of neglecting the poor with the so-called guardians; that, by receiving less than a just reward for their services, they degrade themselves, and damage not only the interests of their fellow-labourers with their own, but indirectly those of every practitioner in the kingdom. A competition, unlimited like this, degenerates into unlicensed selfishness, which can only be checked by judicious combination. These rival principles may both be considered useful when properly balanced. Some degree of honest rivalry or emulation is needful to develope the energies of mankind; and some degree of combination equally so to protect the interests of class or profession. The one is a duty we owe to ourselves, the other to our neighbours. The remedy for this debasing system of Poor-Law competition is chiefly in the hands of the Union Officers themselves; but much might be done by a Government acting upon public principles for the public good, and especially the good of the indigent poor, who in the main are the greatest sufferers by these irregularities.

From this discouraging state of things, however, let us turn to the subject of Medical Reform, which at length affords a better prospect. In the opinion of most thinking and well-informed men, the question of medical reform is now ripe, and probably none the worse for having been hitherto withheld. It has been cast into the crucible of public discussion, and has come out purified, and separated from much dross. The contending parties are now wiser, and better disposed to treat upon equitable terms. Upon this ground, therefore, we may look with more sanguine hopes than heretofore; with hopes, I would fain believe, well and solidly founded, that all parties, seeing the propriety of needful concessions, will concur in a plan of practicable and useful reform, which shall have for its basis the principles contended for by this Association, and on various occasions so ably advocated by the President of the Council and his colleagues. The consummation of these hopes, I am afraid, is not very near at hand; nevertheless, the good already effected is great; the progress, though slow, is assured. The moral certainty of some efficient reform should console us for its delay, for there is no fear of retrogression.

In the mean time, gentlemen, it behoves us all, and especially the junior members of our noble calling, to persevere steadily and diligently in cultivating the art and science of medicine; neither deterred by the difficulty of the study, which cannot be achieved without much labour, and no trifling proficiency in the other sciences; nor discouraged by a degree of uncertainty pertaining to it, in common with many other branches of human knowledge. "Whatever can be said of the uncertainty of the art of physic," writes Sir William Temple, "or the disagreement of its professors, they may, I believe,

confidently undertake, that when divines arrive at certainty in their schemes of divinity, or lawyers in those of law, or politicians in those of civil government, the physicians will do it likewise in the methods and practice of physic."

An earnest and truthful endeavour to improve our professional knowledge is the best foundation for public support, and the surest weapon wherewith to defeat the bold pretenders who rise up daily around us. Men of this description, whose maxim is, *ibi fas, ubi maxima merces*, have only themselves to serve:—we, our country and mankind. In such a cause our efforts are ennobled, and we should rather rejoice in being called to such a service.

Let not any man wonder that quacks and impostors should abound even in these enlightened days. They have abounded in all times and in all professions, and probably will never cease; for there is nothing so irrational or extraordinary that some men will not maintain for truth, feeling sure that the credulous and ignorant vulgar, rich and poor, will receive it with implicit belief. We live in an age. for example, supplying humble followers in great numbers to Mormonism, and educated *gobemouches* in crowds to Mesmerism.

It is not my intention to treat of the fashionable follies of the day—the mystifications and legerdemain of Mesmerism, the unreal mockeries and sublimated jargon of homœopathy, nor the more dangerous excesses of hydropathy. All this has been admirably done lately by an accomplished member of this Society. I would observe merely that such aberrations from the path of true medical science should be abjured and repudiated with firm and solemn resolution, while the professors thereof may be left to an avenging Nemesis, which may one day or other overtake them. Let me, however, turn your attention to an evil which has developed itself within our own ranks.

"Iliacos intra muros peccatur et extra."

We have treachery within, and war without. Open adversaries we know well how to deal with; but it is another thing when a man's foes are of his own household. I am grieved to hear that some, even of the legitimate sons of physic, are tainted with the leaven of these new doctrines, that others, like the bat in the fable, take either side as it may suit their purpose, while a few have not scrupled from indifference or crooked policy to countenance this defection, or to shield it by a sort of compurgation. Against this laxity of conduct the opinion of the profession should be unmistakably pronounced. To admit seceders, or doubtful allies, to the privileges of regular practitioners, or to an equality in consultation, is the same sort of treason to the profession as the admission of the wooden horse within the walls of Troy. I trust enough has been said of late to induce those who have extended an ill-timed indulgence to these false brethren to withdraw from further communication with them; for we must never look for peace with quackery in any of its monstrous shapes. As to the apostates themselves, it would be well that by a self-ostracism they quitted altogether the ranks of a profession which by a half-faced fellowship they dishonour and betray, lest, neglecting such admonition, they find at length "forbearance no acquittance". Their secession will relieve us from much embarrassment, and their hostility will have no other effect than to strengthen our mutual confidence, improve our discipline, and excite us to increased exertion.

It has been usual, I believe, on these occasions, to pass in review the characters and services of those members of the Association who have departed this life during the past year. Time will not permit me to dwell upon the worth and merits of each individual; and were it otherwise, I could not perform that melancholy but grateful office, from lack of needful information. But there is one whom I cannot pass over without paying to him the tribute due to a most able and zealous member of this Association; one who, had he been spared, would have been a principal contributor to the proceedings of this day.

I do not take upon myself the office of biographer, but a short summary of the principal events in the life of our late lamented associate, Dr. MACKNESS,

may not be unacceptable. In early life he met with some trials, and was beset with difficulties, which to many might have seemed insurmountable. By dint of patient industry, frugality, and an excellent understanding, wholly unassisted by favour or fortune, he cleared the way at length to eminence, and made good his position. His was no exception, however, to the rule of the poet—

> "Haud facile emergunt, quorum virtutibus obstat
> Res angusta domi."

It would be foreign to my purpose to follow our late colleague through the difficulties he encountered, and so manfully overcame. I intend only to shew you that he sounded all the depths, and passed through all the tides of medical life. He began his professional career as a general practitioner in a country village, whence he removed to a larger field of practice at Northampton, but being unequal, through ill health, to the numerous and very arduous duties of general practice, he retired. In May 1840, he went to St. Andrew's, where he took the degree of Doctor of Medicine. In the year 1843, he became an extra-licentiate of the Royal College of Physicians, London. Soon after he had obtained his degree at St. Andrew's, he settled at Hastings, where he continued to practise as a physician till his death.

In private life he was beloved, and deservedly respected; he was a cheerful and instructive companion; his sentiments were solemnly religious, but elevated and liberal; his manners gentle and unassuming; his professional acquirements were of the highest order. To great skill and readiness in detecting and treating disease, he added good sense, urbanity, and benevolence. Though fully occupied in practice, he found time for several publications; he added to the stock of medical literature (besides minor performances), a work on *The Moral Aspects of Medical Life*, containing a translation of the *Akesios* of Professor Manx. In this work of our late associate some inexperience in the art of composition is apparent; but it is rich in medical ethics, containing a judicious selection of facts, and abounding in interesting anecdotes. He wrote also a monograph on *Dysphonia Clericorum*, a work displaying distinct and accurate views of a disease not heretofore separately treated of, and manifesting great ability and judgment in the application of those views to practice. He was occupied in preparing a *Report upon the Medical Topography of Sussex*, when the hand of death removed him from among us. Dr. Mackness died at the early age of 46. It may be said of him, as it has been said of another eminent physician, that "he worked out for himself an education, a profession, a reputation, and a competence".

The SECRETARY read the REPORT OF THE COUNCIL, from which we copy some extracts.

"FINANCES. The statement is as follows:—

	£.	s.	d.
Balance in hand, 1850	109	18	6
Receipts	1616	19	7
Expenditure	1632	14	11½
Balance	94	3	1½

"MEDICAL REFORM. This difficult question still remains unsettled, but the Council fervently hope that it is approaching a termination that may ultimately prove satisfactory to all parties. The present year has been distinguished by the Council of the College of Surgeons taking the lead in the adoption of a highly conciliatory course of conduct, for which they deserve, and have received, a meed of praise from all parties in the profession. This concession has very considerably lessened the obstacles which stood in the way of medical reform. There are, however, still some difficulties to be overcome, which require calm and careful consideration; but as all parties are now animated by an earnest desire that this long contention should cease,

your Council cannot but look forward to the final settlement of the question at no distant day."

"As soon as it was known that the Council of the College of Surgeons were prepared to yield so much, your Council communicated with many members of the Association, and with the accredited societies, who had worked with them to obtain a legislative amelioration of the profession. The result of this consultation was, that it was deemed prudent by all parties to accept the proffered terms of the College, with some slight modifications. Your Council, therefore, thought it right to address the Secretary of State for the Home Department, and at the same time assured him that they felt gratified by the concessions which had been made by the College; they also reiterated the principles on which they considered any safe medical legislation should proceed."

"Since the memorial no further step has been taken, as the near approach of the anniversary rendered any further movement unnecessary. The Council, however, have thought it desirable to seek the opinion of the District Branches on the course they have pursued, and they are happy to say it has received their sanction."

"Medical Ethics. The subject of medical ethics is very important, and from the commencement of our Institution has attracted more or less attention. A committee was appointed at Worcester to report on this subject, but has not hitherto done so, partly because of the death of one of the members, and the ill health of another, and partly in consequence of the great difficulty of carrying on any deliberation where differences of opinion exist, by any means except *vivâ voce* communications. Some progress, however, has been made in the work, and a portion of the rules are in type. At the present juncture it is highly desirable that we should give a calm and judicious attention to medical ethics; for it is much to be regretted that many regularly educated members of our profession have connected themselves in doctrine and practice with some of the popular delusions of the day. It will be by the judicious consideration of such important matters that the advantages resulting from this Association will become more and more apparent. The inflexible adherence to correct principles and upright conduct, will thus continue to be the rallying point of the members of the Association, and they will evince their determination to maintain amongst them a sound philosophy and unblemished honour. Charles Hastings, President of the Council. James P. Sheppard, Secretary."

On the motion of Dr. Cormack, seconded by Dr. Forbes Winslow, the report was adopted.

Committee on Irregular Practice. Dr. Cormack moved—"That the prevalence of irregular and unprofessional practices ought to be considered at this annual assembly of the Provincial, Medical, and Surgical Association; and that a Committee be appointed to report to-morrow upon the course which it is proper to adopt. Dr. Tunstall seconded the motion, which was agreed to; and Drs. Cormack, Tunstall, and Ranking, were appointed a committee in terms of the motion.

The Address in Surgery was delivered by Mr. B. Vallance, of Brighton, and ordered to be printed.

Second General Meeting.

The Association reassembled, after an hour's interval, at two P.M.

Income-Tax Committee. Dr. T. Smith (Cheltenham) said that for a long time the members of the profession had suffered, most iniquitously in his opinion, from that ill-advised measure the income-tax (hear). To the medical man more especially the income-tax had been oppressive, and often-

times had very seriously affected his future interests. It had been in its operations most unjust, if not something more; and, as an instance, he would state a fact:—A medical man was taken ill shortly after making a return, which was made at a moment when he was in perfect health. He (Dr. Smith) was not now going into a newspaper narrative, but was stating a particular case. The person was taken ill shortly after making a *bonâ fide* return of his previous year's receipts,—perhaps he had compounded for three years; he was suddenly laid on a bed of sickness, and for some time deprived of the means of making up his income, and yet he had no appeal, and could not prevent the tax collector's receiving that full amount of income derived by government from the income-tax. The money was not in that case derived from the labours of the medical man; and such an unjust tax ought to be done away with. The matter had been before government, and the farmer had been allowed to make a claim, and a deduction had been granted to him; but the professional man, stretched upon a bed of sickness, had no appeal. (*Applause.*) It was a matter which ought to be pressed upon the Chancellor of the Exchequer. For his own part, he was most strenuously and decidedly opposed to the income-tax in any way whatever. It was a most iniquitous and unjust tax; and of all the taxes relative to the medical profession, the income-tax was the most unjust. And with regard to the mode of assessment, it was subject to much abuse. All the clerks were sworn to secrecy; but who would be answerable that a young man of eighteen or nineteen, would, upon leaving his employer, still value and adhere to the oath which he had first taken? He did not say that those young men did break their oaths, but still there was a probability that they might. And as regarded the secrecy of the income-tax, it was almost a complete farce. He (Dr. Smith) had compounded under the impression that his income would be kept perfectly secret. He went before the authorities, and, instead of taking his word, they put his name down at £20 instead of about £7 a year, and he allowed it to remain. He went to pay the money, and in that room where everything ought to have been profoundly secret, he saw some twenty persons, and there was a list there containing the names of all the parties who had compounded under what was called the Special Commissioners' Act, and he could have read the whole of that list if he had thought proper to do so. That was considered secrecy! So far as professional men were concerned, it was a matter of great importance that the amount of income derived from their business should not be known. He was not satisfied also with the workings of a measure which compelled the medical men of Great Britain to pay a tax from which their brethren in Ireland were exempt. If the medical profession were free in one part of Her Majesty's dominions, it ought to be free in another. (*Applause.*) And also, as regarded the assessment-tax, their brethren on the other side of the water were exempt, whilst they had to pay, and on these grounds a favourable opportunity existed for the medical profession to bestir itself, and endeavour to influence the legislature to make a reduction of those taxes which so seriously affected every member of the profession. And with regard to the assessed taxes, there was a movement on foot at the present time, to make the tax upon coach horses more equalized. He knew several parties who were independent, and could ride in their carriage without having to pay that tax, whilst they (the profession) worked hard and laboriously to earn their bread, and yet were compelled to pay that tax. The farmer could now have his horses exempt, but medical men had not the slightest exemption, and government always imposed taxes upon the profession whatever the effect of the imposition might be. And again, with regard to the house duty, they had to pay 9d. in the pound as professional gentlemen, whilst the merchant, rolling in wealth, had only to pay 6d. He hoped that the meeting would carry his motion and appoint a committee to inquire into the laws affecting taxation, and more especially with reference to the income-tax. He moved,—"That a Committee be

formed for the purpose of investigating the subject of taxation, so injuriously and oppressively affecting the medical profession."

Mr. NEWNHAM, of Farnham, seconded the motion.

The motion was carried unanimously; and an influential committee was formed in accordance with it.

BENEVOLENT FUND. Mr. NEWNHAM read a very interesting Report of the Benevolent Fund. The cash account is as follows:—

DONATION FUND.

Dr.	£	*s.*	*d.*	*Cr.*	£.	*s.*	*d.*

Dr. W. CONOLLY moved the adoption of the report.

Dr. T. THOMPSON (Stratford) had great pleasure in seconding that motion. In the whole range of the Association not another gentleman would be found willing to devote so large a portion of his time to the promoting the objects of the Benevolent Fund, as their respected friend, Mr. Newnham. *(Cheers.)*

EMPIRICISM. Dr. MALDEN (Worcester) read a very talented essay on this subject, which was ordered to be printed.

PROGNOSIS OF INSANITY. Dr. CONOLLY, of Hanwell, read a highly valuable practical paper on this subject, which will likewise appear in the Transactions of the Association.

At six o'clock the members assembled in the Banquet Hall of the Pavilion, in compliance with the invitation of Dr. Jenks and the other medical gentlemen of Brighton, to partake of a splendid cold collation.

DR. MANTELL'S ADDRESS. After dinner Dr. MANTELL delivered a lecture, in the Music Room, upon "The Medical Topography of Sussex".

THIRD GENERAL MEETING.

THURSDAY, AUGUST 14TH, 1851.

The PRESIDENT took the chair at twelve o'clock; and immediately called for the Report of the Committee on Irregular Practice.

DR. CORMACK said: I have the honour, sir, to be commissioned to offer for the acceptance of this great meeting the Report of the Committee, which was yesterday appointed, to consider the course which the Association ought to adopt with reference to the prevalence of irregular practice, and unprofessional conduct. The great amount of important business to be disposed of

before we separate, suggests the impropriety of a long speech: and yet it does seem essential for me briefly to state the general principles upon which the Committee have proceeded, and in particular to mention the grounds upon which they have founded certain Resolutions, which they hope the Association may adopt as its own.

Although the terms of our appointment might have justified a more general notice of the prevailing delusions and impostures of the day, we have thought it best to direct your attention solely to what is called homœopathy, as along with it are almost invariably associated some of the other fashionable systems of charlatanry. I am anxious to state, at the outset, that we have not thought it necessary to adopt the language of controversy; and that we have conceived the main duty of this body to be *defensive*, and not *offensive*. If there were no fear of quackery, in one of its most seductive and demoralising forms, creeping into our society, to spoil our social meetings, and canker the integrity of our professional intercourse with each other and with the public, it might be wrong to enter on this discussion; but when we see members of the medical profession fighting the battles of a mischievous charlatanry, under the banners of legitimate medicine, it is time for us to be stirring, lest these apostates, when actually sheltered by this Association, damage its respectability, and perhaps ultimately endanger its very existence. Unlike the Colleges, we have no Royal charters upon which to rest in supine and dignified tranquillity: our only charter is the association of numbers in defence of truth and high-toned professional honour. This charter—the best of all charters—it is our duty and our privilege to defend. We are not required, however, to make an aggression upon the allied armies of quackery; but the aspect of society, and of the profession, do loudly call on us to raise bulwarks and defences sufficient to prevent this enemy from stealing a march upon us, and destroying our citadel ere even the cry of danger has been heard. Such, then, are the general principles which ought to guide us; and which, when applied to the actual relation of the profession to homœopathy, mark out the necessity of excluding from this Association three classes of practitioners; first, those who really (and some of them honestly) practise homœopathy; second, those of a mixed or bastard breed, who practise homœopathy, in combination with Mesmerism, hydropathy, allopathy, or *any-pathy* which the patient may fancy the most; and third, those who, under various pretences, hold professional intercourse with homœopathic practitioners. *(Cheers).*

It would be an unseemly waste of time, to prove before this assembly that homœopathy is a mere chimera—a system opposed to reason, common sense, and all medical experience; but I may be allowed to state in a few words what Hahnemannism is, and briefly to explain who are the incongruous crew who range themselves against us, under the flag of homœopathy. Three leading doctrines, or rather dogmas, were promulgated by the German dreamer:—First, that all diseases depended upon three inherent taints, the principal one being the itch, or psora, as he called it; second, that "like cures like"—*similia similibus curantur;* and third, the giving of infinitesimal doses. It has been often and elaborately shewn, that these dogmata, these chimeræ, have not only no scientific basis, but have neither facts nor even probabilities to rest upon. The statements made about medicines acting when divided into the millionth or decillionth of a grain, are so transcendently nonsensical as to be entertained even as a subject of consideration, for an instant, only by an unhealthy mind. The simple fact is this, that Hahnemann's doses cannot be demonstrated to exist, and are so small, that the mind of man can form no conception of their minuteness. Some homœopaths repudiate, in a sort of half-and-half way, the small doses; but the public who fee homœopathic doctors, generally conceive that their medicines are given to them in the attenuations of Hahnemann, in quantities ranging from a millionth to a decillionth of a grain. "Little pills" were yesterday lauded

by a platform speaker at the Homœopathic Meeting in Freemasons' Tavern; but his laudations were perhaps applauded by men who give as freely, or more freely than many of us would dare to do, strychnia, aconite, and other such like drugs, the most terrible doses of which may be administered in drops, and fractions of a grain. Large doses of our common medicines, as I well know, are also every day prescribed by men who come forward as candidates for homœopathic practice among the wealthy and the noble. "Little pills" may be, but certainly a little quantity of physic is not a criterion by which to know the practitioners who range themselves under the flag of homœopathy. Dr. Quin openly advised what I may term very large doses of camphor in cholera; and in my own experience I have found that patients had been taking, along with the globules, (under the name of adjuvants), the same medicines, and in the same doses, which we employ, and which experience has sanctioned. What is now called homœopathic practice, may, I aver, mean any kind of practice. (*Hear, hear.*) I have said enough to show you how vain it is to define what is meant by homœopathic practice, when I mention that, at a recent meeting of the Annual Congress of homœopathists, there was present, as a large participator in the business, Dr. Wm. M'Donald, who, besides being a homœopathic practitioner, is a leading man as a believer in, and lecturer on, the highest degrees of Mesmerism. Then Dr. Macleod (whose autobiography I hold in my hand), the keeper of a water-cure inn at Benrydding, in Yorkshire, is a chosen champion of homœopathy,—a man whom the *Homœopathic Times* delights to honour, and who treats his patients by globules and wet sheets. Dr. Henderson, of Edinburgh, Dr. Calvert Holland, and Mr. Kingdon, of London, prescribe infinitesimal or ordinary doses, according to their own or their patient's fancy. I select these gentlemen as my examples, because their acts are before the public, in print. The medical creed of these practitioners it is impossible for us to comprehend. They are, however, a large and increasing class; and on that account they seem to claim special attention in our Report. It is, then, the opinion of the Committee, that both the real homœopathic practitioners, and those who practise homœopathy in combination with other systems of treatment, ought not to be members of this Association.

But, besides the legitimate and the bastard homœopaths, there is another class of men who have no right to be associated with us in this Society. Regarding this class, I wish to say little, but that little must be plain, and it is this:—that we must not—not one member of the Association must for the future hold professional intercourse with those traitorous men who meet at the bedside with practitioners whose medical creed and character I have (though perhaps too mildly) depicted. A broad line of demarcation must be drawn, and it must be done this day. (*Loud cheers.*) Private friendships have perhaps made some of us too long in adopting this painful, but only right course. To error or imposture there never can be made an honourable concession. (*Hear, hear.*) I would here remark, that no retrospective legislation is contemplated; nor is it proposed to enact new laws to-day. We only wish certain general principles to be sanctioned, as the basis upon which laws for the future governance of the Association are to be framed, and afterwards submitted to the next annual meeting for ratification. By adopting this course, the respectability of the Association will be sufficiently guarded and maintained; and no one will be able to bring against it the charge of having acted precipitately, or under the influence of excitement. (*Hear, hear.*)

One of the most curious features of the homœopathic quackery is this, that while its professors vilify the science of medicine as we follow it, and abuse us through the press, the platform, and the pulpit, they yet eagerly seek their credentials from our Colleges, and even try to enter our more private Medical Societies. This, however, must not be allowed; and it is incumbent upon us, as representing the medical practitioners of England, to tender

hearty thanks to the Scottish Colleges and Universities, for their repudiation of homœopathic practitioners.

The mention of *the pulpit* brings to my recollection a topic which cannot be passed over, and which I approach with feelings of the deepest pain and sorrow. I will not yield to any man in my respect for the sacred office of the ministry; myself the son of a clergyman, I have always felt that the only other calling more noble than our own is that of preaching the everlasting Gospel; but, when clergymen assail us from the pulpit, and injure our influence with our patients, by their zeal in converting proselytes to Hahnemann, neither delicacy nor duty can justify our silence. Numerous facts have been laid before your Committee, from which we have ascertained, that in some districts of the country the zeal with which the clergy have taken up quackery knows no bounds, and many of our brethren have had their patients wiled away, by clerical canvassing, to homœopathy, hydropathy, and Mesmerism.

I would not have ventured, however, to bring this prominently before you, did I not hold in my hand a sermon preached by a rev. vice-president of the Hahnemann Hospital, in Bloomsbury-square, from which it is necessary that I should read some extracts. The preacher was the Rev. Thomas R. Everest, Rector of Wickwar. He selected his text from the Gospel of St. Matthew: "And as ye go, preach, saying, the kingdom of Heaven is at hand: heal the sick, CLEANSE THE LEPERS, raise the dead, cast out devils: freely ye have received, freely give."—Chap. x, 7, 8. In this text the rev. gentleman finds revealed the doctrine of Hahnemann! But I will give you his own explanation of the words of the Evangelist,—"Heal the sick and cleanse the lepers. *Cleanse the lepers?* Why pick out disease at all from amongst all the ills of men? And if so, why that particular one? Why not blindness, or madness, the stone, or the dropsy, rheumatism, or the gout?" (p. 29.) The leprosy of St. Matthew, and the psora of Hahnemann, are the same thing. That, in fact, is the grand idea of the sermon.

This reverend vice-president of the Hahnemann Hospital broadly and plainly proclaims from the pulpit of St. Augustine, Cheapside, that our Saviour's atoning sacrifice was scarcely available to fallen man till Hahnemann appeared. (*Sensation.*) Bear with me while I read a short passage to make good my assertion. It is almost too bad to read aloud; but I must do so, to save me from the charge of misrepresentation. "At the fall of man sin entered into the soul, and disorder into the physical frame (with which that soul is connected) at the same moment. God sent his Son to repair the mischief, and he bade his ministers preach the Gospel, and heal the sick; that is, cure the moral disorder and the physical disorder together; and for 1,900 years that precious wisdom has cried in the streets unheard. The preacher of the Gospel, not aware that that Gospel could never have free course until the physical leprosy of man was cleansed, and his chronic tendencies cured, has handed over to a separate profession the business with which his Lord entrusted him. And that profession, unconscious of its privileges, its duties, its powers, has, so to speak, ignored the whole question. It leaves those mad whom it might have cured, or it maddens men by large doses of powerful medicines; and then we wonder at the crimes and folly that mark the career of man."

"Let us be assured, brethren, that there is in the Gospel of Jesus a life, a power, a spirit, which is so much in harmony with man's happiness, and brings with it so much good, that if it had been understood by those who teach it, and had had fair play, it would long ago have altered the whole face of society. But in spite of Moses, in spite of Jesus, in spite of the law of Nature, alike deaf to God's voice and blind to facts, the medical profession has left the leprosy of the flesh to entwine itself with the leprosy of the soul. Between the two, man's tendencies to sin are increased by the disorder of his

reason, caused by the abnormal working of his machinery; and the Gospel finds in that individual in whom God intended that all should be normal, but with whom it can only communicate by means of nerves in a chronic state of irritation and a brain in discordant working, not a gentle convert but a hardened criminal, a perverse unbeliever, a furious fanatic, or an eccentric, unreasoning lunatic. But old things are passed away, behold all things are new made unto us. Let us now see what the new system proposes to do for the human race" (pp. 40, 41). That is to say, let us see how homœopathy is to render available the hitherto almost useless Gospel of Jesus Christ—unable, till Hahnemann appeared, to make head against "large doses of powerful medicines".

The preacher traces all the diseases and vices of the human race to our "frantic medicines": and this he brings out in many parts of the sermon: and, as example, I quote one paragraph—it is his appeal to the pockets of his audience on behalf of the Hahnemann Hospital:—

"Mothers! do you wish to see your children washed clean of that leprous tendency to disease which fills our grave yards with sweet young flowers cut off untimely, and which, to those who survive, transmits a legacy of pain, sin, and sorrow? THEN AID US! Fathers! do you wish to see your sons grow up faithful Christians, and sensible men, with a normal allowance of health, able to use calmly the reason which God has given to man for his comfort here, far from all extravagance, and all eccentricity, holding a course of life steady, reasonable, religious—such a course as man, healed, God-fearing, and intellectual, should hold? THEN AID US! Governors of God's heritage, monarchs, parliaments, magistrates! There is a gloomy thunder-cloud collecting on the horizon, rolling its deep masses over the face of day, threatening, lurid, portentous; but no man knows exactly of what. It is called Socialism, Communism, the Rights of Man, the Rights of Labour, the Red Republic. It is earnest, dark, sombre, avenging. It has been lashed up by hunger, low wages, glaring inequality, wicked passions of psoric origin, roused by alcohol and medicines, maddened by burning eloquence. It has no strain of gentleness in it. It is arrested by neither ridicule nor menace. There is not one smile, or one jest hidden beneath its fantastic Swirls. The sword has cleft it, but it re-unites more baleful than before. The cannon has poured its hail against it, but it rolls on as dense and as red as ever. The priest has cursed it; society trembles to hear of it; but there it hangs, in the calm that precedes the earthquake; baffled, perhaps, but biding its time till the 'hour come, and the man'. Shall I teach you to draw the lightning quietly from it ere it bursts upon your throne and your altar, and piles all your institutions into one heap? AID US!"

I must still inflict two other extracts upon you: they give more concisely than any other which I can select, the preacher's contrast between homœopathy (which he designates the "Good News of Great Joy"), and our system of medicine, which he maintains to be the origin of "gaols and gin-palaces; terrible crimes, for which scarcely the siege of Jerusalem could find a parallel; bands of prostitutes gathering round the dome of St. Paul's", etc. etc. After pointing out that from the womb the infant must be prepared for heaven by means of globules, he thus announces the result of such treatment:—

"The medicine of love has prepared the soil for the Gospel of love. The seed of the Word will soon strike root in such a soil, and bring forth much fruit; not the fruit of thievery and crime, afflicting folly and snarling religion, that exist at present, but a wholesome crop of sensible actions and sound opinions ripened by the steady rays of reason and religion. Growing up thus amidst calm, and sunshine, and love, and harmony, induced by the medicine of harmony, the education of the young candidate for heaven commences. The first care of the parents is, by proper dynamic medicines, (for

medicines in a brute, material state, having a totally different action on the human organism, are perfectly useless, or rather merely injurious) to eradicate all those psoric tendencies which cause or increase all our aches, pains, ill tempers, obstinacies, rebellions, cachexies, and all chronic diseases. Life in the beginning does so long for harmony, that if thus gently aided, it soon overrides all discordant tendencies. The molecular attraction proceeds normally. The infant developes into a normal child of the normal type, in whom all tendencies to irregularity, whether of body or mind, growth or disposition, are much weakened and simplified. It has never been exacerbated by frantic doses of powerful medicines, never been excited by poisonous diet, never been beaten into obstinacy, never imitated the quarrels of its elders, never been spoiled into selfishness, never indulged into evil tempers; continuing the physical education, and watching carefully the cries which life utters for assistance, in order to relieve her just where and when she wants aid—never by mere palliatives, but always by dynamic remedies, whose energumenic power, akin to life itself, has been subtilly awakened and called forth from the brute mass in which it lay slumbering, and, if well chosen, will, by its unfailing elective attraction, restore to life at the very spot, by the very nerve wherein it labours, the very FORCE in which it is deficient—you commence the moral and religious training of the child. Plain, simple, easy, and charming, is THE GOOD NEWS OF GREAT JOY." (pp. 48, 49.)

So much for "the medicine of love"; now let us hear one or two of his sentences regarding our system:—"There was once a marriage made in heaven; but you put asunder those whom God joined together in heaven when you separated the healing of the sick from the preaching of the gospel, and made two professions out of that which Jesus made one; and therefore it is that the art of cure separated from the holy principles of love has lost its way, and fallen into foul company, and consorted with all unloveable things—cathartics, moxa, the lancet, emetics and blisters." (*Laughter.*) "And therefore, too, the Gospel parted from its earthly yoke-fellow, and preached by those who share in the sickness and leprosy of the race, has succeeded so partially, and brought forth the harvest of contradictions that you see in the Christian world." (p. 35.)

Now, sir, you have perhaps had more than enough of homœopathic divinity; but I was anxious to let the preacher speak for himself. Remember that Mr. Everest is vice-president of the Hahnemann Hospital—that the sermon was preached in aid of that establishment, which is under the immediate patronage of much of the wealth and aristocracy of this country. Advertised upon this sermon we find, as hospital office bearers, (along with the name of the preacher), his Excellency the Chevalier Bunsen, his Grace the Duke of Hamilton, the Earl of Wilton, the Earl of Shrewsbury, Lord Robert Grosvenor, M.P., and many others, prominent in society, both for rank and riches. To such lists we are generally referred triumphantly: and I admit that it would not be difficult to add to them the names of several members of Parliament, noblemen, bishops, and, at least, one archbishop—Dr. Whately: but alas! has not the train of St. John Long, and many other noisome London quacks, been swelled by a similar throng of noble and reverend personages? Might not the same authorities be cited on behalf of the flimsy impostures of the present idol of fashionable fools, Mademoiselle Julie? Medicine cannot be acquired in leisure hours; it must be learned by patient and painful study at the bed-side and in the closet; and I have therefore yet to learn that statesmen and archbishops, even though they be good men, are authorities in matters of medical experience. Not all the coronets and mitres in England can give dignity to error, or transform a lie into the truth; and layman though I be, I hesitate not to proclaim in this public Christian assembly, that the sermon from which I have quoted is replete with quackery, heresy, and impious doctrine. *(Applause.)*

There is one other point in our Report which requires notice, and it is a recommendation to give great publicity to our determination not to have any kind of professional intercourse with homœopathic practitioners. It is necessary that the public be told authoritatively, and through the usual channels of information, that *they must select;* that, as for us, we positively refuse, *under any pretext whatever*, to hold professional intercourse with such persons; that with them we have no principles in common, and that, therefore, to take fees for meeting with them, would be something worse than degrading,—it would be appropriating money under false pretences; for a consultation without common principles would be a mere sham—it would be no consultation at all. *(Hear, hear.)* It is in this way that the public will be led to inquire into what homœopathy is; for I feel persuaded that not one in a thousand of its dupes has the slightest conception of the vastness of its absurdity, and the Protean wiles with which—setting honesty, consistency, and common sense, at defiance—it bewitches the sick and the silly.

Without further introduction or comment, I now read the

REPORT ON IRREGULAR PRACTICE.

Brighton, 14*th August*, 1851.

Your Committee have, after consultation with numerous members of the Association, maturely considered the subject referred to them, and beg respectfully to suggest the adoption of the following Resolutions:

1. That it is the opinion of this Association, that homœopathy, as propounded by Hahnemann, and practised by his followers, is so utterly opposed to science and common sense, as well as so completely at variance with the experience of the medical profession, that it ought to be in no way or degree practised or countenanced by any regularly-educated medical practitioner.
2. That homœopathic practitioners, through the press, the platform, and the pulpit, have endeavoured to heap contempt upon the practice of medicine and surgery as followed by members of this Association, and by the profession at large.
3. That, for these reasons, it is derogatory to the honour of members of this Association to hold any kind of professional intercourse with homœopathic practitioners.
4. That there are three classes of practitioners who ought not to be members of this Association, viz.,—1st, real homœopathic practitioners; 2nd, those who practise homœopathy in combination with other systems of treatment; and 3rd, those who, under various pretences, meet in consultation, or hold professional intercourse with, those who practise homœopathy.
5. That a Committee of seven be appointed to frame laws in accordance with these resolutions, to be submitted to the next annual meeting of the Association.
6. That the thanks of the Association are eminently due, and are hereby given, to the Presidents and Fellows of the Royal Colleges of Physicians and Surgeons of Edinburgh, for their determined stand against homœopathic delusions and impostures.
7. That the thanks of the Association are also due, and are hereby given, to the Universities of Edinburgh and St. Andrew's, for their resolution to refuse their diplomas to practitioners of homœopathy; but the Association feels imperatively called on to express its disapproval of any school of medicine which retains among its teachers any one who holds homœopathic opinions.
8. That these Resolutions be printed, and transmitted to all the Medical Licensing Bodies and Medical Schools in the United Kingdom; and that they likewise be inserted in the *Times* newspaper, the *Morning Post*, the *North British Advertiser*, *Saunders's News Letter*, all the British and Irish medical periodicals, and in such other journals

as the Council may sanction upon the recommendation of the Branch Associations.

In proposing these Resolutions for the adoption of the Association, your Committee are anxious to state that they are actuated by a strong sense of the importance of the subject in its relation both to humanity and morals. They most conscientiously believe that the countenance afforded to the form of charlatanry herein alluded to, is detrimental to the true interests of the public, as it is subversive of that strict integrity which ought to characterize practitioners of medicine, and which has ever distinguished the profession in these kingdoms.

John Rose Cormack, M.D. Edin., Fel. Royal Col. Phys. Edin. (of Putney).
James Tunstall, M.D., Edin. (of Bath).
W. H. Ranking, M.D., Cantab. (of Norwich).

[*The reading of the Report was followed by prolonged applause*].

Such, then, is the Report of your Committee. It has been carefully considered; and it was not framed till the opinions of many associates had been collected and weighed. We, therefore, earnestly, and with confidence, as to the propriety of the course indicated, ask you to adopt it as an expression of the sentiments of the Association. It is a plain, straight-forward manifesto; but I sincerely trust and believe that it does not contain one expression which is in any way distasteful to a single member who now hears me. We must not think of what we are about to do as a matter of good or bad policy—we must only feel that we are this day called on to maintain, in the face of the world, the honour of our noble profession; and to express, in simple phrases, what we conscientiously feel to be the truth. Let us say our mind plainly, firmly, and calmly. Silence would be far better than the giving forth of a feeble and uncertain sound. (*Cheers.*)

Dr. C. J. B. Williams (of London) said:—Having been asked, since I entered the room, to second the adoption of the resolutions, I cannot hesitate to do so. Unprepared as I am, I cannot help saying a few words on the subject, although, so far as I can judge from the demonstration of feeling which has greeted the report, the meeting seems pretty unanimous already. It might be a question, whether it is the province of this Association to take up matters of this kind, and express a decided opinion upon them. But I only ask, if you do not take them up, where is the body that will? You see all sorts of quackery, with homœopathy foremost, rampant through the land; deluding, by its unaccountable infatuations, the powerful, the learned, the rich, and, worse than all, the poor, in multitudes; and not only are riches placed at the command of the instruments of these fallacies, but what are far more precious, and, this is far more terrible to contemplate, the lives of our fellow creatures! In fact, there is at this moment throughout this country an awful system of trafficking or gambling with the issues of life and death, and a perilous tampering with the elements of mortality—nay, a jeopardising, not of the body only, but even of the soul! for who can say—where victims are hurried out of the world by a delusion, and for want of proper treatment—who can say that some of such might not have been saved alive, and given time for repentance as well as recovery? It is altogether an awful consideration; and I quite shudder when I look back at the number of melancholy cases which have come to my knowledge, where, at the eleventh hour, the regular practitioner has been called in when it was too late; when the precious time, in which medicine might have availed, had been wasted with homœopathy; and we could only shake our heads, and lift up our hands, and exclaim, "Alas! what folly!" and, I fear, we might add, "What knavery too!" (*Cheers.*)

But do not such heart-sickening scenes, do not the general interests of humanity and science, loudly call for some guardian influence to warn the

infatuated public with a voice of some authority? We naturally look to our Colleges, and to the corporate heads of the profession, who are, or ought to be, the guardians of the public health, and the protectors of the medical commonweal. But what have our Colleges done? With the honourable exception of the Edinburgh Colleges of Physicians and Surgeons, the aristocracy of the profession has done nothing. Then we must look to the practitioners at large; and I do think it most fitting that this great Association, so largely and ably represented at this numerous meeting, should speak out clearly and decidedly on this subject:—and your voice will, in truth, be the voice of the whole profession!

It is, indeed, high time that the profession should boldly and intelligibly speak out, for the public are profoundly ignorant in the matter: they really know little what homœopathy is, and still less can they perceive how utterly irreconcileable it is with all that is established and true in medical experience and science. I often hear people talking of medicine and homœopathy as merely exhibiting instances in which doctors differ, which they are privileged to do, and one side may be as right as another. It seems a common mistake that homœopathy is a new system of medicine, which may or may not be true; but that it is entitled, as much as the old system, to compete for public favour, and claim public confidence. Thus they make no distinction between that which has resulted from the accumulated experience of ages, which is continually undergoing the tests of judgment and experience at the hands of hundreds of thousands of regular practitioners throughout the civilised world; which is receiving innumerable accessions and improvements, from the careful labours and discoveries of skilful men, in all the departments of science and art ancillary to medicine; they make, I say, no distinction between this noble and enduring, although unfinished structure, and a wild chimera of the day, which, reared by a fanciful mystic, and worked out by his designing followers, is fostered and flattered into an ephemeral notoriety by the patronage of a few whimsical lords and ladies, and other well-known victims of charlatanry.

I say the public, and the profession too, ought to know a little better what homœopathy is;—I mean *honest* homœopathy, as propounded by Hahnemann, and practised by the consistent and genuine of his followers—not that dishonest mixture of homœopathy with hydropathy, and Mesmerism, and ordinary medicine, which I can only call professional swindling, and obtaining money under false pretences (*cheers*); which, if possible, is more disgraceful and disreputable than quackery itself. But genuine homœopathy needs only to be known to be scouted by all soundly-thinking men. You have heard enough to laugh at, to pity, and to deplore, in the extracts read by Dr. Cormack; but do you really know what is meant by infinitesimal doses, which are the curative agents in this system? In the *Times* of yesterday, there is a report of the proceedings of the Homœopathic Association; and the reporter, by way of ridiculing the whole affair, remarked, that probably any one of the ancestors of the speakers had taken medicine sufficient to have doctored all the homœopathic patients in Golden Square. But this shows that he did not know the value of an infinitesimal dose. Our ordinary doses could be reduced to homœopathic tenuity only by dividing one man's dose among ten thousand times—(I speak much within bounds)—ten thousand times the inhabitants of the whole earth! Such are the absurdities of the homœopath. In fact, they deal with figures and numbers that are quite incomprehensible and inconceivable. It is all easy enough to talk of the trecillionth and decillionth of a grain, but I would appeal to the chemist and the natural philosopher, who are accustomed to appreciate minute realities, whether such numbers are not nonsensical when applied to experimental agents? One of the most delicate tests known, sulphuric acid, might possibly detect one hundred thousandth of a grain of lead in solution; and perhaps the same might be said of chlorine and silver. But the one hundred thou-

sandth part of a grain would have to be diluted a million times more, before it would reach the homœopathic tenuity. And homœopathy teaches that the disease that attacks the body,—disease of the most destructive kind, tending to subvert functions and destroy structures—disease that is clogging the very springs of life—that such disease is to be counteracted by something a million times less than the smallest quantity to be detected by the finest chemical test that was ever discovered! It is by such preposterous notions as these that homœopathists delude themselves and the public. It is on such ineffable absurdities that fashionable fools rely for aid in sickness; and (who would believe it?) it is with men who profess and believe in such inanities that some of our profession have degraded themselves by consulting. I quite agree in the spirit of the resolutions, that there should be *no shadow of compromise;* and that under no pretext of meeting for diagnosis, for surgical aid, or for any other purpose, should there be any intercourse between regular practitioners and the abettors of this monstrous and mischievous delusion. (*Cheers.*) Believing, nay, knowing, as we do, that homœopathy is entirely a fallacy, we must feel it our bounden duty to discountenance it in every way, and boldly to warn the public against its mischievous sophistry and fatal infatuations. (*Cheers.*)

Dr. Crisp concurred in the Resolutions; but thought that they did not strike at the root of the evil—the relations of the government to quackery, and quacks.

Dr. Cowan of Reading said:—Allow me, Sir, to make a few observations in favour of the adoption of this report. I am not a raw recruit in the anti-quackery ranks, having for many years done my utmost to expose and denounce the numerous delusions of the day, especially those affecting our own noble science. I am rejoiced to see the hearty and healthful tone of feeling with which the report has been received; for it appears to me most proper and most important for this Association to take the present opportunity of pronouncing its formal and its unanimous (*cheers*) rejection of homœopathy. The increase of homœopathy, I look upon with a very grave view; I regard it as one of those portentous moral phenomena which are stealing over the age. It is not the *practice of medicine* only that is at stake—it is the *practice of sound thinking.* When we supplant by mushroom theories truths which have hitherto occupied the minds of men, and been tested and confirmed by the experience of ages;—when we bring into existence new phantasies of the human mind, and give them the outward formality of facts, we surrender the stability of our judgment, and depart from all soundness of thinking. With us, as medical practitioners, the rejection of homœopathy is a question of principle, not of doses,—a question of morals, and not of etiquette. (*Loud applause.*)

The man who believes in homœopathy is a mystic—his creed is at variance with all rational experience, and subversive of all previously acquired knowledge. He has lost the ballast of his reasoning faculties, and set at defiance all those means by which the human mind is regulated. I distrust his judgment upon any subject—belief in homœopathy is but the symptom of a mind without stay or ballast, liable to be driven hopelessly into any folly, ever ready to spurn to-day what it yesterday believed. Hahnemann, the founder of homœopathy, was an enthusiastic visionary who preferred the wretched mushroom spawn of an inflated self-esteem and an extravagant fancy to those slowly growing, and ever deepening truths which ages had accumulated, and the wisdom of the wisest and the best of men had augmented and confirmed. If homœopathy be true, then are we all believing a lie, as all our forefathers have done; but if it be utterly baseless and false—as in my inmost soul I believe it to be—it can only be regarded as a deadly parasite upon Rational Medicine, which ought to be boldly excised, and cast aside by every sound-thinking mind.

This is an age of moral and intellectual anomalies not in physic only, but also in divinity. We have amongst us the monstrosity of Romish doctrines being consistent with Protestant preferment (*Hear, hear*), and the equally anomalous paradox of men educated as members of our honourable profession availing themselves of their titles and degrees while adopting and practising opinions which if previously avowed would for ever have excluded them from their present qualifications. Were a homœopathist a consistent and honest man, he would at once disassociate himself from a school whose best philosophy he proclaims to be a lie, and spurn a diploma which only pledges him to error. To eject homœopathic practitioners from our ranks, and exclude them from professional fellowship, is no act of tyrannous intolerance or bigotry, but a necessary measure of self-respect and self-defence—a consistent testimony to the principles we profess—the only method of extricating truth from apparent alliance with what we unhesitatingly assert to be a folly in philosophy and a dangerous delusion in practice. (*Applause.*)

In discussing homœopathy, I do not attempt its refutation by merely pointing out its arithmetical absurdities, and physical improbabilities; but I banish it at once beyond the pale of discussion, and class it amongst the fallacies too extreme for investigation. If a man say to me "Two and two make *five*," I do not speak to him twice; the man is *gone;* and if a man profess to me his belief in homœopathy, I am apart from him for ever. (*Repeated cheers.*) He admits as facts things at variance with rational experience, and in these circumstances I must stand aloof from him. (*Long-continued applause.*)

We have read of *mental epidemics* in the middle ages, but we are apt to forget how extensively they prevail in our own. In the midst of such restless excitement, such morbid extravagance, to adhere to the "old paths" and to sobriety of judgment, is no easy task. To be for ever seeking *first principles*, and to be without a standard *within*, by which new pretensions can be tested, is the condition of multitudes of all classes among whom we live—it is one of the most dangerous characters of an age of over-heated intellectualism. We rush wildly forth upon the field of experiment, mistake our fancies for facts, our expectations for principles; and are soon hopelessly enrolled in the rapidly swelling ranks of the deluded and deluding.

But I must not farther enlarge. Let me only say in conclusion, that to me our present duty seems very plain—it is to repudiate principles at variance with an honourable and a rational profession. Whether as an Association we perish or survive, let us nail our colours to the mast, and sink or swim in the good old ship of Rational Medicine. (*Cheers.*)

The motion was put from the Chair, and unanimously agreed to.

The following Committee were then appointed in terms of the fifth Resolution.—Dr. Cormack of Putney, Dr. Tunstall of Bath, Dr. Ranking of Norwich, Dr. Malden of Worcester, Dr. C. J. B. Williams of London, Sir Charles Hastings, M.D. of Worcester, and Dr. Cowan of Reading.

The Address in Medicine. Dr. King of Brighton then read the "Address in Medicine," which was warmly and justly applauded. It has since been published by Mr. Churchill.

A vote of thanks, proposed by Dr. Malden, and seconded by Dr. Hodgkin, having been unanimously carried, the President "feared to say anything on the subject, after the truly eloquent address from Dr. Malden on the eloquent paper of Dr. King. To his colleagues in Brighton, there was nothing in it to surprise them, because they knew his excellent character, and his goodness of heart (hear, hear); but he hailed it with delight, that such a paper should have been read to this meeting of the Association by a physician of Brighton."

The vote of thanks was carried by warm acclamation.

The Anniversary Meeting for 1852 was fixed to be held at Manchester; W. J. Wilson, Esq., of Manchester, to be President-Elect.

Communications. Several hours were then devoted to cases and papers. Mr. Caleb Williams (York) read a paper on the change, during the last thirty years, in the types of disease. Dr. R. Hall read a paper entitled "Observations with Hutchinson's Spirometer." Dr. Sibson exhibited an improved form of his "Chest Measurer." Mr. Smith (Southam) read a curious paper, tending to show that the diminution of the age of man since the creation, had not been *gradually*, but by jumps; and that in each case, some great sin, such as pride, lust, idolatry, hardness of heart, had been precedents of those changes. He enforced the importance of our adopting the opposites of these, which might have the effect of diminishing disease, and prolonging life. Mr. Bottomley read a paper, detailing the successful treatment of a curious case of gangrene in the foot and leg. Mr. Domville read a paper on the causes of deafness. Dr. Crisp read a paper, the object of which was to show that kousso was not absolutely a specific for tape-worm. Mr. Hunt read a paper on the skin, as a diagnostic of health. Dr. Oldham read a paper descriptive of a successful Cæsarean section under chloroform. He recommended an opening from below, as small as possible, to be afterwards enlarged according to necessity, instead of resorting at first to the major operation, so as to avoid excessive hæmorrhage.

Dr. Conolly moved a vote of thanks to the President. The motion having been seconded by Dr. Hodgson, was carried by acclamation.

The President returned thanks, remarking that their kind expression of feeling towards him would be always a gratifying recollection.

An adjournment now took place, at five o'clock, to afford an opportunity for the members to prepare for the dinner, which took place in the Royal Banqueting Hall, recently restored by the Brighton Town Commissioners; and scarcely less gorgeous than when used for the reception of royal guests in the time of George IV, under whose immediate direction it was designed, built, and decorated.

Dr. Jenks, the President, ably filled the chair. Although many had to start for their distant homes before dinner, there were about 250 present, including in addition to the members, Dr. Paris, President of the College of Physicians; Mr. South, President of the College of Surgeons; the Bishop of Chichester; the Rev. H. M. Wagner, Vicar of Brighton; the Rev. T. Cooke; the Rev. S. R. Drummond; Rev. J. Nelson Goulty; Montague Scott, Esq., High-Constable of Brighton; W. Furner, Esq., Judge of the County Courts of Sussex; Eardly N. Hall, Esq., Banker; Lewis Slight, Esq., Clerk to the Brighton Commissioners; P. R. Wilkinson, Esq.; Jacob Bell, M.P.; Mr. Jackson of Boston, U. S., etc., etc. The band of the 1st Dragoons (Royals) played before and during dinner. The party broke up about midnight.

TO OUR READERS.

Our desire to give a full report of the important proceedings of the Provincial Medical and Surgical Association, has caused the omission from this number of the Appointments, Obituary, and various short articles of Miscellaneous Intelligence.

We congratulate the profession on what has been so nobly done for the vindication and preservation of its honour by the Association. The Resolutions could not be better, or more explicit. It must be gratifying to those who took a lead in the business, to find that their exposures of homœopathy have caused a cry of agony to issue from the charlatanic press, which tells of a wound.

Record of the Medical Sciences.

OCTOBER 1851.—No. XXXIV.

ORIGINAL COMMUNICATIONS.

ON THE VAGINAL, OR DEEP BURSÆ MUCOSÆ.

By WILLIAM COULSON, Surgeon to St. Mary's Hospital, etc.

My former paper[1] had for its object an examination into the nature of the superficial or subcutaneous bursæ, to show in what respect they differ from all other structures, and more especially from the deep or profound bursæ. My present object is to consider the nature of the deep bursæ. By deep bursæ mucosæ, I mean the synovial membranes, usually vaginiform, interposed between two or more tendons, between tendon and bone, or between tendon and ligament, for the manifest purposes of protecting the structures from the injurious effects of friction, and of facilitating motion.

In the upper extremity, where we have chiefly to deal with morbid conditions of these bursæ, the synovial membrane extends downwards as far as the distal insertion of the tendons, and upwards for some distance beyond the fibrous sheath. Each tendon is covered by a reflexion of this vascular membrane, and is loosely attached in the whole, or in part, of its course, to the walls of the canal, by a fold similar to the mesentery, and called meso-tendon. These folds limit the movements of the tendons in a slight degree: they may be torn by some violent movement, and are occasionally the seat of disease.

Anatomical Arrangement. Upon the dorsal surface of the wrist, there are distinct sheaths,—1. For the extensor carpi ulnaris; 2. For the extensor minimi digiti; 3. For the extensor communis digitorum and the indicator; 4. For the extensor secundi internodii pollicis; 5. For the two radial extensors; and, 6. For the extensores ossis metacarpi et primi internodii pollicis. Any one or more of these sheaths may become distended, and assume the characters of a bursal swelling. There are also five or six thecal sheaths on the palmar surface, and these are the most frequent seat of enlargement. Enlargement of the bursæ in this situation is a most formidable disease.

[1] London Journal of Medicine, January 1851.

The sheaths of the extensor ossis metacarpi, and of the extensor primi internodii pollicis, and of the extensor carpi radialis longior and brevior, merit special anatomical notice, as they are often affected with morbid changes. The two first, free in their fibrous sheaths, but covered by the same visceral layer of synovial membrane, can only be partially separated; and there are some anatomists who regard the two tendons as divisions of one and the same muscle. The two extensors of the radial side of the wrist are likewise retained in apposition by a common visceral layer of membrane, as far down as their point of separation to their respective insertions. The synovial membrane there leaves the extensor carpi radialis brevior, being continued only over the extensor longior. Throughout their whole course a meso-tendon attaches them to the posterior wall of the sheath.

Along the anterior or palmar surface of the wrist and forearm we have two sets of bursæ; some small, and often overlooked, others of considerable size. The palmaris longus and brevis are each enveloped in loose areolar tissue, abounding in thick serous secretion; and it is easy to comprehend how such a structure would become converted into a complete synovial sac under favourable circumstances. About three months ago, I removed from the hand of a working-man a thick walled cyst, lying between the integument and the palmar fascia, and containing a sort of synovia. It had doubtless been originally a bursa, thickened by the constant pressure of the hand upon the hard iron handle of an immense hammer. The patient described it as originally a small elastic swelling, situated under a part of the hand where the skin had for a long time been very much thickened; as the tumour increased in size, it pained the hand, and, interfering then with his work, made him anxious for its removal.

The tendon of the flexor carpi ulnaris has a large and well-marked synovial sheath, especially loose and sac-like, near its insertion in the pisiform bone.

Finally, there are the general synovial bursæ, which invest the tendons of the flexor muscles of the fingers, and of which many different anatomical descriptions have been given. Fourcroy and Bichat affirm, that there is but one synovial bursa at the level of the carpus. Velpeau and Cruveilhier describe two, one common to the flexor tendons of the fingers; the other proper to the long flexor of the thumb. Monro, Koch, and Bourgery, enumerate a much greater number of bursæ in the anterior region of the wrist.

Some of the deep bursæ communicate directly with the joints. The bursa beneath the crureus muscle belongs to this order, likewise the large bursa below the iliacus and psoas; its frequent communication with the hip-joint is well known. On the other hand, there are some which greatly resemble the cellular bursæ in various stages of transformation towards the perfectly developed bursæ. Of this kind is the extended bursal arrangement around the tendon of the plantaris muscle; another, equally remarkable, is between the middle tendon of the omo-hyoideus and the sterno-mastoid; and a third interposes between the long abductor and extensors of the thumb on the one hand, and the radial extensors on the other.

These structures resemble in many respects the serous membranes, and are yet more closely allied to the synovial, with which, as I have

said, they are not uncommonly continuous. Upon their free surface we find a stratum of epithelium, supported by a basement membrane, and under this is a layer of blood-vessels, which may be filled with injection in a part rendered soft by partial decomposition. The blood-vessels form a net-work many layers thick. No one would suspect the existence of such a number of arterial and venous capillary tubes, from the examination of this structure in its normal condition after death. In many situations are found vascular fringes, first noticed by Havers in the joints, and described by him as the source of secretion of the synovia. They are found along the thecæ of tendons, and in some of the bursæ in the neighbourhood of the knee, and are composed of loops of vessels. Although we may not be able to prove experimentally what tissue secretes, and what absorbs the oily fluid contained in these sacs, yet we may infer, that both processes go on most actively wherever the blood-vessels are most numerous. The vascular part of the bursa seems to cease where the membrane is firmly attached to a bone, as along the phalanges of the fingers.

Symptoms and Pathology of Enlarged Vaginal Bursæ. In using the terms *superficial* and *deep*, I allude, of course, to the primary connexions of these structures, and in no way to the situations which they may subsequently acquire. A collection of fluid, either in the large theca of the flexor tendons of the forearm, or in a sac connected with this membrane, may make its way towards the surface so as to elevate the skin like the pointing of an abscess, and to render it thin and discoloured; and yet we must include this under the head of deep bursæ. The same remark may be applied to the bursa in the neighbourhood of the knee-joint, connected with the tendon of the semimembranosus muscle, which frequently becomes enlarged and projects into the popliteal space.

The clear albuminous fluid, secreted in the healthy state by these structures, undergoes various modifications by inflammatory action. At first it becomes thinner and more sparing than natural, and the part, when examined, communicates to the fingers a crackling sensation. Then it may be more abundant, and cause distension of the sac, attended by severe pain. If this affection be deeply seated, and beyond the reach of surgery, it gives rise to very considerable suffering, and excites symptoms which are not readily understood. If, for example, it occur in the bursa of the tendon of the psoas and iliacus muscles, it may be readily mistaken for incipient disease of the hip-joint. In course of time, the fluid of an inflamed bursal sac entirely loses its oily nature, becomes serous and watery, and is frequently of a yellow, or even reddish-brown hue, from admixture of blood.

But there are sometimes found, especially in the synovial theca of the flexor tendons of the wrist, numerous hard fibro-cartilaginous bodies, like millet seeds, floating loose in the distended sac. They have been improperly called hydatids, but are, in truth, growths from the vascular fringe of the membrane, projecting inwards towards the cavity, and covered by epithelium. As they increase in size, the pedicle connecting them with the membrane is eventually broken by the friction of the parts contained within. We have instances of similar bodies becoming loose in the cavity of a synovial sac, in certain rheumatic affections of joints. The enlarged bursa is not uncommonly

loculated, or divided into partitions by septa or bands. In general, however, the compartments readily communicate one with another.

The most frequent seat of enlargement is the synovial sheath, which invests the flexor muscles of the fingers, and extends from the forearm under the annular ligament to the palm of the hand. When distended by fluid, it produces a considerable elevation, which is often constricted and divided into two parts by the annular ligament of the wrist. The walls, when laid open, are found to be thicker than natural; the lining membrane is rough; the fluid contained within is opaque, yellow, or yellowish-brown, and thick, and it frequently contains those small bodies above-mentioned, which are smooth externally, and often hollow; some, however, are solid, of fibro-cartilaginous structure, and resemble grains of rice in general appearance. The cyst, when minutely examined, is generally found thickened and of fibrous structufe; externally it is connected to the parts around by loose areolar tissue. Internally it presents a velvety or roughened appearance, and there proceed from it numerous fringes, of which some are pedunculated. Embedded in these fringes are sometimes those hard white bodies, which are frequently found free in the sac; some of them are elongated and seed-shaped, others flattened and triangular, or round. The smaller are generally solid; the larger contain a cavity. These bodies were described by Dupuytren as hydatids; and the term "hydatiform" has been applied to the bursal swellings about the wrist, under the idea that such parasites were the cause of the enlargement of the sac, and of the collection of fluid. Deviations, both in the quantity and in the consistence of the synovial secretion, may produce a peculiar condition of these fibro-serous canals, which yield upon pressure a crepitating or crackling sensation. This sound may be heard in whatever region of the body fibro-serous grooves naturally exist. It is commonly heard in the region of the shoulder-joint, where it is connected with a morbid condition of the sheath of the long tendon of the biceps flexor cubiti. M. Poultain relates a case, in which these symptoms gave rise to the notion of fracture; and in the *Lancet* for 1836, 1837, the late Mr. Wallace of Dublin mentions a case, where an affection of this kind, in the extensor tendons of the thumb of a young woman, had been mistaken for fracture. The same sound has been heard about the tendons of the hamstring, and behind the internal malleolus in the sheaths of the flexor muscles of the foot; behind the external malleolus, along the course of the tendons of the peronei muscles and those upon the instep, and in other parts.

Although violence is often assigned as the cause of this affection, its origin, in the greater number of cases, is obscure. It is more likely to depend upon the influence of some constantly acting source of irritation than on any sudden injury, and the symptoms which usher it in support this view. At times, indeed, there is at the commencement acute pain, which, however, gradually subsides when the part is at rest, and is excited only upon movement. But more commonly there is little or no pain felt by the patient, until he makes a greater effort than usual, when the attention is for the first time directed to the part. Upon awaking in the morning, the part is stiff, but the stiffness goes off after a little exercise. There is rarely either heat or redness;

the latter is generally secondary, and referable to accidental rubbing and friction. There is always some amount of swelling, the form of which depends upon the natural connexions of the part affected. If the disease occur in the sheath of the extensores ossis metacarpi and primi internodii pollicis, the tumour extends obliquely across the lower part of the forearm, from the ulnar to the radial side. If it affects the radial extensors, the swelling, wider below than above, passes over the inferior and outer part of the broad extremity of the radius. Any anatomist can tell in what groove this affection is situated, by making the patient move under his direction the different muscles of the forearm. In severe cases, the stiffness of the limb, the sensation of weakness, and the pain upon movement, are so considerable, that a man is unable to follow his employment; and, in the higher ranks of society, accomplishments, such as instrumental music, which require great freedom of movement, have to be suspended, or, indeed, entirely given up.

The manner in which these tumours shew themselves, is as obscure as their etiology. Sometimes a peculiar creeping sensation is experienced down the fingers, wrist, and forearm; at other times there is stiffness, weakness, and difficulty of movement. In other cases, it is the tumour which first attracts the patient's attention; and the symptoms above related are felt only at intervals, and after any greater exertion than usual. The shape of the swelling, as it affects the large bursa mucosa surrounding the flexor tendons of the fingers, is variable; sometimes it commences in the palm of the hand, at other times in the lower part of the forearm; and in both instances it soon becomes bound down by the annular ligament. Indolent, and painless upon pressure; fluctuating, and presenting irregular projections, it appears as a bilobed mass, upon which the fingers have an involuntary tendency to close. If the contents be steadily and forcibly squeezed downwards towards the hand, a movement may be communicated to the fingers, along whose thecæ the fluid is pushed. And during this examination, when the fluid is pressed backwards and forwards from one end to the other of the enlarged sac, a peculiar *frottement* is felt, upon which Dupuytren laid great stress as a diagnostic symptom.

The pain and sensation of weakness produced by such a tumour is so great, that the limb soon becomes useless; the fingers are permanently bent, and any attempt to extend them excites a dragging sensation along the entire cyst.

Cases occur, when the tumour is large, in which the ulnar artery and the superficial palmar arch are raised upon the swelling; the radial artery, too, may be separated from the bone, before it turns under the styloid process of the radius. The integument of the palm of the hand becomes thin from want of use, loses its transverse markings and lines; it is elevated into a soft, smooth, compressible swelling, extending, in severer cases, along the flexor surface of the fingers. Continued position of the fingers in this abnormal state, leads to permanent changes in their articulating surfaces, and in the ligaments which unite the bones one to another; hence it arises that in old cases, where the flexion has existed for a considerable time, the evacuation of the cyst, or the cure of the bursal enlargement, does not restore the mobility of the fingers.

Diagnosis of these tumours is not at all times so easy as many surgeons have affirmed. If situated on the palmar surface of the wrist, the bursa is recognised as a fluctuating bilobed mass, the shape depending upon the size of the sac, and the constriction of the annular ligament. But the contents may be of such consistence, that there will be no fluctuation. But the crepitation to which I have before alluded, produced by the passage of the fluid containing the hard grain-like bodies from one compartment to another of a sac, through a narrow orifice, may be taken as characteristic of the nature of the tumour, in connexion with the constriction produced by the annular ligament.

M. Robert, however, has recorded the following case of fatty tumour of the hand, resembling, in many of its physical signs, the affection which we are now describing. [*Annales de Thérapeutique*, tome ii.]

A young man, aged 27, a butcher, was admitted into the hospital, with a tumour of the size of half an orange, situated upon the ulnar side of the palm of the right hand. It was subcutaneous, soft, and elastic, giving a peculiar crackling sensation upon pressure, and lying in front of the flexor tendons: it was trilobed, and deeply grooved. The fingers were slightly flexed upon it. The patient had noticed it first when about twelve years of age. It remained stationary till three years ago, when it suddenly increased in size. After an exploratory puncture, a crucial incision was made, and the skin was reflected back, when a tumour was exposed, composed of two portions set one within the other; the inferior flat, but deeply hollowed in the middle; the other portion of a cylindrical form, lodged in the hollow of the preceding. The second portion was moveable upon the first; and the friction thus produced, communicated to the hand the "crepitating sensation" above referred to.

An important point of diagnosis, rendered more valuable by accurate modern research, is derived from the consideration of the natural connexions of the bursal sac affected by disease. The origin of the tumour, its inclination rather towards the ulnar than the radial side, the effect produced upon the fingers, the free movements of the thumb,—these are points which indicate that the disease originates in the bursa of the general flexor tendons. The circumscribed swelling of the radial side of the hand, the weak condition of the thumb, the inability on the part of the patient to bring it into firm apposition with the rest of the hand, pronounce the bursal affections to be limited to the tendon of the flexor longus pollicis.

Prognosis. Many years may elapse before these tumours acquire any great magnitude. Slow in their growth; often painless; obscure in their origin; they pass unheeded, especially among those whose occupations require neither the exercise of great strength, nor the application of great delicacy of touch. Ultimately, after years of enlargement, they become stationary, but they do not disappear; at least, there is no satisfactory case of the kind upon record. All, then, that we can expect nature to effect, after the establishment of the disease, is the arrest of the further enlargement of the tumour.

As regards the serious nature of these affections, those tumours confined to a single finger, often limited in extent, are less to be feared than those in the palm of the hand, involving the entire bursa, and

requiring the performance of an operation, which, though simple as regards execution, may be followed by dangerous symptoms.

Treatment. It is customary, in the chronic cases, to employ counter-irritants, such as blisters, irritating ointments, etc. The emplastrum ammoniaci cum hydrargyro, spread upon leather, may be applied to the limb, and secured by a firm bandage; the whole to be worn for several weeks. If the fingers are stiff, friction of the limb and passive motion may be resorted to, when the swelling has in great measure disappeared, and the fluid is nearly absorbed. The arm may be soaked and rubbed in a warm arm-bath daily. When the limb is immersed in a heated fluid, much greater force may be used with impunity, than under the ordinary circumstances.

The operations which have been recommended for the cure of these synovial tumours are the following: — Extirpation; incision, either simple or combined with irritation of the surface of the cyst; subcutaneous puncture; and iodine injections.

As regards extirpation, it is extremely difficult, on account of the extent of the connexions of the sac.

I have generally contented myself with making an incision longitudinally through the most prominent part of the swelling, and evacuating the contents. Some amount of inflammation usually supervenes; and the cavity becomes obliterated in the usual manner. But there is a risk of the inflammation proving very severe, and extending along the muscles of the forearm, attended with a high degree of fever and constitutional disturbance. Death has ensued from such an attack; and in other cases, in which the inflammation has been subdued by active treatment, the mobility of the fingers has been permanently impaired.

Case. Maria Hughes, aged 63, thought that she had run a splinter, about nine years ago, into the skin over the palmar surface of the first bone of the right fore-finger. A swelling of the size of a small nut soon afterwards appeared, and continued slowly to increase to a tumour of considerable size, extending from the first bone of the finger along the metacarpal bone. The swelling was very tense, projecting into the palm of the hand, but well defined, and not reaching beyond the palmar region of the fore-finger; the thumb and middle finger were free, and the dorsal surface of the fore-finger was natural. The motion of the fore-finger only was impeded. In August 1850, I made a free incision into the extremity of the swelling over the first phalanx of the finger, and evacuated a wineglassful and a half of concretions of a lozenge shape and size. After evacuating the cyst completely, I placed a compress over the part, and used firm pressure; but severe constitutional symptoms, almost threatening the life of the patient, ensued; the pressure was obliged to be removed, and warm poultices applied. An abscess formed at the other extremity of the swelling, and another at the dorsal surface of the finger. Both were freely opened, and a good deal of pus evacuated. The opening at each extremity of the swelling discharged freely; and after three months the walls of the sac united. At the present time there is a slight thickening in the course of the sheath, and the second and third phalanges are bent backwards. She has but little motion yet of the finger. Mr. Toynbee analysed the bodies which were evacuated from the cyst for me. He says: "The bodies which you sent me consist of gelatinous matter,

enclosed in a very delicate membraneous capsule. Upon microscopic examination, this matter is found to be composed of a homogeneous jelly-looking substance, without the presence of any corpuscles or nuclei. I have frequently examined the gelatinous matter removed from enlarged bursæ at the back of the wrist; and I have found it to have the same composition as the bodies you sent me."

The use of the seton may lead to results difficult of management, and even dangerous to life. The following case, recorded in the *Leçons Orales* of Dupuytren, shows how a fatal result may follow its employment.

Case. A carpenter, aged 35, received (Dec. 1812) a sprain in the right wrist, which healed in a short time without trouble. About two or three months afterwards, he remarked a small tumour in the palm of the hand below the annular ligament, and soon afterwards a second above the ligament: they were at first very small, and but little troublesome. They impeded at first the free exercise of the hand, and afterwards prevented its motion altogether. Being unable to continue at his trade, he consulted M. Dupuytren, June 7th, 1814. From its position, the nature of the tumour was suspected; and examination rendered the point clear. The following day, an incision was made into both tumours, and a multitude of little white bodies immediately escaped. The aponeuroses of the hand and of the forearm were liberated by means of a blunt-pointed bistoury, that there might be no constriction in the event of inflammation. A seton was introduced to inflame the walls of the cyst; and a poultice was then applied to moderate any inflammation that might arise. Severe pain supervened on the evening of the operation. It increased, accompanied with great swelling, on the second, third, and fourth days; a greyish fluid, mixed with flakes of lymph, flowed from the wound. The seton was removed the fifth day. The inflammation extended to the arm, and to the axilla; and constitutional symptoms of the most distressing kind arose on the eighth day; some gangrenous aponeurotic structures were divided. An abscess, which had formed between the first and second metacarpal bones, was opened. Compression expelled a quantity of pus, which had formed sinuses the whole length of the forearm and hand. On the tenth and eleventh days, there were shiverings, with convulsive action of the jaws, lasting about ten minutes. The pus was extremely fetid. There was general weakness, which resisted the most powerful tonics; and death ensued on the fifteenth day from the operation.

This case made a great impression upon Dupuytren, who for the future changed his mode of operation. In place of a simple opening in the most prominent part of the tumour, he made large incisions; and substituted for the seton a piece of lint interposed between the edges of the wound, to prevent their union. Mr. Syme of Edinburgh, impressed with the same fear of constriction in these cases, has recommended the preliminary division of the annular ligament, as was suggested a long time ago by Warner. Mr. Syme has published a successful case in the *Edinburgh Monthly Journal* for October 1844.

Professor Gerdy has successfully practised the subcutaneous incision; and such an operation has much to recommend it, as there is not that fear of the severe inflammation which often attends the exposure of the cyst. The operation should be combined with pressure;

still, though less dangerous, it is also less sure than incision, and there are many cases in which it is impracticable.

Iodine injections have been recommended by Velpeau in the treatment of these bursal enlargements, but many objections have been raised against the practice, on account of the chance of severe inflammatory disturbance. I am inclined, however, to recommend this plan for adoption.

M. Chassaignac has related a case in the *Gazette des Hôpitaux*, in which, after having evacuated the fluid, he injected through a canula, first some warm water to clean out the cyst, and next some tincture of iodine. The cyst was then emptied, moderate pressure upon the walls was exerted by means of a compress, and the opening made by the trochar was properly secured. Some inflammation supervened; but it yielded to treatment, and the case terminated favourably.

An analysis of the cases in which this treatment has been tried is decidedly favourable to the practice, although I am not quite prepared to agree with Michon, that there is less chance of inflammation than of relapse and the re-collection of the fluid. An attack of inflammation of the hand is always a serious matter, often so impairing its movements, as no subsequent endeavours on the part either of the patient or of the surgeon may be able to rectify.

Professor Bouley has demonstrated the superiority of iodine injections over other means of exciting inflammation, and he has succeeded thus in dispersing tumours of large size, without danger or inconvenience. If therefore simple puncture or incision should fail in the first instance, I recommend this practice as far preferable to the introduction of setons and other foreign bodies.

It must not be supposed that the surgeon has effected all his task by the evacuation of the fluid and the obliteration of the cyst. There remains for him to restore the mobility of the fingers, long since become stiff, semi-flexed, and in great part useless. For this purpose he must recommend exercise, passive motion, baths, etc., and by perseverance the hand may again be brought into a useful state.

It is singular that this affection of the bursa of the flexor muscles of the forearm and hand should be rare in the corresponding structure in the lower extremity, more especially considering how the foot is compressed in tight boots, and exposed to constant violence and injury. A case, however, of the kind is related in the *Medical Times*, July 13, 1850. A young lady, aged 20, of slight frame, but in the enjoyment of very good health, consulted Mr. Stanley for a painful swelling of the right foot and ankle. Five years previously, she had been greatly fatigued by a walk of extreme length, and she arrived home much exhausted, but was sufficiently recovered in a few days to go about as usual. From that time, however, the right foot and ankle were weak and painful, and swelled upon her taking the least exertion. About two years ago the swelling became permanent, and the ankle, which was easy when at rest, was so painful when she attempted to walk, that she was obliged permanently to keep the horizontal posture. Every variety of treatment had been adopted without avail; the swelling about the joint increased until the integuments gave way, and there formed an ulcer, whence flowed a thin sero-purulent fluid. There was a large swelling between the tendo Achillis and the os calcis, extending down to the

sole of the foot; part of the swelling was firm, part was elastic, as if containing fluid; the integuments covering it were thinned and livid, and had given way in one spot, exposing a fungous-looking mass of granulations: the movement in the joint was perfect. The limb was removed, and the morbid change was found to be limited to the synovial thecæ, which surround and accompany the tendons of the tibialis posticus and the flexor communus digitorum muscles to the sole of the foot. It was therefore strictly circumscribed and surrounded by healthy structures. The thecæ were thickened: their usual bright synovial surface was converted into a dull, uneven velvety structure, from which was produced a soft growth composed of cystoblasts, and a small quantity of delicate fibrous tissue. This growth made its way upwards between the posterior surface of the tibia and the tendo Achillis, and downwards into the sole of the foot, between the flexor brevis digitorum and the flexor accessorius muscles, both of which were quite healthy. The flexor tendons were unaltered in structure, but were surrounded by the soft growths above described, and by a large quantity of morbid synovial secretion, which seemed to be contained in more cavities than one; for behind the malleoli it was of pale straw colour, and somewhat stringy, whilst in the sole of the foot it was of watery consistence, of red colour from admixture of blood, and contained coagula.

I cannot conclude this paper without strongly recommending those who desire further information on the subject to consult the thesis of M. Michon,[1] to which I am indebted for many of the preceding details.

ON THE INTRODUCTION OF SOLUTIONS OF LEAD INTO THE BLADDER, FOR THE DECOMPOSITION OF PHOSPHATIC CALCULI.

By S. ELLIOTT HOSKINS, M.D., F.R.S.

In a paper which the Royal Society did me the honour of publishing,[2] some account was given of the decomposition of Phosphatic Calculi, by solutions of certain salts of lead, so dilute as to admit of their retention by the living bladder, without irritation or inconvenience.

The adaptation of the principle of double decomposition to the disintegration of vesical calculus, is in strict accordance with chemical usage: it supplies a class of agents, more energetic as regards the concretion, and less injurious to the organ in which it is contained, than any of the uncombined solvents hitherto employed. The *solvent*, no matter how dilute, can only be tolerated for a minute or two at

[1] Des Tumeurs Synoviales de la Partie Inférieure de l'Avant-Bras, de la Face Palmaire du Poignet et de la Main. Thèse présentée au concours pour une Chaire de Clinique Chirurgicale. Par L. M. Michon. Paris: 1851.

[2] Philosophical Transactions, Part 1, 1843.

farthest, and cannot soon be repeated: the *decomponent*, on the contrary, is retained from ten to fifty minutes without discomfort, and may be repeated daily, or oftener if necessary. The cause of this difference is sufficiently obvious: the active agent of the decomponent is liberated gradually, and neutralised by the earthy bases of the calculus, before it can come in contact with the living tissues; whereas the former class of fluids causes such immediate irritation, that their ejection is required before any impression can be made on the concretion. The *base* of the decomponent unites with the *acid* of the calculus, while the acids of the former combine, and form soluble salts, with the bases of the latter. The combined acids are set free in definite proportions, neutralised in their nascent state, and removed from the sphere of action before any stimulating effect can be exerted on the bladder.

The cases which I am about to bring forward, although sufficient to prove the unirritating effect of these decomponents, when thrown into the bladder, are by no means calculated to test the amount of their action on the very concretions which they decompose so energetically out of it. It is not, however, because I cannot cite a host of triumphant cases establishing both points,- that the observations I have been enabled to make, as to the mild character of the solutions, ought to be withheld.

Case i. Mr. F., aged 72, a patient of Mr. Coulson, was affected with palsy of the bladder; the urine was occasionally alkaline, and charged with phosphatic deposit. He suffered much from the accumulation of ropy mucus; it often prevented the urine from flowing through the catheter, without the introduction of which the bladder was never evacuated. The instrument, when passing through the prostatal portion of the urethra, was felt to grate over a considerable extent of calcareous matter impacted in the gland. He had experienced mitigation of symptoms, as regarded the mucus, from the injection of very dilute nitric acid; but in consequence of the irritation it occasioned, he could not bear its repetition a third time. Nevertheless, a solution of lead was, from the first, retained for twenty minutes; it produced a soothing effect at the time, and was not followed by the slightest annoyance. It was continued daily, or every second day, for six weeks, and often retained for half an hour. On rejection the fluid appeared milky, contained flakes of coagulated mucus, and yielded a considerable precipitate of phosphate of lead. The eyes of the catheter often contained gritty particles enveloped in mucus, which yielded a sensation similar to that produced by rubbing the pineal gland between the fingers. At the end of the above-mentioned period, no grating sensation could be felt on passing the catheter; the injection was therefore discontinued for some months, but again resumed, in consequence of a recurrence of this sensation, and of the mucoid secretion. After being persevered in for some time, it was again left off, relief having been obtained.

Case ii. This gentleman was a patient of Mr. Guthrie. His general health had been very much impaired by long-continued suffering. Two calculi had been originally present in the bladder. One had been crushed, and the greater part of it removed; but the fragment retained was the cause of much uneasiness, especially when it rested

on the neck of the bladder. The urine was alkaline and bloody, containing mucus, and apparently pus. A stricture also existed in the urethra. The bladder was very irritable, but bore the presence of the lead solution for twenty minutes, with no more inconvenience than that which resulted from the introduction of pure water. The injection was continued every second day for nearly a fortnight. Particles of calculus frequently came away some hours after its use; they consisted of oxalate of lime, cemented together by triple phosphate. The latter was rapidly acted upon by the lead solution. The patient died soon after. Both his kidneys were found to be diseased, containing pus; the right enclosed four calculi. One stone was found in the bladder, besides that which had been broken up by Mr. Guthrie. A very small portion of the latter remained.

Case III. This was a patient of Mr. Key and Mr. Hunter. His bladder contained a large triple phosphate calculus. He had been lithotritised by another surgeon, unsuccessfully. The operation had caused much pain, and subsequent irritation, which had been soothed by injections of opium and warm water thrown into the bladder. The urine was neutral and turbid, containing blood and mucus. He occasionally passed calculi, of the size of small orange pips, which were readily decomposable by the lead solution. This fluid, when injected, was retained by the bladder without inconvenience, the first time for ten minutes, the second for half an hour, the third, fourth, and fifth, for fifty minutes. The rejected fluid deposited considerable quantities of precipitate on the filter. On one occasion it amounted, when dried, to eighteen grains of phosphate of lead.[1] Owing to some prejudice on the part of the patient, the injection was discontinued after the first week. This was unfortunate, as the case appeared to be favourable for testing the value of this mode of treatment.

Case IV. This was a patient of Mr. Copeland, aged 78, who had laboured for some time under vesical calculus, but on whom it was not expedient to operate. He used the solution for three weeks before his death. It was productive of a soothing effect on the bladder; and, whenever it was used, the ensuing evacuation of urine deposited a number of small crystals, but at no other time were they passed. After death, two large calculi were found in the bladder, and a smaller one sheltered behind an enlarged prostate. The surface of the concretions was studded with crystals, of the same description as those which had been brought away during life by the injection.

Case V. A retired army surgeon, aged 72, had been lithotritised seven years before, after which he had passed many fragments of uric acid calculus, with phosphatic coating. The prostate was enlarged, and the constant use of the catheter required. He tried the solution of lead twice or thrice a day for about a fortnight; but, although the bladder was irritable, the liquid, as he stated to me, caused "no pain whatever; on the contrary, it acted as a sedative to the lining membrane". He had, however, made up his mind to lithotomy, which was performed by Mr. Keate, and a stone, composed of fusible matter, urate of ammonia, and oxalate of lime, removed. On immersing frag-

[1] For this quantity of phosphate of lead, the equivalent is twelve grains of ammonio-magnesian phosphate.

ments of this calculus in the solvent, he found that, "after a few hours, they had diminished one half in bulk and weight; the exterior coating being eaten away, and the nucleus appearing a very different substance, much darker and harder". About three months after the operation, he again felt uneasy sensations, as though another fragment existed. He continued the use of the lead injection, which he found very soothing.

Case vi. Another patient of Mr. Coulson had long been suffering from affection of the urinary organs. He occasionally passed particles of calculous matter, but no stone could be detected in the bladder. This organ was paralysed, and required the constant introduction of the catheter for its evacuation. This gentleman was subject also to severe spasms, from the retention of a morbid secretion of vesical mucus, which, on being voided, was found to contain particles of phosphate of lime. He derived "much comfort" from the injection of the lead solution, and found that it lessened the secretion of mucus, facilitated its expulsion, and thereby lessened the frequency of painful calls to evacuate the bladder. There appeared to be also a greater disposition to expel the urine by natural efforts.

Other cases could be adduced, but the foregoing are sufficient to prove, not only that the bladder, under irritation, tolerates the presence of these solutions of lead, but also that they act as sedatives, and exert a favourable influence, directly and indirectly, on the morbid secretion of mucus which exists in cases of this nature.

After having made trial of most of the vegetable supersalts of lead, all of which act, more or less, as unirritating decomponents, I have returned to the use of that originally proposed, the nitro-saccharate,[1] as by far the most effective. That prepared for me by Mr. Garden, of Oxford-street, is much more energetic as a chemical agent than my own, and equally mild in its physiological effects. It is likewise more decidedly an organic salt, which I consider essential to the fulfilment of the ends in view; and I am strengthened in the opinion that sugar is a necessary ingredient, from the perusal of two papers in the July number of the *Pharmaceutical Journal;* one by M. E. Peligot, On the Combinations of Sugar with Lime, and another by M. Barreswill, On the Solution of Carbonate of Lime in the Saccharates.

One grain of the salt, superacidulated with five drops of strong acetic acid, is the proper proportion for admixture with each fluid ounce of water.[2] It is essential that the salt and the acid should be incorporated before the addition of the water, and that the whole should be brought to the boiling point. Superacidulation is necessary on many accounts; it secures perfect solution, increases the decomposing activity of the liquid, and prevents the formation of any carbonate of lead.

As the salts contained in the urine tend to decompose the solution, and lessen its effects on the concretion, the bladder should be eva-

[1] Philosophical Transactions, 1843, p. 11.

[2] The decomposing power of these solutions is in *inverse ratio* to their concentration; for instance, a saturated solution of the acetate, superacidulated pretty freely, is inert; whereas, in the above proportions, decomposition of phosphatic calculi takes place rapidly.

cuated, and washed out with tepid water before the lead fluid is introduced. A double-current caoutchouc catheter is the best for this purpose, as it enables a continuous stream to be employed; and as, on account of its flexibility, it is less liable to irritate the urethra, which should be sedulously avoided. From four to eight fluid ounces of the solution may be thrown into the bladder at a time, and renewed every ten or fifteen minutes, as often as may be deemed proper. By renewing the liquid at short intervals, much greater effect on the calculus is ensured, than when it is allowed to remain longer; for the precipitate formed by decomposition soon envelops the stone, and puts a stop to further action, until a fresh surface is exposed. Exercise during the retention of the injection increases its effect. Some slight revulsion may be produced by the first introduction of this, or any other fluid, into the bladder; when such is the case, the operation should be remitted for a day or two, and cautiously renewed. The injection may be either warm or cold, as may be most agreeable to the sensations of the patient. Warmth favours the decomposition of the calculus.

If used with proper precautions, I have found that the lead solutions exert as sedative and salutary an influence on the lining membrane of the bladder, as they do on external surfaces under inflammation. They also act upon the mucus, which is so abundantly formed in cases of this nature, coagulating it into short curdy flakes, which are easily passed through the urethra.

When the urethra itself is inflamed, or abraded, the injection will be injurious; for the lining membrane of the canal is, I believe, more sensitive than that of the bladder. The introduction therefore of decomponents should be had recourse to, either before lithotrity, or after the urethra has recovered from the effects of the instruments employed, but can never be used, with any prospect of success, where organic disease of the bladder or prostate exists. The injection should not be employed during the internal exhibition of hydrochloric acid, although it may be freely used when nitric acid is administered. When the bladder is not very irritable, a dilute nitric acid injection, alternating with the lead solution, will hasten decomposition.

The two facts established with respect to the lead salts, viz., first, their toleration by the bladder, and, secondly, their chemical action on calculous concretions, induce me to hope that they may become useful agents in the treatment of various other affections of the urinary organs. I have never presumed to imagine they would prove specific solvents for the stone; but, I trust that, where surgical operation is inadmissible, they will be of some avail for relief, if not for cure, by smoothing asperities, and removing the outward phosphatic coating of calculi, so as to bring them within the verge of the crushing forceps; in short, that they may avail for partial, if not for entire disintegration. The latter is more likely to happen where layers, composed of the urates or oxalates, are bound together by phosphatic cement. On this species of calculus, they are calculated to act as highly carbonated waters do on those of another description.

"Nor is the action of highly carbonated waters", says Dr. Prout, "confined to their mere solvent effects; they undoubtedly possess disintegrating power; that is, the power of disturbing the attraction,

both cohesive and adhesive, by which the molecules of the calculi are held together, so as to render them brittle and easily broken into fragments". This is an additional reason for using decomponents before recourse is had to lithotrity.

Besides the kind of cases already adduced, there is one variety for which decomponents seem to be peculiarly adapted; viz., concretions in the prostate gland. No instrument hitherto devised has been successful in dislodging them. The first case, however, mentioned in the present paper, goes to prove that a considerable quantity of calcareous matter was removed from the prostatal portion of the urethra, by the use of the lead injection.

In the first experiment communicated to the Royal Society, it was stated, that one hundred grains of calculus immersed in lead solution for forty minutes, had lost twelve grains. In the second experiment, the quantity dissolved, from a fragment weighing thirty-seven grains, was, after half an hour's immersion, eight grains. Subsequent experience has verified these observations, and proves that, under favourable circumstances, decomposition takes place in definite proportions; so that, from the precipitate of phosphate of lead, the quantity of ammonio-magnesian phosphate which has been decomposed may be securely estimated.

Since these circumstances obtain out of the bladder, by means of a fluid which can be borne by that organ with impunity, we may reasonably hope, that the mere transference of the scene of action, from the exterior to the interior, will not materially affect the results.

The foregoing communication contains the substance of a paper read before the Royal Medical and Chirurgical Society, the debate[1] on which was founded chiefly on a solitary case, confessedly one of the most unfavourable that could have been selected; one in which "nothing could be injected into the bladder without producing great irritation." The consequence was a natural disinclination to give the lead solution further trial. This paper not being deemed worthy of publication, and the Philosophical Transactions not being read extensively by medical men, the subject has not hitherto been before the profession. Its present publication arises from fortuitous circumstances, and a conviction that there are certain conditions in which the means recommended are likely to be beneficial, rather than from any desire to assume peculiar merit, or from motives of personal interest. I am as far removed by local position, if by nothing more, from the influence of the one, as I am indifferent to the other.

Having ascertained that a certain solution, mild enough to be tolerated by the human bladder,[2] exerts much chemical influence on phosphatic calculi, I am desirous of engaging the attention of those among my professional brethren, whose abilities and opportunities may enable them to pursue the investigation more thoroughly than I can.

Guernsey, Sept. 3, 1851.

[2] My own eye was the first test of its mildness.

CASE OF DIFFUSE PULMONARY APOPLEXY, WITH RUPTURE OF THE PLEURA, AND HÆMATHORAX.

By STANHOPE TEMPLEMAN SPEER, M.D.Edin., etc.

Case. W. B., an individual in reduced circumstances, 62 years of age, had for some time been in a weak state of health, when he was suddenly attacked, in the month of February 1851, with most alarming orthopnœa, extreme distress, lividity of countenance, together with symptoms resembling a fit of congestive asthma. These in a great measure subsided, and when seen by me, on the third day after the attack, the following was his condition. There was still considerable dyspnœa, unaccompanied by pain, but by a sense of weight, heat, and constriction in the chest; there was cough, with very scanty viscid mucous expectoration, untinged by blood; the respirations were twenty-eight in the minute: the pulse was small and irregular. A physical examination gave evidence of a certain relative amount of dulness over both lower lobes, as compared with the upper ones; while, in these especially, there were heard some distant bronchial râles, principally of the dry kind. The expiration was considerably increased, both in length and loudness, while the inspiration was comparatively feeble, both murmurs having a rough, harsh character; these signs were the same on both sides, and were more marked in front than behind. The attack lasted a fortnight, and gradually subsided, without any change in the character of the râles, and with but little in that of the expectoration. No signs of solidification of the lung could be detected; and the case throughout manifested a remarkable want of coincidence between the extreme severity of the symptoms, and the comparative want of confirmation derived from the physical signs.

It is, however, worthy of remark, that the heart's dulness on percussion was totally unappreciable; and that the respiratory murmur was heard over the entire space usually occupied by the uncovered portion of that organ. Its impulse was imperceptible; and its sounds, which could scarcely be detected, but by making the patient hold his breath for a few seconds (a process which could only be adopted towards the latter end of the attack) shewed that irregularity of action existed; this was confirmed by the character of the pulse, which (as before said) was small, feeble, and irregular from first to last. No murmur accompanied either sound.

Although the cardiac symptoms, with the exception of the irregular action, were of a negative character, I entertained a suspicion that the sudden attack of orthopnœa, with the symptoms of pulmonary congestion, were in some measure dependent upon the condition of the central organ of the circulation, which probably was softened or attenuated.

The patient recovered slowly from the immediate effects of the attack, and had resumed his usual occupations (never indeed of a laborious nature), when, on the 16th of May, about three months from the previous seizure, while slowly walking across a yard, he suddenly stopped, threw up about a couple of quarts of dark blood, and expired before medical assistance could be of any avail.

Necropsy twenty-four hours after Death. On opening the thorax, the lungs did not collapse; they appeared to be of great size, filling the whole of the cavity, which seemed scarcely able to contain them. The heart was completely hidden. And the whole surface of both lungs was of the deepest red colour; the right one, when removed, presented a perfect specimen of uncircumscribed pulmonary apoplexy, its entire substance being gorged with very dark coloured blood, which, upon making incisions into the lung, flowed out freely from every part. The substance of the organ was soft and pulpy, as if it had been soaked in blood; while its structures seemed completely obliterated, so great had been the effusion into them. The left lung presented the same appearances, if possible in a still higher degree; in its lower lobe, and at its posterior aspect, the pulmonary tissue was found completely broken down into a soft friable pulpy mass. Corresponding to this portion, was found a rent in the pleura, two inches in length, through which upwards of a quart of blood had escaped into its cavity.

To account for this rare occurrence, no traces of disease of the lungs besides those mentioned could be detected. The bronchial mucous membrane was pale; and, although the tubes contained fluid blood, there were no other morbid appearances connected with them. At the right upper lobe, there were traces of sub-pleural emphysema. The large vessels were all carefully examined, but no aneurism or rupture of any kind could be detected. The aorta itself was quite healthy, but of rather small calibre, as compared with the volume of the pulmonary artery.

The heart was found driven deeply backwards into the mediastinum, by the pressure of the distended lungs. Its valves were all perfectly sound and competent. The muscular substance, however, afforded proofs of disorganisation; it was of a pale yellow colour externally, and for about one-third of the thickness of its wall, when incised. When handled, it was found to alter its shape with great facility, and could be moulded and kneaded in the hands like dough. The walls of the ventricles were soft, flaccid, easily ruptured, and afforded an example of that condition designated as yellow softening of the heart. No superfluous fat was found around it, and its cavities were rather larger than usual.

Remarks. The case just narrated, is undoubtedly one of very rare occurrence; and but few similar ones are to be found on record. One is related by Corvisart, in his translation of Avenbrugger; the second by Hohnbaum, as mentioned in Dr. Forbes's translation of Laennec; another is to be found in the *Clinique Médicale* of Andral; and a fourth is given by Dr. Fergusson, in the first volume of the *Dublin Medical Transactions*. Others doubtless exist, but to the particulars of these alone have I had access; and I find that each observer has remarked the rarity of the occurrence. The four cases just alluded to, all agree with the one narrated above, as regards the appearances found after death. In each, the whole or a portion of the lung was the seat of uncircumscribed pulmonary apoplexy, with breaking down of the lung, laceration of the pleura, and escape of blood into its cavity. During life, moreover, the symptoms were strikingly similar; a sudden shock,

succeeded by a rapidly fatal termination, being the leading features of each case. The principal difference being the absence of external hæmorrhage in two of them.

It is worthy of remark, that in none of the instances were there to be found those cardiac lesions which are so commonly supposed to accompany the circumscribed variety of pulmonary apoplexy; and, in the absence of these, it becomes an interesting inquiry, as to the cause of this condition in the cases which have just been quoted, as well as in the one which forms the subject of this article.

Since the year 1816, when this affection was first noticed, three hypotheses have been hazarded as explanatory of these sudden and copious effusions of blood into the tissues of the lung and pleural cavity; namely, *a*. Paralysis of the Pulmonary Plexus of Nerves; *b*. Diminished Coagulability of the Blood; *c*. Dilatation of that Fluid itself.

Paralysis of the Pulmonary Plexus was advocated by Lorinser, and other pathologists of the German school; and was supposed to act by producing a comparative over-action of the vessels of the lung (*Vide* Forbes' Laennec). The theory in itself does not appear to have undergone much investigation; but it not improbably has some foundation, inasmuch as the occurrence of sudden attacks of local paralysis in other parts is well established. Too little, however, is known on this subject, as applied to the cases in question, to say anything very definite regarding it.

Diminished Coagulability of the Blood. We have reasonable grounds for attributing many instances of passive hæmorrhage into the substance of the lungs, to such a condition of the circulating fluid; and the existence of extravasated blood in the lungs of those dying of purpura, is an argument in favour of the diminished coagulability of the blood being occasionally a predisposing cause of the diffuse form of pulmonary apoplexy. But in cases like the present, such a condition alone can scarcely be supposed adequate to the production of such results. Extravasations of blood, the simple result of diminished coagulability, are invariably of a passive nature; they have all the appearance of gradual formation, and are for the most part accompanied by certain other indications of a purpurous or hæmorrhagic diathesis; or, if that be not the case, they are found after death to have existed in conjunction with advanced cardiac disease, which, in such cases, had by its long continuance so deteriorated the quality of the blood, as to render its escape from the pulmonary capillaries, and its gradual infiltration into the parenchyma, a condition very analogous to the true purpurous extravasation.

Dilatation of the Blood. The morbid appearances found in three cases of severe apoplexy of the lung, occurring suddenly, and with such severity as to merit the term "apoplexie foudroyante" of the French writers, would then appear to suggest the existence of some sudden change, acting either immediately upon the mass itself of the circulating fluid, or through the intervention of its nerves:—consisting either in the withdrawal of a certain pre-existing influence, as in the pulmonary paralysis of the Germans previously mentioned; or in the accession of a new and unaccustomed influence, of which but little notice has ever been taken, but which Laennec considered it

necessary to admit in certain cases of sudden, profuse, and otherwise unaccountable hæmorrhage; namely, dilatation of the blood itself.

Now, without venturing to affirm that such a phenomenon does actually take place, I cannot avoid entertaining the idea, that in a fluid of so complex a nature, possessing such essentially vital qualities, and undergoing such changes as does the blood, whether in health or disease, modifications of bulk, independent of additional material, may, under favouring circumstances, really take place; while, on the other hand, a similar condition may equally be the result of an addition to one or other of the elements of the blood, more especially to the globules. The existence of local plethora is not of unfrequent occurrence; and the great increase in the amount of the globules has been proved to be its characteristic peculiarity; but whether the active distension of the blood-vessels, which exists under these circumstances, be owing simply to the mechanical influence of the augmented globules, or to an increased vital activity in those processes reciprocally existing between them and the more fluid portions of the blood, is not certain. What we know is, that an increase in the number of one of its most important ingredients (the globules) is the distinguishing mark of plethora. Something is in excess; and that excess is equally proved to be a predisposing cause of one form of hæmorrhage. If, therefore, it is in this sense of the word that we are to understand dilatation of the blood (with its similar process to give rise to such effusions) the term does not appear to be so misapplied as we might at first sight suppose.

If, however, we are to understand by dilatation of the blood, a vital change in that fluid, by which (without any extraneous addition being made to its bulk) it occupies or requires a larger containing space than before, we are thrown upon pure hypothesis. Yet, as before stated, the fact does not appear absolutely impossible; for, to quote the words of Dr. Wood of Philadelphia, "The blood may become diseased by a change in the character, as well as in the relative quantity of its constituents, and this independently of the entrance into it of any foreign principle. In what way such changes are effected is not precisely understood. There are not wanting facts to show that they may be produced by the action of the nerves. If, under perverted nervous influence, the products of secretion performed in the capillaries may become unhealthy, as is generally believed, there can be no difficulty in admitting that the blood itself, in these capillaries, may undergo alterations from a similar cause. If nervous action be, as some suppose, analogous to the galvanic, we can readily understand that it may be capable of modifying the condition of the vital fluid submitted to it, in the extreme vessels, as water is decomposed when placed between the poles of a galvanic battery. We may conceive, also, that the constituents of the blood may be modified by the varying condition within the body of those subtle principles, which exercise so powerful a chemical agency without it—namely, heat, light, electricity."

If, therefore, such a condition of the blood does occasionally take place, as its actual dilatation, its cause should, I conceive, be sought for, and connected with, certain modifications of atmospheric and electrical influence. The effects of these upon homogeneous fluids are by no means trifling; but upon a fluid such as the blood, they must, in all

probability, be considerable; and in relation to temperature, the idea would appear to be borne out by the prevalence of those states of the body, characterised by plethora and increased vitality of the blood, during the first accessions of summer heats. This is indeed a fact so generally believed, that few countries are to be found, the inhabitants of which are not in the habit, at this time of the year, of taking measures for diminishing the mass of the blood, whether by baths, venesection, purgatives, vegetable diet, etc.; hence, again, the custom of many of our ancestors of undergoing a precautionary loss of blood in the spring. I have moreover remarked that, as a general rule, the most severe and numerous cases of hæmorrhage occur at the commencement of the first summer heats. Of ten very severe cases, which I have seen since last October, all occurred within a space of two months, from the middle of April to the middle of June; and my own experience has led me to notice a preponderance of such cases every year at the same period.

With regard to the influence of electricity upon the blood, much also may be surmised, if little be actually known. It is well known, that bodies in a similar electric condition have the power of repelling one another; and it has been supposed that the circulation is aided by the electric state of the blood. In his valuable little work on *Electricity and Galvanism*, Dr. Golding Bird says: "That if a vessel containing water, having a very small hole in its base, be connected with the prime conductor of an electric machine, the water will merely escape by guttation; but on setting the machine in action, the particles of water becoming similarly electrified, repel each other, and the fluid escapes in a continuous stream. In accordance with this fact, it was long ago shown, that if a patient have a vein opened in the arm, and the blood happens to escape but sparingly, on placing him on a glass stool and electrifying him, the blood will, like the water in the vessel just alluded to, escape *pleno rivo*." Holding this fact in view, and remembering the difficulties that have always been experienced in explaining the capillary circulation, we may possibly have another clue to those perturbed conditions of this circulation (independent of any change in the functions of the central organ), which so frequently occur at a season of the year, when undoubtedly great electric changes are going on in the atmosphere; but here again we are forced upon a supposition as to the *modus operandi* of this agent on the circulation. It is possible to conceive, that the particles of the blood being highly charged with electricity would tend to repel each other; but this in itself would not contribute to produce onward movement in the whole bulk of the fluid. It would certainly cause a separation of the particles one from another, but this might take place in one direction with as much facility as in another, and thus no assistance of an impulsive character would be derived from it. But the blood being subjected to a considerable amount of *vis a tergo*, the repellent action can only act in one direction, since those particles which might otherwise tend to retrograde, are entirely prevented from doing so by the bulk of the fluid behind them, urged onwards by the motor power of the heart. In this way we may conceive, that the electrical repulsion of one set of particles is exercised upon another, which, from mechanical causes, is unable itself to develope this property; and hence the repellent power

becomes merged in one continuous onward wave, the first impetus to which is given by the heart, and is then maintained by the electrified particles shunning one another; and as they can only do so by moving in one direction, a continuous circulation is thus kept up. It is needless to add, that the above can only be considered in the light of an hypothesis, and as such, may be taken for as much as it is worth.

In two cases of pulmonary apoplexy related by Hohnbaum, the appearance of the lungs, and the symptoms, both prior to, and at the moment of the fatal event, both pointed to the existence of a condition of the blood, very different from that which would indicate diminished coagulability alone as the cause. In these instances, the individuals had both suffered from symptoms of plethora; they had both lived in a manner capable of inducing and keeping up such a condition; and, in both, there was evidence of derangement in the pulmonary circulation, as evinced by dyspnœa, contraction of the chest, and paroxysms of asthma. When examined after death, the lungs, in both instances, appeared too large for the cavity of the thorax, so dilated and gorged were they with the immense accumulation of blood in their tissues, while in neither case, was there any disease of the heart or other organ found, to explain the morbid appearances; and whether these are to be attributed to some modification of the blood itself, or to a sudden palsy of the pulmonary nerves, (as suggested by the narrators), must necessarily be a matter of uncertainty; probably the two causes may have acted simultaneously.

The following case, although not of a fatal nature, presented certain symptoms so identical with those which preceded death in those previously mentioned, as to merit a slight outline. A gentleman, of middle age, and in perfect health, while occupied in his bed-room, suddenly experienced a pain in the chest, and fell senseless on the floor; he remained in this condition for nearly twenty minutes, and when consciousness returned, he found himself free from headache or any other cerebral symptom, but his breathing was short, he had dull pain in the left side, a small, quick, thready pulse, great anxiety and uneasiness, and altogether he presented a very unpromising appearance, especially in relation to the thoracic symptoms; these, nevertheless, both in their invasion and in their combination, were of so anomalous a character, that it appeared difficult to refer them to any of the more ordinary diseases of that cavity. A physical examination was not much more satisfactory; the left upper lobe, both before and behind, was the seat of rough and diffuse bronchial breathing, with an obscure sound of crepitation, which did not resemble the ordinary moist sounds usually heard in the tubes or air-cells. There was also slight comparative dulness over the same part; the right lung presented nothing abnormal, and the heart appeared perfectly healthy. These signs underwent no alteration of character, but gradually subsided, still, however, preserving their somewhat anomalous character; inasmuch as, neither from their own evidence, nor from that of the symptoms, could the ordinary phlegmasia of the lung be diagnosed; while, on the other hand, there was enough to show that the affection was not a purely nervous one. The mode of invasion, (which I learnt fully some days after first seeing the patient), precluded the idea of previous chronic disease, besides which, his health had been perfectly sound for a length of time.

Coupling therefore these circumstances with the sudden shock, the sensations in the chest, the anxiety, small rapid pulse, but absence of true febrile symptoms, and the physical signs, I surmised the existence of a latent pulmonary apoplexy, depending (as I cannot forbear imagining) upon one or other of the causes just alluded to. Had there been any visible hæmorrhage, I should have felt certain as to the nature of the attack; but it is well known that this is not a necessary accompaniment of pulmonary apoplexy.

I may add, that this individual recovered perfectly, and subsequent examinations served only to confirm belief in the gradual absorption of blood extravasated into the intervesicular structure of the lungs. Had this case proved suddenly fatal before the return of consciousness, it would have been attributed to a cerebral affection in all probability; and it is not unlikely, as Dr. Forbes remarks, that this error may have frequently been committed under similar circumstances.

With regard to the case which has formed the subject of these remarks, it would appear a matter of equal difficulty, to explain satisfactorily the sudden occurrence of so extremely severe an attack of pulmonary apoplexy. Reasons, however, might be adduced for attributing it, in part, to each of the conditions suggested as capable of producing it. The sudden shock might be owing to the supervention of the pulmonary paralysis of the authors previously mentioned. The appearance of the lungs on dissection, gorged and distended with dark blood, might suggest the probability of an increase in the bulk of the fluid; while the apparent absence of coagulability, the manner in which the blood flowed from every incision, together with the character of that which was found in the pleura, might lead to the supposition that diminished coagulability had likewise a share in the phenomena observed upon dissection; more especially when taken in connexion with the fact, that the individual had been in early life, and, indeed, up to within a few years of his death, in easy circumstances, but that during this latter period, the change in his mode of living, his diet, etc., had been of a very inferior description, and perfectly sufficient to account for any impoverished condition the blood might have undergone. His cachectic appearance, moreover, tended to countenance such an opinion.

The softened condition of the heart may have had a passive share in the production of the hæmorrhage and its consequences. It has been found to exist, independent of any inflammatory process, in cachectic persons; and what is more to the point, has been shown by Dr. Hope to be very influential in the production of pulmonary apoplexy. In three cases of softening, detailed in the last edition of his *Treatise on Diseases of the Heart*, two gave evidence of most extensive apoplectic effusion; and he alludes, in addition, to several other cases of the same kind. The principles upon which he states this lesion to act are the following. The left ventricle, weakened and generally attenuated in its parietes, becomes unable to expel its contents; an obstacle is thus offered to the entrance of blood from the left auricle, and this at once produces an obstruction to the free disgorgement of the pulmonary veins, and a consecutive retardation of the whole pulmonary circulation. If, then, we admit that in the case narrated above, a similar condition of the lungs existed habitually, in connexion with a softened heart, it is no longer difficult to believe that a sudden change, whether in the bulk

of the fluid itself, or in the nervous influence regulating its distribution, might cause a general exhalation of blood into the various tissues of the lungs, more especially if (as is not improbable) a previous tendency to diminished coagulability had rendered its extravasation comparatively easy.

In intimate connexion with this subject of the dilatation of the blood, I may mention that, since the preceding remarks were written, I have had my attention directed to the fourth chapter of Dr. Cormack's *Prize Thesis on Air in the Organs of Circulation* (Edin. 1837), entitled "Remarks upon the Generation of Air in the Living Body, especially in the Blood-Vessels; with observations on the consequences which may result from its presence there". He shows that "there are various facts and arguments, which render it exceedingly probable that, owing to the sudden formation of air within the blood-vessels, death may be produced either by arresting the contractions of the right side of the heart, or by producing a fatal action on the brain."

Cheltenham, August 29, 1851.

ON SOME DIFFICULTIES IN THE STUDY OF HYSTERIA.

By SETH B. WATSON, M.D., formerly Physician to the Ratcliffe Infirmary, Oxford.

The Benevolent Power presiding over universal nature, has determined that, for the most part, diseases dangerous to animal life should quickly attain a crisis, in the recovery or death of the sufferer. Of such diseases, whatever may be the theory of their treatment, the course is apparently settled, the reasoning upon them clear and simple, and the result, from its rapidity, in some measure satisfactory to the spectator. But there is another class, whose continued presence is quite compatible with animal being; and of these, as it is their property to remain without full destruction to the organs they disturb, so is their progress unsatisfactory, and the means taken for their removal uncertain, conjectural, and obscure. In these, the physician provides himself from all sources, and from his personal experience (contracted as far as possible to obtain concentration), with certain types, or ideals of diseased states, from which he insensibly selects one, towards which the case before him appears most to approximate; for, in reality, he must rest satisfied with such an approach to truth, as an escape from the extremes of useless scepticism, and blind credulity. Hysteria may be placed among this class, as one of the most difficult; so much so, that a perfect treatise on hysteria would comprehend within itself the primal foundations on which the structure of medicine, as an art, must finally be raised. I say as an art, in opposition to its popular development as a practice, each requiring a different constitution of mind; to the perfection of the former, self-distrust being as conducive, as self-confidence is necessary to the latter. The modes and processes of the human intellect are not favourable to the exact study of this class of diseases. There is a tendency in our minds, by their levity and volatility, to overlook with ease all the many failures in dreams, charms, omens, and prophecies, but obstinately to remember the very few that are successful. Now the opposite state is required; we should have the capability of

recollecting, and a pleasure in dwelling with exactitude, on failures equally with successes. Nor can imposture cease, till the stimulus of praise or gain are unnecessary to an accurate remembrance.

Again, if in youth, by a too close attention to professional facts, those subjects on which the imagination, or an inferior faculty closely allied thereto, ought legitimately to be entertained, are totally shut out; if these professional discoveries too closely and too entirely occupy the student's mind, the imagination, deprived of its proper nutriment, is reverted on this state of practical life, and becoming thus diseased, and unguided by the beautiful, busies itself in working out and colouring medical cases, supplying, as the results of medicines and treatments, what exists only in a heated and disordered fancy. By the law of association, also, from constantly reading, and hearing that certain medicines produce certain symptoms in the progress of disease, we are accustomed in their use, with unshaken faith, to attach the cure to the remedy, destitute of the boldness to innovate, or of the irreverence which seems to be implied in doubting their efficacy. Our fears of words and names are too great, to allow us calmly to observe what would be the result of the total abstinence of our assistance. With us, coincidence and concurrence are allowed the weight of sequence. Even as students of the art of medicine, difficulties beset us, from which students in the other arts are free. For instance, in painting and sculpture, a habit of patient quietude, and concentration on single objects is encouraged, and a hurried walk round a gallery of pictures and sculpture would be considered confusing, rather than beneficial. In these arts, also, we consider the absence or presence of truth in the production, as the test of the degree of perfection in the artist. But man is naturally an animal believing in medicine; and nothing will wholly root out this instinctive proneness and declivity to believe, without proof, in the statements of cures. This is not more present, though more visibly so, in the medicine-men and charmers, than in the civilised and enlightened. It cannot be overlooked and contemned; for the painful fact must be acknowledged, that a love of such error is not accidental, but essential to our nature; and that in our progress toward medical truth, old open errors are too often exchanged for the newer and more recondite. Men, too, in their time of strength, and the even temperament of health, may neglect external forms; but, in their hour of weakness and depression, they cling to the visible and tangible—the form of something active, something being "done" for the patient, is called for by the superstition of the friends. To what other principle, than an instinctive knowledge of this working in minds under suspense, can be attributed the attempts to bleed drowned and crushed men, and others in a similar condition?

In the study and treatment of hysteria, we have all these difficulties to contend with; and these must excuse our want of permanent success. We can conceive hysteria to be a diseased mode of the will, which becomes inveterate from taking place in a disordered body, without its originating therein, or being wholly cured thereby. If it be considered a bodily disease alone, we should be forced to exclude the effects which a consciousness, or the being conscious of their corporeal existence, excites on the action of the nerves: for it will, I think, be granted, that there are few forms of hysteria, in which the

patient's attention is not fixed on some nervous receptacle, with too great a continuity and intenseness.

In some cases, hysteria appears to be the accumulation of unexhausted energies, of whatever kind; as if this spiritual or nervous accumulation became too great for its corporeal dwelling. When these energies find a proper vent, the hysteria disappears. Some impression made upon the heart or imagination, calling up a train of morbid sensations, continued without intermission, destroys the regular function of volition, and by over-exercise damages the bodily instrument of its operation.

It is curious to observe the mental character of the hysterical—the vacillating tone, and the halting between two opinions, which characterises the statement of their sufferings. Where there is actual disease, there is less delight in describing it; and the symptoms are comparatively clearly and succinctly related. With the complications of hysteria, the creations of fancy supersede the plain offspring of fact. A tendency to unsoundness in thought and expression, when only partial, and meeting with partial resistance in will, often takes the form of the hysteric paroxysm in those muscles over which the will predominates. Yet, when this resistance is wholly overcome, the tide of unconnected thought, feeling, and expression, sweeps on, and total incoherence is established.

A strong desire for the sympathy of those around, which is sometimes, unfortunately, to be obtained alone by the exhibition of the paroxysm, is one grand cause of its excitement. The attention of the hysterical is accidentally drawn to some other form of disease by proximity; and this in some gives rise to the artistic energy of imitation, without the wish to fraudulently simulate the disease. Women, with all their elegance and delicacy of perception, are not inventive, and rather work on what has been already presented, than originate even a new form of disease. Their want of self-consciousness, in many of their acts and feelings, has brought upon the hysterical the charge of active imposture; when, instead of this, they would be found defective in the power of placing their actions before their own eyes, and viewing them as the acts of strangers. The self-contemplating power of Hamlet and Macbeth, in opposition to the female characters of Shakspeare, will best explain this.

We cannot fail to observe that the hysteric paroxysm is restrained, and sometimes extinguished, in the moral atmosphere of women of clear understanding, as it is nourished by the weak sympathies of the reverse. With the same diet, air, exercise, and medicine, a patient will remain hysterical, with certain companions or attendants; and, under the same external circumstances, recover in the society of others; the want of attention to, and interest in, the exhibitions of the disease, being the only apparent difference. Old cases disappear under changes of scene, air, and passions, particularly the latter. Short walks, repeated at intervals, seem to break up and dissolve the morbid impressions, and gradually and insensibly increase the self-control, especially if these walks be taken in company with those of their own sex, of that temperament more likely to perceive the ludicrous than the tragic, in the common affairs of life.

16, Norfolk Street, Park Lane, September 1851.

BIBLIOGRAPHICAL RECORD.

Reasons for Embracing Homœopathy. By Charles Ransford, M.D.Edin., Fellow, and lately one of the Examiners, of the Royal College of Physicians of Edinburgh; Physician to the York Homœopathic Dispensary. pp. 24. London: 1851.

Letter to Professor J. Y. Simpson, President of the Royal College of Physicians of Edinburgh, concerning the Resolutions recently passed by that body in reference to the Therapeutic Practice commonly called Homœopathy. By Wm. Macleod, M.D., Fellow of the Royal College of Physicians of Edinburgh, Physician to the Wharfedale Hydropathic Establishment, and to the Llhlen Hydropathic Hospital. pp. 45. London: 1851.

Letter to the Patrons of the University of Edinburgh on the late Resolutions of the Medical Faculty. By William Henderson, M.D., Fellow of the Royal College of Physicians, Professor of General Pathology in the University of Edinburgh. pp. 24. Edinburgh: 1851.

Drs. Ransford, Macleod and Henderson are a notorious triumvirate: they are Fellows of the Edinburgh College of Physicians, and practitioners of homœopathy! Two other gentlemen, Drs. Macdonald and Gregory, we believe, complete the list of fellows who have joined the quack alliance, which, in common parlance, is termed homœopathy. Dr. Macleod combines homœopathy with hydropathy; Drs. Macdonald and Gregory are Mesmeric homœopaths; and Dr. Henderson, Professor of General Pathology in the University, avowedly practises several *pathies*, though he sneers at modern Mesmerism, and maintains that his own apostasy is not so much the cause of the decline in the number of students attending the Medical School, as the "Mesmeric *soirées* of the Professor of Midwifery, and the *Letters to a Candid Inquirer* of the Professor of Chemistry".[1] The settlement of intestine quarrels we must leave to those who are better acquainted than we are with what Dr. Henderson calls "the history of the last session"; but we think it right to say, that Professor Simpson has satisfactorily repudiated Mesmerism. Our present object is to give a short account of the three pamphlets before us, and to call attention to the deplorable predicament in which the Royal College of Physicians of Edinburgh, and the Medical Faculty of the University, are now placed:—anxious to act with consistency and propriety, but hesitating to do what they feel to be both right in itself, and necessary for their own respectability.

Dr. Ransford gives us some scraps of his personal history, which, however, require amplification. The curiosity of the reader is excited, but not gratified; we are told that the writer successively abandoned "ordinary practice" in Edinburgh and Alnwick, and that he is now trying his luck at homœopathy in York. We crave for further details. The propriety of entitling the pamphlet *Reasons for Embracing Homœopathy*, may in this way be fully vindicated: in its present unfinished state, it is a very lame attempt to defend and dignify the history of the author's migrations and doctrinal transformations. That Dr. Ransford is afflicted with a weak and illogical mind, a perusal of his pamphlet puts beyond doubt; for it is a production which could only have been published as a statement of "reasons" by a man incapable of understanding a medical inquiry. But while we discover and proclaim his mental deficiencies, we are not inclined to excuse him on these grounds.

[1] Dr. Gregory's book was reviewed in our last number, p. 820.

He seems to have sighed for homœopathy, "even while holding office in the Royal College of Physicians of Edinburgh, as a determined opponent of homœopathy and its disciples". He thus describes the state of matters in relation to homœopathy, when he was a candidate for Edinburgh practice.

"The conscientious, highly educated, and accomplished follower of Hahnemann, whose only object was to substitute in therapeutics, certainty for uncertainty, order for confusion; this man, we repeat, was treated as a Pariah, an outcast. Homœopathy was always pronounced to be on the wane, nevertheless *we found to our cost that it took from us our best patients;* we fondly hoped that these misguided people would, after a little time, return to their former orthodox creed and practice; but no, they not only deserted us, our cathartics, sudorifics, alteratives, derivatives, blisterings, bleedings, *et illud genus omne*, but, charmed with the superiority of their new favourite, in the most unkind manner they persuaded others to follow their example." (p. 5.)

It is always a most severe trial of integrity to see quacks grow rich, while honest men suffer from a want, or general desertion of patients: the result of such defection, to physicians without private fortune, is poverty; and poverty is too often the parent of charlatanry, even among men who, in other circumstances, might have resisted its meretricious allurements. Hiffernan's ethics, though too often followed, cannot be defended. "Paul Hiffernan", says Washington Irving in his *Life of Goldsmith*, "was something of a physician, and elevated the emptiness of his purse into the dignity of a disease, which he termed *impecuniosity*, and against which he claimed a right to call for relief from the healthier purses of his friends." Now it strikes us forcibly, that if Paul Hiffernan had lived in the present day, he would have adopted homœopathy as a cure and a prophylactic for his disease; and that many in his plight, as well as in that described by Dr. Ransford, have adopted a similar course, it is impossible to deny. We wish to draw no offensive parallel between Dr. Hiffernan and Dr. Ransford; but we do mean to say plainly, that the extract which we have given from the latter's *Reasons for Embracing Homœopathy*, compels us to suspect that—perhaps unconsciously—Dr. Ransford's conversion was simply the consequence of a wish to be converted. He ardently desired for "reasons to embrace homœopathy", just as the love-lorn lassie of the Scottish song wished her sister "*to advise her* to marry Tam Glen", in preference to "the laird o' Drummeller". We hope the Doctor thought as little of pelf as did the damsel.

> "There's Lowrie, the laird o' Drummeller,
> 'Gude day to ye, lass', he comes ben:
> He brags and he blaws o' his siller,
> But when will he dance like Tam Glen?
> Come, counsel, dear tittie, don't tarry;
> I'll gie you my bonnie black hen,
> Gin ye will advise me to marry
> The lad I lo'e dearly, Tam Glen."

Dr. Ransford's cases are detailed after the fashion of those which figure in the newspaper advertisements of Professor Holloway: they are calculated to mislead the public, but with the profession they can excite only contempt for the writer. Having made this remark, we think it right to quote the whole of the cases, with the comments upon them, contained in Dr. Ransford's pamphlet; and we shall be surprised if any of our readers can see in either, the shadow of an argument in favour of homœopathy or infinitesimal doses.

Let it be clearly understood, that we would not encumber our pages with Dr. Ransford's balderdash, were we not anxious to afford the profession a true picture of the calibre and morality of the man who writes himself "lately one of the Examiners of the Royal College of Physicians of Edinburgh". Is it surprising that a College which could appoint such an examiner, should be unsettled by medical scepticism and rampant quackery?

The quotation which follows is one continuous passage.

"His determination to test it was strengthened by attentively considering

the letter of his late ever to be lamented friend, Dr. Andrew Combe,[1] whose writings are so widely known and so justly appreciated in Europe and America. Dr. Combe had no cause to serve but that of truth. Truthfulness was his characteristic. The writer knew but too well, that so far as the uncertainty of medicine was concerned, he could scarcely be worse off; for professional intercourse (and this was considerable) with many eminent practitioners, had not tended to increase his confidence in drugs nor in medicine generally; nor did Dr. Forbes give him comfort, when he issued his celebrated number of the *British and Foreign Review*, containing the well known article entitled—'Homœopathy, Allopathy, and Young Physic'. In order to take his first step with every precaution, the writer acquainted his friend Dr. Russell of Edinburgh with his difficulties, and received from that gentleman every direction for the proper investigation of the homœopathic practice; he likewise went to Newcastle and introduced himself to Dr. Hayle, who received him with his wonted urbanity, and advised him, if he wished to be speedily convinced of the *power* and efficacy of homœopathic preparations, to select for trial *acute* cases of disease. He returned and commenced his investigations, carrying them on in such a manner, that with scarce an exception, his patients were ignorant of his proceedings, and did not suspect any deviation from ordinary practice, save that they were agreeably surprised to find themselves cured and relieved by medicines tasteless and colourless. The result of his first trials utterly confounded him. Acute inflammatory cases, of such a description, as are by consent of all authorities in medicine, ordered or recommended to be treated by bleeding, either general or local, and other debilitating measures, yielded much sooner to homœopathic remedies appropriate to each case. One of the earliest of these was the following instance of

"Bronchitis. Mr. P.'s infant, aged six months, residing two miles from Alnwick, was seized on the 26th of March, 1850, with cough and dyspnœa; attended with thirst, hot skin, and quick pulse. Domestic remedies, such as antimonials, castor oil, friction with Bow's liniment, had been resorted to; but as the symptoms increased in intensity, I was hurriedly sent for, early on the morning of the 29th, and found the infant lying exhausted in her mother's lap, suffering from cough, short, harsh, dry, and constant in its character; dyspnœa urgent, the nostrils dilating widely at each inspiration, skin hot, the pulse much accelerated; she could not take the breast. Tinct. aconiti and ipecacuanhæ, one drop of each was ordered to be given alternately every quarter of an hour. Relief was afforded within an hour. A messenger was sent to me, to prevent a repetition of my visit in the evening. I saw her the next morning, and ordered her Hepar sulph. This completed the cure. She did not require a third visit. When I prescribed for this case, it was with the determination that it should be the experimentum crucis; and that if a mitigation of the child's sufferings did not speedily take place, I would abandon the homœopathic treatment, and resort to the old system of leeching, emetics, etc., etc. Neither imagination nor diet could have had any share in the recovery; for the patient was an infant, and its only diet its mother's milk; and the same remarks will apply to another case, occurring at the beginning of this year.

"Mr. B.'s infant, aged six months, a stout plethoric child, was taken ill on the 20th of January, 1851, with cough and febrile symptoms. I saw him on the 22nd, the cough was dry and constant, face flushed, hot skin, quick pulse, and constant thirst. Tinct. aconiti and bryoniæ, one drop of each was ordered to be given alternately every half an hour. The patient was relieved before the evening. January 25th.—The cough being still somewhat troublesome, and accompanied with mucous râles over the chest, tinct. ipecacuanhæ, gtt. vj. was given in divided doses: the child required no further treatment.

[1] A man of most unsound faith, both in medicine and religion. Ed. Lond. Journ. of Med.

"A third case affecting the respiratory organs, likewise occurring in a child, who knew nothing of homœopathy, shall here be inserted. I was sent for on the 30th of September, 1850, to see Miss M. R., æt. 12, who was affected with bronchial irritation, fever, headache, and spasmodic cough Aconite was taken throughout the day, in one drop doses. My opinion given to her sister was, that something more serious than ordinary cough was impending. Tinct. of bryonia was administered the following day; in two days, hooping cough was fully developed; tinct. of nux-vomica was now prescribed in drop doses, and this had a marked effect upon the character of the cough: in ten days she was quite well, and returned to school. No other medicines than the above-mentioned were administered. A slight return of the cough took place after exposure to a cold east wind, but ipecacuanha in one drop doses gave relief within two days.

"Another case of a different character tended to make him still more satisfied with the superiority of homœopathic practice.

"Cerebral Convulsions. On the 30th of January, 1851, I was requested to visit Mr. H.'s son, aged thirteen months: he had been seized previous to my arrival, or that of another practitioner (who in my absence had been sent for), with general spasms of a violent character, accompanied by insensibility. The muscles of the face I was informed had been distorted, and the thumbs turned inwards towards the palms. When I saw him the face was very pale, and covered with a cold sweat; the gums were swollen from the pressure of the molar teeth upon them. I scarified the gums, ordered cold to be applied to the head, and administered tinct. of belladonna, one drop. 31st.—Has had a restless night, continued thirst, at noon the convulsions returned. Ordered tinct. ignatiæ one drop, to be taken immediately, and tinct. coffeæ one drop, to be administered in the evening for the purpose of producing sleep. From this time the spasms did not return, and convalescence rapidly took place. The teeth did not pierce the gums for several weeks afterwards, so that very little, if any benefit, could have arisen from the scarification of the gums, and I did not resort to it in the second case of difficult dentition occurring in Mr. S.'s child, aged eleven months. He was suffering from cough, hoarseness, hot skin, thirst, and restlessness; the eyelids were glued together with muco-purulent matter, and he was much griped. Castor oil had been given to him before I was sent for. Ordered nux-vomica, two globules, third dilut., to be taken every four hours. The next day I found him much relieved; excessive thirst was his chief ailment. Chamomilla was ordered, and the child was convalescent on the following day.

"The efficacy of minute doses of chamomile is strikingly exemplified in the two following cases. Mrs. P.'s child was seized (without any evident cause) on the evening of February 7th, with pain of abdomen and vomiting. Chamomile two drops, in divided doses, was all that was required to relieve him. The second case was Mrs. A.'s child, who sent for me on the evening of April 21st, 1850. He was complaining of pain in the stomach, accompanied by vomiting; the cause assigned was eating 'early greens'. One drop of the tinct. chamomil. gave immediate relief.

"So soon as I was convinced that the homœopathic preparations, administered according to the homœopathic law, were more efficacious in curing acute cases of disease than the old method of practice, I corresponded with several of my medical friends of the allopathic school, mentioned my experience on the subject, and requested their opinions. *Not one met the case on its merits;* one ridiculed the idea that such effects could possibly result from a decillionth of aconite, etc.; another dismissed the subject very summarily by saying, that 'he knew nothing whatever of homœopathy, but that he considered the administering of such small doses in really dangerous cases to be a trifling with human life': another's response was to this effect—'I have seen some narrow escapes from homœopathic treatment'. One friend, whilst opposing homœopathy, made this somewhat remarkable admission—

'I have no doubt but that patients will get well sooner under the homœopathic treatment'; a fifth saw no objections to my continuing the investigation secretly, believing that a return to my 'first love' would be the result of a more extended experience. Several of my patients of the higher ranks asked me whether I was practising homœopathically. I replied in the affirmative, but added, that as yet my mind was not sufficiently decided upon the matter; they did not care how I treated them, providing I did so conscientiously; and all my medical correspondents urged me not to proclaim my 'perversion' (so they termed it) until a few months longer should have passed away.

"The following cases are a few selected during those months of probation.

"Scarlatina. Mrs. L., near Alnwick, sent for me on the 20th of August, 1850, to see her niece. I found her labouring under a smart attack of scarlatina, with swelling and redness of the tonsils and fauces. Belladonna tr., six drops, was all that was required to cure her; her recovery was so rapid and complete, that it was only requisite for me to see her twice.

"The cases which follow occurred in adult subjects; they did not, with one or two exceptions, suspect me of any homœopathic tendencies, they having formerly heard me express myself strongly against it. Imagination, therefore, cannot be considered an element in the result; but let it be borne in mind, that there was no concealment on my part when questioned.

"Hemiplegia with Cerebral Congestion. D. T., Esq., aged 62, residing four miles from Alnwick, has had two attacks of paralysis in Edinburgh; he is now hemiplegic. On April 20, 1850, I was summoned to see him. He complained of headache and noise in the ears; the eyes were dull; the conjunctiva injected; pulse 90, full and bounding. He presented the same appearance (so Mrs. T. informed me) prior to his last attack; he has been accustomed to take colocynth pills for the purpose of relieving constipation. Lachesis, six doses, of three globules each, relieved him in a week, and his health has been uninterrupted (with the exception of his hemiplegic constitution) ever since.

"Congestive Headache and Catarrhal Ophthalmia. Miss —— had for some years suffered the infliction of an issue in one leg, in order to avert headache and ophthalmia (which desirable result, however, it failed to produce). At my recommendation the issue was healed. Pulsatilla gave her relief. The ophthalmia does not return, and the headache is much less severe in its character.

"Catarrhal Ophthalmia, with Ulcer of the Cornea. Miss —— sent for me to Alnemouth, July 18, 1850. She was suffering from inflammation of the conjunctivæ, accompanied by a febrile state, profuse lachrymation, and intolerance of light. On the right cornea was a small ulcer. Aconite and belladonna were the remedies at first employed; afterwards, sulphur, calcarea, and silicea. She completely recovered.

"Bronchitis. Miss K. was seized on the 19th of March, 1850, with severe frontal headache; pain in the sternum, increased by deep inspiration; frequent hard cough without expectoration; quick pulse; thirst, and hot skin. Aconite and bryonia were administered alternately every three hours. Before the expiration of twelve hours, a marked remission of the symptoms took place, followed by refreshing sleep. Mercurius, sulphur, and china, were the only additional remedies resorted to.

"Cynanche Tonsillaris. Elizabeth R., aged 21, was suffering on Jan. 14, 1851, from inflammation and swelling of the cellular membrane of the fauces and tonsils, accompanied by fever, difficulty of swallowing and speaking. Aconite and baryta carbonica cured her in twelve hours.

"Gastrodynia. Isabella S. is subject to pain in the stomach after eating, with occasional vomiting of food. Pulsatilla, sulphur, and baryta carbonica cured her: up to the time of my last seeing her (eleven months having elapsed) there has not been any return of the disorder.

"Gastrodynia and Hematemesis. C. B., a servant girl, left her place on account of severe and continued pain in the stomach, accompanied by frequent vomiting of food. She had been under medical treatment, and had swallowed a large quantity and a considerable variety of drugs without deriving any relief. She had resided in the country for six weeks with her mother when I first saw her, on the 22nd of December, 1850, but was not better. Pulsatilla immediately relieved her, and followed by sepia, completed the cure. Three months afterwards she went to service in the country; her complaint returned, and in addition to the former symptoms, she threw up a large quantity of dark grumous blood. I ordered her bryonia, which completely relieved her.

"Dyspepsia, Anorexia, and Vomiting of Coffee-coloured Fluid. Miss —— has been the subject of this affection for several years; she is opposed to homœopathy, but I persuaded her to try nux vomica, which gave her greater relief than any former remedy. If imagination had any influence in this case, it certainly was not exerted in favour of homœopathy.

"Vomiting and Acute Pain in the Stomach. Miss ——, residing some miles from Alnwick, was seized on the night of January 17th, 1851, with constant vomiting and violent pain in the epigastric region, increased on pressure. She attributed her illness to having eaten boiled greens at dinner. Repeated draughts of tepid water emptied the stomach, but nothing except bile was ejected. I saw her at 3 a.m. and gave her chamomilla tr., one drop; two doses of this relieved her. The next day, on account of headache, pulsatilla was given, and three doses of sulphur on the following day; convalescence was then complete.

"Gastrodynia and Vomiting of Food. Miss ——, residing in the country five miles from Alnwick, has for a long time been subject to anorexia, pain in the stomach after eating, and headache. She has during this period become emaciated and desponding. I saw her on the 18th of January, 1851, and ordered her three doses of sulphur, followed by sepia, twelve doses. 27th. Saw her again. The appetite has improved; pain of stomach has ceased; vomiting occurs more rarely. Feb. 4th. Continued improvement; complains only of debility. Ferrum, eight doses. Neither pain nor vomiting has returned up to this date, March 21st.

"Cholera Britannica. Several cases of this affection came under my treatment in May, 1850. I have selected for illustration the following. Miss B., aged 14, was attacked on the 12th of May, 1850, with vomiting, purging and tenesmus, hot skin, quick pulse and thirst. Belladonna, antimonium, rhubarb, sulphur, nux vomica, and calcarea, were administered in succession. Her convalescence was complete in eight days, not requiring tonics to restore strength. The disorder was epidemic, and under the ordinary treatment was much longer in its duration.

"Miss B., a phthisical subject, was seized, on the 9th of August, 1850, with vomiting, and purging, accompanied with coldness of the extremities. Veratrum and arsenicum were given, and she was convalescent on the 14th.

"Mr. ——, brother of this lady, was taken ill with somewhat similar symptoms on the 11th of August. Mercurius restored him in two days.

"Miss G. was seized, on October 31st, 1850, with the ordinary symptoms of autumnal cholera, attended by smart fever, face flushed, pulse 110. Aconite, veratrum, arsenicum and ipecacuanha, relieved her in four days, and she regained strength immediately without any other drugs.

"I could add several similar cases, one of a lady, aged 80; but it is unnecessary. I will merely remark, that, with one exception, all were alike ignorant of their being the subjects of homœopathic treatment.

"Pleurisy. Mrs. R., residing two miles from Alnwick, was seized on January 19, 1850, with pleurisy of the right side of the chest; respiration much impeded; pulse strong and frequent; hot skin, with thirst. Aconite and arnica alternated relieved her in two hours. The cough yielded in a day or two to ipecacuanha.

"Neuralgia Facialis. Miss —— has been for years subject to severe attacks of facial neuralgia, accompanied by swelling and redness of the lining membrane of the mouth. She had been treated by leeches and various remedies, but the paroxysms yielded slowly, and great prostration of strength was the invariable consequence. I was called to see her on the 17th of March, 1850, and ordered her belladonna, three globules every quarter of an hour; within two hours, relief was afforded, and the cure was completed by arsenicum, succeeded by graphites. No tonic nor any other remedy was required, as had been the case invariably after former attacks.

"A lady who knew of the preceding case sent for me; she was suffering in a similar way; she suspected that homœopathic remedies had been employed upon her friend. I told her that her suspicions were correct. She was not anxious to have them used in her own case, but I overcame her scruples; her thankfulness and surprise for the complete and speedy relief afforded by belladonna was to me most gratifying.

"Threatened Abortion. Mrs. A. (who had previously miscarried at about the same period), was about thirteen weeks advanced in pregnancy. She was seized on the night of Sunday, April 9th, 1850, with bearing-down pains, and sanguineous discharge. Homœopathic preparations and doses of belladonna, aconite and opium, cured her, and gestation went on to the full period.

"Puerperal Inflammation. Mrs. G. was seized on June 23rd, ten days after delivery (under the superintendence of a midwife), with shivering and pain in the uterine region, increased by pressure, attended by suppression of the lochia, and mammary secretion. Tongue was red and glazed,—pulse 110, with constant thirst; anxiety and suffering were depicted in her countenance. Aconite, chamomilla, nux vomica, and calcarea were successively administered. She was convalescent on the 30th, and has continued to nurse her infant.

"Odontalgia. Several cases of almost instantaneous relief have occurred to me; I will relate the particulars of only one. I was called to Master B., suffering from violent tooth-ache, arising from two decayed molars, in the right side of the upper jaw: the gums were hot and swollen. Belladonna and aconite taken alternately every quarter of an hour, afforded speedy and permanent relief, and extraction by the surgeon was rendered unnecessary.

"It would occupy too much space to give details of many *chronic cases* in which I was satisfied of the superiority of the homœopathic practice. In diseases peculiar to women and children, in the protean forms of hysteria and dyspepsia (some of the latter affection we have reported already), we have in our materia medica resources of the most satisfactory kind. In one case always present to my mind, the sufferer who had for long been the victim of daily and nightly opiates, has not for more than twelve months taken a particle of this drug, pain and restlessness having been most effectually relieved by homœopathic preparations *alone*. Those conversant with the distressing sequelæ of opiates, can readily appreciate the greatness of such a boon.

"One case of anasarca I will relate, simply because the subject of it, a man aged 65, had been under allopathic treatment without gaining any relief by it. When I first saw him, his legs and feet were very much swollen and œdematous, ascites likewise existed. The urine was scanty, and of a deep red colour. After taking bryonia tinct., one drop twice in the day, followed by pulsatilla in the same doses, the swelling almost *entirely* disappeared.

"Profuse Discharge of Mucus from the Nostrils. A lady, the subject of this troublesome affection, consulted me respecting it. She was cured by two doses of nux vomica.

"Rheumatism and Sciatica. Thomas R., aged 45, had been confined to the house for two weeks, but had suffered from rheumatism for some weeks prior to his keeping within doors. I found him unable to walk, complaining

of muscular pains in the back and loins, with severe pain down the course of the sciatic nerve. Two days after taking as many doses of bryonia, he was at his out-door work, and has continued to work ever since.

"*Had I continued to entertain doubts upon the reality of action in homœopathic remedies, these would have been removed byt he following proof. I gave a lady for a chronic affection, Mercurius nine globules, divided into three doses; upon calling upon her a few days afterwards, she told me that salivation had ensued. Let it be remarked that she was ignorant of the remedy prescribed, and moreover believed that homœopathic medicines were inert.*

"The foregoing cases then, each one treated by myself alone, convinced me that all my pre-conceived opinions upon homœopathy were erroneous, for it was to the *action* of the remedies administered that the results were due."

We have not space to examine in detail Dr. Ransford's cases; but they are so essentially defective in all that gives value to the history of therapeutic experiments, so identical in their getting up with the style usually adopted by bold charlatans, and so unlike the precise and cautious statements of a truth-seeking scientific man, that we think that by quoting them, with the author's remarks, we have done, perhaps, all that is required to point out their worthlessness. A word or two, however, may be said in reference to the astounding paragraph which we have placed in italics, in which Dr. Ransford announces that, which if it could be repeated, would be admitted by us as a crucial experiment in favour of infinitesimal doses.

If Dr. Ransford salivated his patient with eight globules of a mercurial preparation, he was not administering the drug in Hahnemannic, but in ordinary doses. If patients can be salivated with infinitesimal doses of mercury, the discovery would not have remained for Dr. Ransford to make; and we can only say, that if we be shown globules prepared in such a way as only to contain the millionth part or the decillionth of a grain of mercury, and if we can also see these globules, in our own hands, or in the hands of trustworthy persons, produce salivation, we will from that moment cease to assert that quantities so minute have never yet been proved to produce an effect upon the animal economy. Dr. Ransford's case of salivation, however, proves too much for his new friends; he ought to have known that the homœopaths delight in telling their patients that their medicines cannot salivate, or produce any other violent action! We advise Dr. Ransford to learn from Hahnemann's *Organon*, and Mr. Everest's sermon, the nature of homœopathic Mercurius.

Dr. Ransford's dashing exploit with Mercurius is an excellent example of a circumstance which was alluded to at Brighton, and which, as regular readers of the homœopathic press, we have long been aware of,—the utter impossibility of stating the homœopathic creed. It is likewise a good illustration of what Dr. Cormack described upon the same occasion, as "the Protean wiles with which homœopathy sets honesty, consistency, and common sense at defiance". Let us compare Dr. Ransford's salivation story with the writings of Hahnemann, Drysdale, and Black—the master, and two of his most famous British pupils.

In a paper by Dr. Drysdale, in the first volume of the *Homœopathic Journal*, of which he is one of the editors, he says that homœopathic remedies possess neither physical nor chemical characters; and produce no sensible effect, except the removal of the disease. Dr. Black, in his *Principles of Homœopathy*, writes as follows: "No danger whatever can arise from the administration of the small doses of mercury used in homœopathic practice; so that the slightest danger of injuring the constitution, the great bugbear in allopathic practice, need not be dreaded" (p. 117). Lastly, we think that the following short paragraph from Hahnemann settles the point as regards Dr. Ransford's homœopathic practice. "In the employment of the most appropriate homœopathic remedy, it is only the symptoms of the medicine

that correspond to the symptoms of the disease that are called into play, the former occupying the place of the latter (weaker) in the organism, and thereby annihilating them by superiority of power".—*Organon*, CLV.

As Dr. Ransford is evidently in the hot or first stage of his love, when caresses are yearned for, and criticism ill submitted to, we cannot leave him without one word of comfort and of kindness. "When", said our fair friend in the song, will the laird o' Drummeller "dance like Tam Glen ?" "When", exclaims Dr. Ransford, "will the ordinary doses of blue pill, sublimate, or calomel salivate like our glorious globules—the infinitesimals which offend no palate, which have neither physical nor chemical characters ?" Dr. Whateley, with the ladies of May Fair and Belgravia, in ecstasies re-echo, "WHEN ?" But to be serious ; it is evident that our author not only belongs to that rapidly increasing and most influential class, recently described in *Household Words*, under the honourable and thrilling designation of WHOLE-HOG MEN, but that he is entitled to the most exalted position among them. When the Whole-Hog Men get a Royal charter, (which it is said they are to apply for during next session), they will naturally require to appoint examiners, and in discharge of a public duty we now recommend for elevation to the office of President of that Board, the ex-Examiner of the Royal College of Physicians of Edinburgh. We feel assured that the whole of the press—the Fourth Estate of this Realm—will concur in giving him a first-class certificate.

DR. MACLEOD issues his letter to Professor Simpson, from a Water-cure Establishment at Benrhydding, Otley, in Yorkshire, of which he has the charge; but from which we have heard he was recently on the point of being displaced by the proprietors. We have been told, that along with the testimonials of other candidates, those of Dr. Ransford were sent to the shareholders, upon a probable vacancy being rumoured. There is not much to notice in Dr. Macleod's pamphlet. It is the autobiography of a shallow, self-conceited young man, leavened with a great deal of abuse and misrepresentation of Rational Medicine, especially as taught and practised in Edinburgh. Dr. Macleod eulogises very much his own industry when a student ; but the method he pursued, if correctly chronicled, was certainly ill-adapted to the formation of sound views in therapeutics.

Dr. Macleod states that, though private practice in Edinburgh was "better for his pocket", he eagerly tried to obtain his present post, "with little regard to pecuniary remuneration", and for "the rare opportunities it might afford for the development and promulgation of truth". We should like to know the extent of Dr. Macleod's pecuniary sacrifice. It is sad to think that this young man should have sacrificed his fortune as well as his professional status at the shrine of hydro-homœopathy,—a nondescript system, which is even more disreputable than real homœopathy. His pamphlet is very unfair in its statements, and as offensively flippant in its style as it is heterodox in its philosophy. In point of scientific knowledge and literary tact Dr. Macleod seems to be superior to Dr. Ransford; but he is less ambitious for status in the fraternity in which Dr. Ransford is so pre-eminently entitled to hold office.

DR. HENDERSON possesses the unenviable notoriety of clinging to the emoluments of a school by which he is despised, and of eating the bread of a University, the fame and income of which he is rapidly destroying. In point of talent he as much excels Dr. Macleod, as Dr. Macleod excels Dr. Ransford ; but his controversial cleverness is of that character which distinguishes the unscrupulous advocate : he has not in him any of the bearing of a right-minded pleader: weighty points in morals and in ethics are decided by quibbles, and throughout, there is a scattering of malicious and irrelevant abuse of his colleagues, and an artful attempt to reach "the Patrons" through their passions, as if they were an illiterate jury, whom he was addressing from the bar of the Old Bailey.

On the 24th of June last, the Medical Faculty of Edinburgh, at a meeting attended by ten out of the thirteen members, unanimously adopted the following resolutions :

"1. *That the public profession of homœopathy by the Professor of General Pathology, is inconsistent with the efficient discharge of the various duties which belong to that chair, and is calculated to injure the University as a Medical School.*

"2. *That the Senatus Academicus be requested to transmit a copy of this resolution to the Patrons of the University, together with the expression of a hope on the part of the Medical Faculty, that some step may be taken to avert the danger thus threatened to the University.*"

Notwithstanding Dr. Henderson's pages of quibbling and declamation, we still remain unable to perceive any ambiguity in these resolutions. He says: "It is scarcely possible to peruse the resolutions without being reminded of the celebrated paradox, that language was given to man in order to conceal his thoughts". On the other hand, the meaning conveyed to our minds by reading the resolutions was, and still is, exactly the plain, common-sense meaning of the words used ; viz., that a man publicly professing homœopathy cannot efficiently discharge the duties of the Edinburgh chair of pathology, which, in addition to the teaching of pathology, embrace the examination of candidates for the degree of doctor of medicine. In performing these functions, Dr. Henderson must either keep back his convictions, or he must avow them, and thus endanger his professorship. By selecting the former alternative, so far as he is concerned, he has reduced medical teaching and medical examining to a hollow formality—a mere selling of diplomas ; for no candidate can be approved by Drs. Alison and Christison, whose thesis and prescriptions are in accordance with the public profession of Dr. Henderson.

After stating that he keeps free from homœopathy in his lectures, Dr. Henderson attempts to show that it is quite honourable and quite moral in him to sit at the same examining board with Drs. Alison, Christison, and Bennett, and Mr. Syme. His morality and his medical creed are so very strange, that we think it best to give his own account of them ; no language of ours could so well point out the character of the man, and the idiosyncrasies of his mental constitution. It will be observed that he quotes Dr. John Forbes of London, as is now the fashion, both with real and bastard homœopaths. Drs. Ransford and Macleod likewise call him in to their aid ; but what advantage they get by garbling the writings of that physician we cannot perceive. Dr. Henderson says,—

"There is but one other professorial duty which I have to perform—the examination of candidates for graduation ; and I have been told by one of the members of the Faculty, who concurred in the resolutions, that there are two parts of that examination, with the conducting of which a *belief* in homœopathy is supposed to be inconsistent. One of these is the criticism of the two or three prescriptions which each candidate is required to write. Now I have not only never denied the existence of allopathic and antipathic modes of administering medicines, but six years ago publicly and plainly, in a treatise on homœopathy, expressed my conviction that such methods of treatment have their measure of advantage, and that in judicious hands many of them are of no inconsiderable service. It matters not that I believe the homœopathic method to be of greatly superior efficacy ; homœopathy is not taught as yet by any professor in the University, and I am not entitled to demand from students a knowledge of what they never were required to learn. In admitting that there are other modes of treatment besides the homœopathic, which may be of service to the sick, I am no more to be charged with inconsistency, than I should be in maintaining that there are slow coaches on the old roads, as well as railway trains on the new. And where only slow coaches are permitted to be employed, I can see no reason why I should be disqualified for passing my opinion on them, merely because

I deliberately think that railway carriages are greatly to be preferred. If a very moderate estimate of the common remedies be inconsistent with a candid judgment of ordinary prescriptions, will the Faculty hold that one of the most eminent of their own school, Dr. Forbes of London, could not discharge that very simple duty, and would be unfit for a medical professorship, because he has declared that things in the old system have came to such a pass 'that they must mend or end'? I apprehend they would not; and yet I do not suppose that I think so meanly of the old system as that gentleman does.

"Precisely the same remarks apply to the other part of these examinations—the criticism of such theses as are submitted to my judgment. The exacting of such essays at all from candidates is an idle custom, and, as in the examination for admission into the Faculty of Advocates, little if anything more than a form. The advocates, I understand, invariably buy theirs; the medical graduates *may* do the same: there is no check to prevent them, and they doubtless often take advantage of the laxity. That I am not singular in thinking lightly of this great duty, will appear from the following anecdote of the late Dr. Gregory, which I have heard from the benignant lips of the present occupier of his chair [Dr. Alison], the almost fabulous strength of whose conservative principles is attested by the circumstance that they could not bend his noble nature to a seeming acquiescence in these proceedings of the Faculty. That celebrated professor, on being condoled with by a friend, on the labour of perusing so many long dissertations as were piled on his table, replied to the following effect: 'You don't suppose I read them through! Do you eat up a whole gigot in order to know the quality of your mutton? A slice is enough.' As for me, I may think our inaugural mutton not always of the best quality, but if it be as good as our pastures at present afford, I am bound to be satisfied, trusting that the progress of scientific culture will provide us by and by with a superior description of both." (pp. 13, 15.)

If the Medical Theses were in Latin, and notoriously written by grinders, as in the days to which the anecdote refers, we could better excuse its introduction; but, as it now stands, it is like many other parts of Dr. Henderson's pamphlet, introduced for the purpose of, by inference, suggesting a calumny. It is very well known, that since 1837, the Edinburgh Theses have been written in English, and have been distinguished for their great ability. And it is also known, that they are carefully classified, according to their merits, by the Medical Faculty.

In farther justification of our criticisms, we quote the conclusion of the pamphlet—the peroration to the Town Council.

"The *odium medicum* can be more tyrannical than the employers of Haynau, and more intolerant than the imperial jailor of Siberia. It may not be easily believed that the prompter of the notable resolutions of the Faculty is the conductor of a medical print published weekly in London, and under the ostensible editorship of the notorious coroner of Middlesex, and radical member for Finsbury; yet I can discover no other explanation of that precipitate revolution in their opinion and purposes to which I have adverted in a former part of this letter. While some member of the Faculty was penning the admission that they did not see 'how they could take cognizance of the principles upon which their colleague chooses to conduct his private practice', that publication had begun a series of abusive articles, in which the Faculty were threatened with extinction if they did not endeavour to get rid of their obnoxious colleague, or protest against his heresies. It is astounding that men in their position should have been terrified by so much bad English, and bad temper, and from such a quarter too; or should have attached the smallest weight to the statements of a writer, who, as Addison says of all 'party liars', is plainly anxious 'to commend his zeal, without any concern for his veracity'. If, in order to prosper, the Medical School of Edinburgh must doff its dignity and independence, and stoop to such a patron

as this, I hope, for the honour of the country, that prosperity at such a price will appear to my fellow-citizens too disgraceful to be endured. I believe, however, that no such humiliation is necessary in order to preserve even that kind of prosperity which the Faculty seem to regard as of primary importance ; and nothing can contribute more to such a result than the cultivation, by each member of that body, of his own department of science without prejudice and without fear, and the exercise of a liberal spirit towards his colleagues. These may not be the arts to win the applause of vulgar and violent men, but they are essential to the happy consciousness of personal rectitude, and to the approbation of the good and the wise ; whose approbation alone is the sure foundation of honour as well as of success. I have the honour to be, my lord and gentlemen, your very obedient servant, Wm. Henderson." (pp. 23, 24.)

We have now enabled our readers to judge of the three pamphlet writers ; but let us leave the mere personalities thrust upon our notice by these gentlemen, and allude to a subject of more general interest and importance.

In our number for June, p. 588, we laid before our readers the Resolutions of the Edinburgh College of Physicians, in which homœopathic charlatanry and its abetters were repudiated. The Edinburgh College did well in passing those resolutions ; but we must say that their subsequent inaction requires some explanation. To rest satisfied with an appeal to the honour of such men as the authors of the publications, the titles of which we have placed at the head of this notice—simply to ask such men to resign, is, we fear, an indication of want of power. What a gratifying contrast to the inaction at Edinburgh, is the uncompromising conduct of the Provincial Medical and Surgical Association of England, which at the last meeting—the most numerously attended of its nineteen anniversaries—unanimously declared— "That there are three classes of practitioners who ought not to be members of this Association, viz.—first, real homœopathic practitioners ; second, those who practise homœopathy in combination with other systems of treatment ; and third, those who under various pretences meet in consultation, or hold professional intercourse with those who practise homœopathy." If the Edinburgh College of Physicians have not the power of expelling quacks and others who set its laws at defiance, it is its duty to demand an amended charter, giving the same power of refusing to admit, and of expelling, which is possessed by unchartered bodies, and without which no community can continue respectable. If an amended charter cannot be obtained, then let the honest men abandon the College ; for to remain in compulsory fellowship with Henderson, Ransford, Macleod, Macdonald, and Gregory, is a truly humiliating position to the individual fellows ; and the existence of a College openly and avowedly composed of regular and irregular practitioners, is an abomination which the profession will not long endure. Action, vigorous and determined action, must be taken in this matter.

We would also call upon the graduates of the Edinburgh University to aid the Medical Faculty in their attempts to eliminate Dr. Henderson. "The question" (as Dr. Cowan well remarked at Brighton) "is one of principle, not of doses—one of morals, and not of etiquette". If the Patrons do not, or cannot respond to the voice of the profession, as addressed to them through the Medical Faculty, or if Dr. Henderson do not voluntarily resign, the doom of Edinburgh as a School of Medicine cannot, we fear, be averted ; for already has its reputation been deeply wounded by lengthened tolerance of a colleague of unenviable fame. Parents very naturally feel that apart altogether from his homœopathy, Dr. Henderson's public ethical profession is a dangerous example to unexperienced youth.

A Practical Treatise on the Management of Diseases of the Heart, and of Aortic Aneurism, with especial reference to the Treatment of those Diseases in India. By Norman Chevers, M.D., Civil Assistant Surgeon, Chittagong, Bengal. pp. 144. Calcutta : 1851.

The present work of Dr. Norman Chevers is an important contribution to the treatment of Diseases of the Heart and of the Aorta. This author had creditably distinguished himself in this country by his pathological investigations, and this treatise on cardiac diseases will still farther increase his reputation, more especially in a portion of the globe where this class of affections appears hitherto to have been inadequately studied, and where, indeed, they appear but rarely to occur, at least, comparatively with their frequency in European countries. We are happy to quote the following passage from the Preface, and we need hardly remark, that we cordially concur in the sentiments therein expressed.

"I am not anxious to recommend the perusal of this treatise to extra-professional persons. It is addressed exclusively to the profession : and I am confident that whatever benefit any reader, not well versed in pathology, might derive from the application of the hygienic rules which it contains to his own case, or to the case of his friends, would be more than counterbalanced by the disadvantage of his contracting a certain proportion of those erroneous views, exaggerated apprehensions, and impulses to injudicious acts, which thickly haunt every item of that grievous evil—a little knowledge of medicine."

In the First Chapter, the author gives a general view of the diseases of the heart and their treatment, remarking very justly, that although the accurate knowledge which has been lately acquired of the pathology of the heart has not hitherto thrown any very striking light upon the treatment, yet the attempt to connect the two should ever be the object of the practitioner, who should reflect, "that pathology and therapeia are inseparable, and that each is the only satisfactory expositor to the other". The author then proceeds to remark, that notwithstanding the serious nature of cardiac disease, it should be recollected that the heart possesses a great variety of compensatory resources to relieve itself from temporary embarrassment, or even to adapt itself to the inconveniences caused by permanent disease, so that it cannot be wholly disabled, unless by causes which absolutely suspend its nervous supply, or destroy some vitally important part of its mechanism. "When", says Dr. Chevers, "we find that life may be continued for many years where the heart is crippled by such defects as closure of the ostium of the pulmonary artery, or obliteration of the thoracic aorta, a hope of obtaining the aid of nature's adaptive resources in our plans of treating much less formidable impairments of the organ, becomes our leading encouragement. We then learn to perceive the necessity of not trusting merely to the symptoms in heart disease ; but, having diagnosticated the particular lesion which exists, our object is to be enabled to judge, with almost mathematical precision, what consequent morbid changes are likely to occur ; and to perceive, with the utmost clearness, those saving adaptations of parts and compensatory alterations of functions, which also have a tendency to become established. This done, our main efforts will be directed to averting the former, and to promoting the latter." (p. 7.)

We cannot resist the temptation of comparing the above passages with some remarks made by Dr. Semple, in a paper published in this Journal in November last, upon the same subject as that treated so ably by Dr. Chevers, and of expressing our satisfaction, that two writers in different parts of the world should have arrived at the same important conclusions. "If", says Dr. Semple, "it can be proved that actual organic disease of the valves of the heart may exist for a considerable period, and without shortening the average duration of life, such a conclusion may tend to divest this class of

maladies of some part of the terror which their existence now so commonly inspires. . . . . And if such be the consolation which may, I think, be fairly afforded to those suffering under confirmed and extensive disease, how much more applicable is it to those who are affected only by some of those minor affections of the heart and its valves, which occur so frequently among the sequelæ of rheumatism?" In another portion of the same paper, Dr. Semple alludes to the accuracy which now attends the diagnosis of cardiac disease, but asks, "whether this branch of medical science has not been pushed somewhat too far in modern days; and whether, led away by the brilliancy of the researches into cardiac diseases, and fascinated by the simplicity which now attends their investigation, some practitioners do not lay too much stress upon the aids derived from auscultation, and neglect the attendant phenomena, which modify the healthy and morbid conditions of the central circulatory organ?"

Dr. Chevers then proceeds to show that most of the prominent symptoms which occur in cardiac disease, are evidences of nature's attempts to assist the heart in the performance of its functions, or to overcome an impediment to the circulation. Palpitation, accelerated pulse, quickened respiration, and the signs of hypertrophy, are some of the earlier, more favourable, and more successful symptoms; while dilatation, pulmonary, hepatic, splenic, and renal engorgements, hæmorrhages, dropsical effusions, and dyspnœa, are the later and less fortunate.

In the Second Chapter, the author sketches out the following indications of treatment, which he comprises under six heads. "I. To diminish, if possible, the valvular or other immediate causes of obstruction. II. To endeavour to remove all causes of impediment to the circulation existing in the lungs, abdominal organs, and capillary system generally. III. To lessen vascular distension by reducing the bulk of the circulating fluid, without impoverishing the system. IV. To sustain or restore the power of the heart, and to reduce the capacity of its dilated cavities. V. To equalise the circulation, and to maintain free vascular action in the surface, by regulating the temperature, clothing, etc., and to provide due access of pure and well-oxygenised air. VI. To remove and avert irritation and excitement of the nervous system, and to procure, as far as possible, rest and tranquillity of body and mind." (p. 13.)

In fulfilling the first indication, the author of course does not pretend to recommend any plan for the removal of old-standing obstructions of the cardiac orifices; but he very justly and very forcibly points out the necessity of paying the greatest attention to the earliest evidences of endocardial and arterial thickening, and of removing the deposit while it is still recent and plastic. The impediment may be due either to the presence of clear fibrinous deposit in the sub-endocardial fibrous tissue, or to the deposition of lymph or fibrinous coagula upon the free endocardial surfaces of the obstructed orifice; and each of these conditions will require appropriate treatment. The author admits, however, that it is not very easy to distinguish these two states, but he considers that the sounds of the heart will materially assist the diagnosis, and that these will be louder when the deposit is on the surface of the valves, than when it is below the lining membrane. He also conceives, that the case is far more curable when the deposit is confined to the fibrous tissue, than when it is situated upon the free surface of the valves. The treatment which the author considers to be most beneficial in removing the products of inflammatory action from the cardiac orifices, consists in the cautious administration of long-continued mild courses of mercury, alternating with iodide of iron, and iodide of potassium; but he deprecates salivation, starvation, or the excessive use of tonics, or of iodine. The mercury should be given in small doses, and carried only so far as just perceptibly to affect the patient's breath. The mercury should be discontinued at the end of about two months; but the use of the various preparations of iodine may be

persisted in, with occasional intervals, for at least a year. Frictions of tartarised antimony should be continued as long as they can be borne, and, subsequently, one of the best external applications is a plaster spread with ung. hydrargyri mixed with camphor. But far better than any treatment adopted *after the deposit has taken place*, is the attempt to cut short the disease at its onset, or even to prevent its appearance; and although there are few practitioners who are ignorant of the risk of heart-disease supervening on acute rheumatism, yet the subject is so important as to justify us in placing the following passage, in reference to this subject, before our readers.

"In every case of acute rheumatism, cardiac inflammation is threatened; and in every case of acute rheumatism occurring in a young adult, the danger of that untoward complication is so imminent, as almost to appear inevitable to one who has repeatedly watched these cases. Here, then, it becomes one of our leading duties to watch, almost hourly, for the first evidences of the change from mere febrile excitement of the heart, to that evident disturbance and embarrassment; that disordered, but muffled action, which generally characterise the onset of acute cardiac disease. These warnings may usually be recognised and acted upon long before præcordial distress is complained of, or the patient is aware that his chest is in any way affected. This is the stage at which a small local bleeding, followed by active counter-irritation, and the cautious use of mercurials, is most effectual. It is true that the early employment of these means will not always prevent the development of the advancing pericardial or endocardial lesions; but it evidently breaks the force of the first onset of the acute disease more effectively, and moderates the attendant symptoms more rapidly, than is almost ever the case, when the same or stronger measures are employed at a later stage." (p. 27.)

Dr. Chevers recommends local in preference to general bleeding, which is in accordance with the views generally held by British practitioners; and in recommending the use of colchicum, he states that in India this drug requires always to be guarded by opium, as in that country a few moderate doses are liable to set up a dangerous and intractable form of diarrhœa.

After treating at large of the remedial measures to be employed in acute disease of the heart, the author next details the methods which ought to be adopted, in order *to remove all causes of impediment to the circulation existing in other organs;* for he very justly remarks that, even where confirmed heart-disease exists, yet, if the other organs of the body continue in a moderately healthy condition, the patient's life may be spared for many years. "We know," says Dr. Chevers, "that the most ordinary forms of exocardial and endocardial disease, adherent pericardium and valvular contraction, certainly do not, generally and of necessity, destroy life, by their own advance and by the influence which they exert in gradually impairing other organs, in less than from ten to fifteen years: and the duration of their progress is found to be occasionally longer even than this. The occurrence of death from causes confined to the heart itself, is a comparatively rare event. In the generality of fatal cases, life is cut short prematurely, either by the outbreak of acute disease in other organs, or by the superaddition of diseased actions of a more insidious character to those gradual deteriorations which the fixed error of the circulation is itself imperceptibly working. It is especially the pulmonary and hepatic structures which suffer under these circumstances. Acute disease of the lungs destroys life in at least three-fifths of the cases of chronic heart-disease." (p. 48.) The author then proceeds to classify the causes of obstruction to the circulation, exterior to the heart, into two divisions, namely, the *permanent*, and the *removable*. Among the *first*, he enumerate malformation of the chest and spine, organic disease of the bronchial tubes and lung substance, large aneurisms of the aorta, stricture or obliteration of that vessel, organic disease of the great abdominal viscera, and obliteration of the great venous trunks: among the *second*, he specifies

bronchitis, pneumonia, ascites, anasarca, immoderate obesity, congestive disease of the abdominal viscera, and habitual distention of the stomach and bowels. Judicious methods are then laid down for ameliorating the patient's condition, as far as possible, in the first class of cases, and for removing the complications in the second.

In enlarging upon the third indication, namely, to *lessen vascular distention by reducing the bulk of the circulating fluid, without impoverishing the system*, the author strongly recommends very great abstinence in the ingestion of liquids, upon the principle that mere distention of the vessels and of the cavities of the heart, increases materially the embarrassment of the circulation in cardiac disease, while, in cases where the quantity of circulating fluid is small, there is entire or comparative absence of dyspnœa. Although, therefore, the author does not adopt the extreme views of Valsalva, he nevertheless recommends, in heart-disease, a systematic reduction in the quantity of the fluid and solid ingesta, together with the production of diaphoresis and diuresis, and the occasional employment of *small* bleedings. In relation to the ingestion of liquids, Dr. Chevers thinks that a very small quantity is required, even in the healthy condition ; and declares his own conviction, founded upon personal experience, that on the average, a man requires no more than about one pint and a half of liquid in the twenty-four hours, in cold or temperate weather, and will scarcely be compelled to exceed two pints in a hot climate; and in all cases of cardiac disease, and in asthma and chronic bronchitis, he strenuously recommends that the patients should reduce their supply of fluids as nearly as possible to the above standard. The directions for acting upon the skin and the kidneys, and for the cautious adoption of small bleedings, are judicious and sensible, but do not contain any novelty worthy of detailed description.

The fourth indication is *to maintain or restore the power of the heart, and to reduce the capacity of its dilated cavities.* In this section the author very elaborately combats the idea of hypertrophy of the heart being a morbid condition of that organ, and regards it rather as a compensatory arrangement to counterbalance the injury to the system which would result from a dilated and therefore attenuated condition of the cardiac walls. He entirely disbelieves in the existence of "concentric hypertrophy"; which disbelief he shares with the greater number of pathologists, who justly consider this state as resulting from muscular contraction only, apart from morbid change ; and eccentric hypertrophy he regards as being always superadded to dilatation : he also combats the idea that a hypertrophied heart induces a morbid condition in other organs, and quotes Dr. Walshe, who has adduced many arguments to prove, that cerebral effusions are by no means so commonly associated with hypertrophy of the heart as is sometimes supposed. Even when these two great organs are both affected, Dr. Chevers by no means admits that the hypertrophy of the heart is the *cause* of the morbid condition of the cerebral vessels : he rather regards the dilatation and weakness of the cerebral vessels to be a contemporaneous change with the dilatation of the heart, but considers that the latter organ has been strengthened by the supervention of hypertrophy, while the cerebral vessels have remained weak from the absence of any similar compensating process, and have therefore eventually given way under circumstances of excitement. Dr. Chevers therefore considers that dilatation of the heart and of the vessels is a truly morbid condition, and that it constitutes a most dangerous form of disease ; but that hypertrophy is to be regarded rather as a healthy than as a morbid process, and that no attempt should be made to treat it by remedial means. This view of the subject is not that which is generally adopted by the best writers and practitioners, and, as far as we know, the only authority who advocates the same opinions is Dr. Joseph Ridge, who is mentioned by Dr. Chevers in terms of great respect : but we are so struck with the ingenuity with which the question is treated, that, while not entirely agreeing with these authors in

their novel interpretation of the pathogeny of hypertrophy, we nevertheless hesitate to condemn their speculations, founded as they are upon practical experience, and backed by some sound pathological reasoning. In the corollary, however, drawn by Dr. Chevers from his previous arguments, we by no means coincide; for he asserts, that the employment of digitalis and other sedatives is inadmissible, either upon occasions of great emergency or when systematically administered. We are by no means advocates of the indiscriminate use of digitalis in heart-disease; when the valves are seriously affected, we believe it to be more injurious than beneficial; but in cases of hypertrophy, without valvular disease; when the impulse of the heart is strong, and the sounds muffled; when the organ beats like a sledge-hammer against the walls of the chest, elevating the ear and head of the stethoscopic observer; when its action is tumultuous, and there is dyspnœa on the least exertion,—in such cases we have been invariably in the habit of employing small doses of digitalis, combined with opium or henbane, and always with the happiest effects; the tumultuous action of the heart gradually subsides, the respiration becomes easy, and the countenance less anxious, and after this cautious administration of the remedy, the patient, although not restored to perfect health, is placed in a condition of comparative comfort.

In considering the fifth indication, the author makes some very appropriate remarks upon the necessity of warm clothing, the avoidance of chills, and daily friction of the whole body, in cases of cardiac disease; and he also insists upon the necessity of a due supply of pure air. He enters also at some length into the consideration of the modes of dress adopted, both in military and civil life, and points out some of the injurious effects produced upon human health by the tyranny of fashion, or the absurd views entertained by the superior military authorities, and he particularly alludes to the stiff stock of the soldiers, the cuirasses worn by some of them, the habit of wearing thick woollen cloth, even in the hottest climates, as among the fertile causes of diseases of the circulatory organs among our army.

In enlarging upon the sixth indication, the necessity of removing irritation and excitement is particularly insisted upon, and the author warmly advocates the establishment of asylums for patients afflicted with heart-disease, as the most humane method of alleviating the sufferings of this portion of the community, and of prolonging their span of life, by extending to them comforts which, at present, they are unable to obtain, such as "the happiness of crouching over a brilliant fire in winter, and of basking undisturbed in the summer sunshine", and an immunity from those cares and anxieties, which prey heavily enough upon those who enjoy tolerably good health, but which inevitably shorten the days of the cardiac sufferer.

We have entered into a somewhat lengthened analysis of Dr. Chevers' book, in consequence of the sense which we entertain of its great merits. We cordially recommend it as one of the best works on the treatment of cardiac diseases which it has been our fortune to peruse. We regret to observe that the author is not acquainted with the valuable papers of Dr. Williams and others on this subject, which have appeared in the London Journal of Medicine.

Homœopathy Unveiled; or Observations on Hahnemann, his Doctrines, and Treatment of Disease. By William Perrin Brodribb, M.R.C.S.E.ng., Member of the Court of Examiners of the Society of Apothecaries. pp. 29. London: 1851.

Of all the forms of quackery which abound in the present day, to the discredit of the profession, and the injury of the public, that which goes by the name of homœopathy is undoubtedly the most flourishing. Yet, strange to say, the success of this system is in the inverse ratio to its merits; and while of all the grades of empiricism it is undoubtedly the lowest, so, on the other

hand, has it the greatest number of disciples and advocates. Every other kind of quackery has some basis to rest upon: we believe that the system of scouring out the bowels by Morison's pills is not destitute of something like a plausible foundation: the drenching of the patient by floods of water externally and internally, as adopted by the hydropathists, is another instance of a good thing carried to excess: and the Mesmeric humbug is not without a certain degree of credibility, and affords some amusing instances of the vagaries of the nervous system when in a morbid state. But a doctrine like that of homœopathy, which tells us that diseases are caused by the same remedy which cures them, and that the efficacy of a medicine is in the inverse proportion to its dose; and which then builds upon this sandy foundation a superstructure which has no sort of relation to it, and, indeed, overwhelms it—such a doctrine, we say, it is idle waste of time to attempt seriously to controvert. But as there are, no doubt, some conscientious persons who are anxious to know the merits of a system which finds at present so many advocates, and as the silence of the respectable members of the profession on the subject might be construed into an acquiescence with its dogmas, we are not sorry that Mr. Brodribb has favoured the profession and the public with the pamphlet now before us. We may remark, that he has treated the subject with remarkable calmness and perspicuity; and unless the persons who subscribe to the homœopathic doctrines have entirely taken leave of their senses, we think they cannot fail to be convinced by Mr. Brodribb's clear and luminous mode of argument.

The worst feature in the homœopathic quackery is the enormous amount of duplicity and prevarication with which it is mingled, and of which the late cases of Mr. Hayle, who graduated at St. Andrew's, and of Mr. Pope, who attempted to graduate at Edinburgh, are flagrant instances. We feel a sentiment of pity for the imbecility which leads even clever men to make mistakes in doctrine and practice: but we have no compassion for those who know what is right, and pursue what is wrong.

The London and Provincial Medical Directory. London: 1851.

This work is worthy of much commendation, for the amount of information which it supplies, and also for the general accuracy of that information. It ought, however, to be called "The Medical and Quack Directory": for we find Hahnemann Hospitals, Hahnemann Medical Societies, and lists of homœopaths and hydropaths set forth, as if the profession looked on them as portions of the medical commonweal: as if medical men and quacks had an equal claim to the confidence of the public. We beg to tell the conductors of this work, that they have, in their last edition, perpetrated—inadvertently, we believe—an insult upon the medical profession—and that it must not be repeated. The first offence may be excused; but if the *Directory* for 1852 be not expurgated of the names of the notorious charlatans to whom we have alluded, and who are now formally repudiated by the Scottish Colleges, and by the unanimous vote of the most influential and most numerous association of medical men in England, the profession will deal with the editors as deliberate transgressors.

We refrain from farther remarks at present: and we trust that when the volume for next year issues from the press, we may be able to bestow on it an unmingled meed of praise. In the mean time, we advise our readers not to order the work till the editors have given an assurance of its being, as its name implies, only a "*Medical* Directory".

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

ANATOMY AND PHYSIOLOGY.

SUPERNUMERARY FIMBRIATED OPENINGS IN THE FALLOPIAN TUBE.

M. A. Richard, Junior, in making examinations of the Fallopian tubes, has discovered the occasional presence of supernumerary fimbriated extremities in these organs. He found them in five subjects out of thirty. The normal extremity existed in all the cases. Below this, at a distance of from some millimètres to two or three centimètres, there was a second orifice, furnished with fringes like those of the normal opening. A wire could always be passed through the fimbriated extremity, so that a communication between the interior of the tube and the peritoneal cavity could be made out. By gently pushing the wire towards the abdominal or the uterine orifice, it passed either through the true fimbriated opening, or into the uterus.

Of the five subjects, one was a fœtus at the full period, presenting two supernumerary orifices ; another was a girl, aged 15, who had not menstruated—she also had two additional orifices ; the other three were adult women, who each presented one supernumerary opening.

M. Richard hints that this structure may throw some light on the cause of the abdominal variety of extra-uterine pregnancy. [*Reports of Biological Society of Paris*, in *Gazette Médicale*, June 28, 1851.]

PRACTICE OF MEDICINE AND PATHOLOGY.

CONGENITAL SYPHILIS.

The transmission of Syphilis from the parent to the offspring has of late excited much attention, and especially has been made the subject of an animated discussion in the French Academy of Medicine. The articles which we propose to bring under the notice of our readers are—

I. A memoir on Syphilis in Children, by Dr. Deutsch, of Nicolai in Upper Silesia, published in the *Journal für Kinderkrankheiten* for March and April 1851.

II. Discussion in the Académie de Médecine in Paris, between MM. Cazeaux, Paul Dubois, Ricord, Gibert, etc. Vide *Gazette Médicale de Paris*, June 21, July 5, 12, and 19 : also a case related to the Académie by M. Depaul, published in the *Gazette Médicale* for July 26.

Dr. Deutsch's Memoir. It is well settled that syphilis can be communicated to a fœtus by its parents : experience has proved it, and has controverted the opinions of those who have asserted the contrary. It is beyond doubt, that the child of a woman suffering from constitutional syphilis comes into the world with evident syphilitic symptoms, or exhibits the trace of the mother's disease in its weak, sickly development. But it is not so clearly established that a child begotten by a syphilitic father will, when born, show such marks of disease, unless the mother have been also affected : experience seems to have only pointed out that, as a consequence of syphilis in the father, the child will be born with a depraved constitutional habit, generally in the form of scrofula or rickets. Notwithstanding that the subject has occupied much of the attention of physicians, several questions still remain obscure : these are,—1. How is it to be explained, that syphilis does not always pass from the parent to the child—that, indeed, instances of this are not very rare ? 2. How is syphilis communicated by the father to the child, without the intervention of syphilitic affection in the mother ? 3. Is it

established by experience, that miscarriages very frequently result from syphilis in the parents, and that the fœtus is then usually born in a putrid condition ; many physicians have made the observation, that such abortions more frequently follow when the father than when the mother is affected ;—is this really the case, and, if so, how is it to be explained ? 4. Why are the symptoms in new-born children much more rarely those of primary than of secondary or tertiary syphilis ?

1. The first question is difficult to be answered : for gouty, hepatic, scorbutic, or carcinomatous parents sometimes produce perfectly healthy children. We can only imagine that the father has been temporarily healthy, especially at the time of procreation ; and that the diseased state of the mother has been interrupted during the period of pregnancy, as is sometimes the case in pulmonary consumption.

2. The second question is sufficiently explained by the fact, that, for the infection of the embryo, it is sufficient that the male fluid be impregnated with the poison, while the mother may escape infection,—the more easily, the less opportunity there is of coming into contact with syphilitic eruptions.

3. It is uncertain whether the fact stated in the third question—that syphilis in the father is more liable to produce abortion than in the mother, is correct. The English surgeons believe this to be the case ; the French, and among them Ricord, contradict it. It may be, that diseased semen, from a syphilitic father, may produce a diseased germ, incapable of coming to maturity ; and that the death of the embryo may thus be produced more readily than when a syphilitic mother has to supply nourishment to an otherwise healthy germ. This view is confirmed by the fact, that men, who have at an earlier period suffered from syphilis, but have been apparently cured, produce syphilitic children far more frequently than women who have been in the same circumstances. Prostitutes, who have often gone through the whole series of venereal affections, are, when healed, more frequently the mothers of sound children, than men are the fathers under the same conditions.

4. With regard to the fourth question, we must remember that primary syphilis is not so rare in new-born children as is generally supposed. Many forms are not recognised as primary, because they appear on unusual parts of the body, as the umbilicus, mouth, and eyes. A primary syphilitic affection can, however, perhaps only arise in new-born children in its passage through the organs of a diseased mother, or from contact with venereal eruptions in the mother, nurse, midwife, or other persons. It will then not be so likely to appear on the genital organs, as wherever contact has taken place ; and especially so, the more ready the child's skin, particularly on certain parts of the body, is for infection.

Secondary Symptoms in New-born Children. The forms under which secondary syphilis appears in children, are mostly impetiginous spots, from the size of a pea to that of a silver *sechser*, of a dirty copper-colour, apparently, but not really, raised above the skin, and unchanged both in a cold and in a warm temperature. Their principal seat is the inner and back of the upper part of the thigh ; they may also occur at the lower part of the thigh, in the vicinity of the joints, on the glutæal region, the face, the hypogastric region, and other parts of the body. Sometimes a desquamation of the epidermis, as in herpes furfuraceus, takes place at their circumference. More rarely there is a formation of bullæ, and this occurs in two forms. Sometimes the bullæ are like those of pemphigus ; they are of the size of a pea, bean, or hazel-nut, and filled with a clear lymph : they easily flatten, and change into large superficial ichorous sores, with ragged edges, having a tendency to spread. The other form is more pustular, very like itch, but the pustules are filled with a much clearer and more transparent reddish pus. The pustules dry on their surface, and form a rough brownish scab ; and beneath them is formed an ichorous ulcer, which penetrates deeply. One or both of

these forms may be accompanied by non-eruptive skin affections, especially by erysipelatous redness and tension, principally in the loins, buttocks, and genital organs, differing, however, from true erysipelas in being painless, and in the permanence of the colour on pressure. Sometimes this pseudo-erysipelas appears on the soles of the feet. There are, moreover, boils of various size and irregular shape, of a doughy feel, painless, covered with unchanged epidermis, and which frequently, after they have long remained of the same size and shape, spread laterally, without being disposed to burst.

Impetiginous syphilitic affections are more rare. They occur especially in the form of verrucæ, closely resembling true pocks just before suppuration, in their size, form, contents, and areola; they are especially numerous on the upper part of the body, principally the neck. In their further course, they pass into purulent and exulcerating pustules.

An old wrinkled face, dull weeping eyes, a flabby, miscoloured, cold skin, desquamation of the epidermis, obstinate intertrigo in the upper part of the thighs, in the axilla, in the neck, and behind the ears, obstinate coryza and stuffing of the nose, panaris and paronychia, and ulceration of the angles of the mouth, are usually the concomitants and the confirmatory symptoms of the syphilitic manifestations described above. Extremely rarely there occur chancre-like, round, fatty ulcers on the genital organs, the anus, the mouth, and the orifice of the nares. Still more rarely, condylomata are found. Mauthner (*Journ. für Kinderkrank.*, Bd. xv, Heft 1 and 2) says, they are not flat before the second year, nor pointed before the seventh. The same writer states that syphilitic diseases of the joints do not occur before the seventh year; I have not yet observed such affections in children.

Syphilitic ophthalmic affections occur in two principal forms:—1. As blennorrhœa, perfectly like the disease known as *ophthalmia neonatorum*, but far more rapid in its course and dangerous to the eyes. 2. Psoriasis of the eyelids, with tylosis and rapid induration of the mucous glandules.

This seems to us to be the proper place to introduce such parts of the discussion in the Academy of Medicine as related to certain alleged symptoms of syphilis in children.

The first object that claims attention is the *change in the lungs*, alleged by M. Depaul, in his memoir presented to the Academy, to result from syphilis; which memoir was the original cause of the discussion. M. Depaul described in his memoir, the purulent collections found in the lungs of infants who are born dead, or who die soon after birth, as indicative of syphilis. This alteration has been already pointed out by several observers, as Baron, Billard, Husson, Sestier, and Cruveilhier. Some of them thought that the collections consisted of softened and suppurating tubercles; others, that they were abscesses resulting from circumscribed inflammation: but no one, before M. Depaul, had ascribed them to congenital syphilis. He has observed them about fifteen times: he cited two cases. In the first case, the mother offered no trace of syphilis at her delivery, but M. Depaul found that she had previously had a chancre, and that she had been treated in a venereal hospital. The infant died some instants after birth. It had bullæ of pemphigus in the plantar and palmar regions; the thymus body was a little larger than usual, and had in each lobe a small cavity, filled with a grumous, yellowish, thick matter. At the apex of the left lung, there was a projection externally, of the size of a small nut, and of a yellowish tint. It was not softened in the centre. In the other case, the state of the lungs showed that the infant had breathed very imperfectly for twenty minutes after birth. The parts into which air had not entered appeared as irregular masses, of various sizes. The upper lobe of each lung contained a mass of the size of a large nut; and smaller ones were scattered throughout the other lobes. On incision, they were found to be formed of a yellowish compact tissue, with a cavity in the centre, containing a yellowish sero-purulent liquid, which, both to the eye and under the microscope, presented

the characters of pus. The thymus body contained a small quantity of pus in each lobe ; and there were a considerable number of bullæ of pemphigus on the hands and feet. The mother of this child said that she had never had syphilis, nor could any traces of it be detected in her. The father had, however, two months before the commencement of his wife's pregnancy, contracted an indurated chancre, which had been merely treated by emollients and slight cauterisation. He had subsequently had secondary symptoms.

This affection of the lungs, according to M. Depaul, rarely exists alone, but is generally accompanied by other manifestations of syphilis, as pemphigus, purulent collections in the thymus, or enlargement of the liver. He believed that this affection of the lungs must be added to those signs which are considered indicatory of congenital syphilis.

M. Cazeaux, who reported on the memoir of M. Depaul, doubted the constant venereal origin of the purulent collections in the lungs. The questions to be determined were:—1. Whether the presence of pus could be explained in any other way ; and, 2. Whether M. Depaul had logically demonstrated its syphilitic origin ? He (M. Cazeaux) believed that these abscesses might arise from common circumscribed or lobular pneumonia, without having a syphilitic origin.

M. Ricord said, there was no doubt that syphilis could produce pulmonary lesions. The ancient writers—and especially Lieutand—were aware of this. He had seen changes in the lung perfectly analogous to those recorded by M. Depaul, and which could not be referred to true tubercles, nor to simple pneumonia, nor to metastatic abscesses, nor to resorptive fevers. They were, on the contrary, closely connected and of simultaneous occurrence with other well-marked symptoms of syphilis, such as deep tuberculisations in the cutaneous tissue, gummy tumours of the cellular tissue, diseases of the fibrous and osseous tissues, etc. Opportunities of making autopsies have rarely been afforded ; but M. Ricord had observed some patients, presenting indubitable symptoms of tertiary syphilis, who had all the symptoms of pulmonary phthisis, except tuberculous expectoration, and who recovered from this under antisyphilitic treatment.

M. Paul Dubois supported the views of MM. Depaul and Ricord.

The subject of *pemphigus* also excited considerable discussion.

M. Depaul stated in support of his opinion, that the purulent deposits in the lungs are venereal, that he found them to coexist with pemphigus, purulent collections in the thymus, or enlarged liver ; which he considered as manifestations of syphilis. This opinion was contested by M. Cazeaux, who doubted the constant specific origin of these affections. In this he was supported by M. Gibert, who observed that "in the child, the most usual manifestations of syphilis were varioliform pustular eruptions, and varicelliform vesicular eruptions, or mucous papulæ or flat tubercles. He had not observed a true pemphigoid affection either in the child or in the adult. True *dartres*—humid and scaly or scabby eruptions of eczema and impetigo—were not among the manifestation of syphilis."

M. Ricord expressed his belief that any organ of the body may be affected by syphilis, though some have a greater resistant power than others. All cutaneous affections, he thought, have their syphilitic representatives ; and he saw no reason for supposing pemphigus to be an exception to the general rule. "If syphilis, in producing its constitutional effects, acts in the same way as other common causes tending to the same results ; and if pemphigus often arise from bad hygienic conditions, such as unhealthy habitations, bad or insufficient food, etc., may it not be developed in the same manner in the fœtus ? Is not a syphilitic mother, in fact, an unhealthy habitation ; and does she not furnish bad material for nutrition ?" M. Ricord long hesitated to admit syphilitic pemphigus ; but he says he was convinced of its existence by two cases, in which pemphigus appeared in syphilitic patients in

common with other symptoms, and was affected, as to increase or decrease, in the same way as they were.

M. Paul Dubois also believed firmly in the existence of syphilitic pemphigus. The following description of the affection was given by him in the course of the discussion in the Academy.

"Syphilitic pemphigus is characterized by vesicles, generally voluminous and closely placed: they are almost always filled with a strongly yellow pus. They are most developed on the palms of the hands and soles of the feet; they rest on the skin, the violet or blue tint of which contrasts with the rosaceous colour of the surrounding part. In these situations, the vesicles are generally so close that they touch, and seem to be joined at some part of the base. The vesicles on the other parts of the body are commonly more separate and smaller; and the skin on which they rest does not present the violet or blue tint in so high a degree; and this tint is even mostly absent on the trunk. Syphilitic pemphigus generally appears before birth; so that there may be seen, as soon as the child is born, some vesicles already empty, while others are just commencing, and others again fully developed. The bottom of the opened vesicles is formed of a red dermis, sometimes sound, sometimes superficially eroded; in a smaller number more deeply so. In the latter case, the borders of the wound are sometimes a little raised and rounded, and there is at various points an appearance of the later stages of ecthyma. This eruption most frequently exists in well-developed infants, in whom nutrition has been quite normally performed up to the moment of their birth. In all the cases where pemphigus has distinctly presented the characters which I have pointed out, the children have died in a few days. The alteration in their health has been so profound and rapid, notwithstanding the care bestowed on them and the precautions taken, that it has been most frequently impossible to attribute their death to any other cause than their syphilitic affection.

"Such are, in my opinion, the characters of the pemphigus of new-born children. I do not consider, as a manifestation of syphilis, a few vesicles, appearing after birth in feeble children, commonly scattered over the trunk, without any alteration of the skin beyond a slightly rose-coloured areola, and disappearing spontaneously in a few days. Krauss was therefore wrong in confounding together, under the title of pemphigus of new-born children, the simple and the syphilitic forms; and it is probably due to the influence of the ideas contained in his work, that the syphilitic characters of pemphigus have been so long misunderstood.

"In most of the cases which I have observed, I have been able to determine old traces of syphilis in the parent, or have obtained confirmatory information from them. When I have not succeeded, it has almost always been in the absence of the father. A remarkable fact was shewn by me to the late M. Cullerier, junior. He had requested me to shew him an infant affected with pemphigus, as he had not seen a case. An occasion soon offering itself, I showed him a child, born alive, perfectly developed, and covered with bullæ of pemphigus. The mother also presented too evident traces of an unhealed old venereal affection, which had just destroyed a part of the nasal bones, producing the characteristic deformity.

"In one of the first infants which I saw affected with pemphigus, and who died almost immediately after birth, there was a shallow elliptical ulceration, covered with concrete pus, on the left anterior pillar of the velum palati. Behind, on the corresponding part of the mucous membrane of the pharynx, there was a deeper patch of ulceration, covered with a layer of partly dried pus. In another child, covered with bullæ of pemphigus, the left ala of the nose, with the upper lip, presented a deep erosion of the skin, covered by a tolerably thick crust: it was evidently the excavated base of a bulla of pemphigus, or rather of a pustule of ecthyma mixed with the prevailing eruption. There was also a superficial ulceration on a neighbouring part of the

pituitary membrane; and another had completely perforated the nasal septum. These lesions were observed immediately after birth.

"About twelve years ago, I attended a young woman whose husband, having at the time primary syphilis, was imprudent enough to cohabit with her; he also neglected to employ effectual curative treatment. After some months, secondary symptoms appeared in both. The young woman became pregnant, and was delivered, at four and a half months, of a fœtus which appeared to have been dead some days. I called M. Chomel in consultation; and we agreed that both the man and his wife ought to be put under anti-syphilitic treatment. It had been followed rather irregularly for three months, when a second pregnancy supervened. The child was unexpectedly born a short time before full term: it was dead, and covered with pemphigus. Becoming pregnant a third time, the young woman consulted M. Moreau. The child was born alive, and apparently well, at the full term; but, in about a fortnight or three weeks, a syphilitic eruption appeared. By the advice of MM. Moreau and Baron, it was put under a course of antisyphilitic medicines, and recovered." M. Dubois then went on to controvert the opinion of M. Cazeaux with regard to pemphigus.

M. Cazeaux, in replying to M. P. Dubois, observed that it is not new to attribute pemphigus to syphilis; and that neither the erosion of the dermis, nor the seat of the disease on the hands and feet, were proofs of the venereal origin of the affection. The characters of the disease, as given by M. Dubois, would also answer for chronic pemphigus. In the cases cited, M. Cazeaux was inclined to believe that, considering the rarity of the occurrence, pemphigus appeared in the children "*although* they had syphilis, not *because* they were so infected."

M. Danyau had seen many children born with pemphigus. Many of them were the offspring of syphilitic parents; of the rest, nothing definite could be ascertained. He would not therefore absolutely allege that pemphigus was a constant sign of syphilis; but he was much inclined to believe, with M. Dubois, in its syphilitic origin.

At the meeting of the Academy of Medicine on July 22, 1851, M. Depaul related a case, of which the following is an abstract.

Case. G., aged 24, was admitted into the obstetric ward of the Clinique on August 2, 1850. She had been of good health, and had lived in Paris three years. Soon after her arrival, she became pregnant by an apparently healthy man, and was delivered of a dead child at the eighth month. She again became pregnant by another man, who appeared quite sound; and, in about two months, she had a sore in the labia majora, which was treated as a chancre by cauterisation, and was apparently cured. Three months after, however, she felt something unusual about the anus and vulva; and, on being examined at her delivery, she presented patches round the anus and on the external genital organs, of a syphilitic character.

The child was small, apparently of eight months' growth. Nothing was discovered on the skin but a well marked violet tint on the palmar and plantar regions. For two days, the infant took the breast readily, and otherwise appeared well, except that the respiration seemed rather imperfect and hurried. Forty-eight hours after birth, there appeared on the palms and soles a pretty large number of circular vesicles, varying from the size of a hemp-seed to that of a large lentil-seed, and all filled with a cloudy milky serosity. From this time, the countenance of the child was expressive of suffering. Several of the bullæ were torn by rubbing against the clothes, and yielded a slight sanguineous exudation. The infant cried constantly, and refused the breast. On the fifth day, there appeared, in the vicinity of the mouth and nares, several groups of small vesicles with a transparent apex and a conspicuous copper-coloured base. About the genital organs there also appeared mucous patches of a decidedly venereal character. On the next and following days, the patches of eczema became converted into blackish scabs; some of them ex-

tended into the nostrils, and greatly impeded respiration. Deep clefts formed on the lips, especially at the commissures.

M. Depaul administered mercury to the infant; and it appeared to go on satisfactorily for a fortnight. At the end of this time, the respiration became impeded; and, in spite of blisters and other remedies, the child died the next day.

On *post-mortem examination*, the mouth, nose, and genital organs appeared to have been getting well. The lungs were bound here and there to the walls of the chest, by false membranes, evidently formed anterior to birth. Each lung contained some small indurated nuclei, none being larger than a pea. Their consistence was that of the liver; their colour a deep red. One alone, which projected slightly under the pleura, was less coloured, and contained pus. All the other parts of the lung were sound, and had been entered by air. The other organs were healthy.

Primary Syphilis in Children. On this subject, Dr. Deutsch writes as follows:

Primary syphilis in children only differs from that in adults, by the unfrequency of chancre on the genital organs. Yet I have had an opportunity of seeing several children at the same time affected in this way. They were the sons of Jewish parents; and the disease was produced in them by the person who circumcised them being syphilitic, and sucking, according to custom, the wound with his mouth. Certain parts of the circumcised prepuce assumed a red, swollen, inflamed appearance; and ulcers were developed, but the gland and body of the penis remained free. In almost every case, there were also buboes. On another occasion, I saw perfectly similar ulcers and buboes on some Jewish children, and was enabled to refer them to precisely the same immediate cause as the others. It appeared, however, on the one hand, that these ulcers not only resisted antisyphilitic medicines, but even became worse; and, on the other hand, that no trace of syphilis could be detected in the operator, and that his past and present life would not lead to the suspicion that he had it: his gums were, however, spongy and scorbutic.

Syphilitic ulcers on the lips, tongue, anus, and once on the umbilicus, have come under my notice: but never without direct infection from the mother, midwife, nurse, or some other person. In all such cases, there were also buboes in the inguinal glands.

Weisse (*Abhandlungen der Petersb. Aerzte*, 1842, pp. 240 and 304) appears to have seen some peculiar alterations in the tongues of syphilitic children, in the form of furrows, and even rhagades.

Ulcers, having a strong resemblance to chancre, are sometimes found in female children from four to eight years of age, as a consequence of ascarides. They are principally developed on the internal labia, also in the anal region; and give rise to a profuse discharge of purulent corroding mucus. In a case which I observed, the entrance of the vagina, the external organs of generation and the upper part of the inner surface of the thigh, as well as the perinæum, were ulcerated throughout. Every antisyphilitic remedy, whether external or internal, aggravated the disease; but it was soon subdued by frequent cleansing and washing with weak solution of chloride of lime, and by fomentations of sage and nut leaves.

Treatment. In treating syphilis in children, a distinction must be made between the primary and the secondary affection. Mercury is undeniably the principal remedy: but there is a difference of opinion as to, 1. Whether it is judicious to use it only externally or internally, or in both ways at once; and 2. Whether it is always necessary to give the children mercury, or whether it is sufficient that the mother or nurse who suckles the child use it. Without doubting that cures have been brought about by the internal use of calomel and Hahnemann's mercury, I must mention the fact, that these remedies are not certainly sufficient in secondary symptoms; and

that, in primary cases, they are more likely to injure the children, than the external use of mercurial ointment (applied round the knee on a piece of flannel, according to Sir B. Brodie's plan). I have employed Cyrillo's treatment with very happy results in several rather extensive cases of secondary syphilis. Six grains of sublimate, and the same quantity of sal-ammoniac, are made into an ointment with two drachms of lard; and a piece of the size of a pea is rubbed nightly on the soles of the feet. Cyrillo recommended the soles of the feet to be softened by means of warm water for some days beforehand; but this is unnecessary in very young children. Twenty such inunctions are sufficient for a cure. The mother or nurse of the child must at the same time be put on low diet, and use blood-depuratory drinks. Many English and American physicians (especially Samuel Cooper, Golding Bird, Cheesborough, etc.), extol the hydrargyrum cum cretâ, given in doses of one or two grains, twice or thrice a day.

Weisse recommends Zittmann's decoction, with red oxide of mercury and sulphureous baths. Nonat gives corrosive sublimate to children of a month old; from one-sixth to one-eighth of a grain is dissolved in an ounce of water, and a teaspoonful given once daily; the mother or nurse being at the same time put under an antisyphilitic course. In obstinate forms of secondary lues, the principal remedy is biniodide of mercury, rubbed up, according to Cazenave's prescription, with some gum and honey or syrup, and either given from a spoon, or rubbed gently on the tongue and gums. It is also the chief remedy in tertiary syphilis in children, especially for affections of the bones, venereal coryza, etc. Iodine alone, notwithstanding its recognised beneficial effects in the lues of adults, does not cure it in children. Bathing of the surface, and careful cleansing of the diseased parts, especially if they secrete much, must never be neglected. If diarrhœa be produced by the mercury,—a troublesome, but fortunately rare occurrence,—opium must be given; but it is generally sufficient to rub it into the hypogastrium. I have not observed salivation in children under seven years of age. About a fortnight or three weeks after the cure is completed, I have found it useful to employ baths of sulphuret of potassium—half an ounce in each bath. The children begin to gain flesh in a remarkable manner, and get a blooming appearance. I have not observed that constitutional diseases of any kind remain after syphilis has been cured. Syphilis undermines the constitution much less readily in children than in adults, probably on account of the greater ease with which antisyphilitic treatment can be properly applied in the former. Whether children are cured by subjecting the wet-nurse or mother alone to antisyphilitic treatment, I cannot say from my own experience. That such is the case, is affirmed; and physiological reasons are not wanting to support it. But a certain result seems scarcely to be expected; and, as the disease is one which requires a prompt and sure removal, and as direct treatment of the child fulfils the indication, it is not advisable to employ an indirect method of somewhat doubtful advantage, especially on account of the unavoidable influence which the treatment must have on the health of the mother.

It is still a disputed question, whether a pregnant woman should be put under an antisyphilitic course for the preservation of her child. Not a few oppose this plan, alleging that the treatment fails in producing the desired results, and that it causes abortion. The first of these reasons is sufficiently controverted by careful experience; and the second is doubtful, for, where abortion occurs under such circumstances, it cannot be determined whether it was due to the disease, or the treatment. We must, however, always bear in mind to use the mildest preparations possible, as the oxides, when we give mercury to a pregnant woman. Iodine is objectionable.

I may now be allowed to relate a few cases, which have occurred under my own notice.

Case I. A young, strong, unmarried woman, was delivered at the full period of a well-formed healthy male child. Another child was discovered to be in the uterus; and, as the labour-pains had in the mean time ceased, the membranes were ruptured, and, by means of turning, a dead fœtus, eleven inches long, already commencing to putrefy, was brought into the world. It was ascertained, that the woman had never had syphilis during her pregnancy or previously, but that she had led a loose life, and had had intercourse with several syphilitic men. There was a probability of superfœtation having occurred in this case. The other child remained well, and shewed no traces of disease.

Case II. A woman was infected with syphilis by her husband, during her pregnancy. The man had had syphilitic ulcers on the genital organs, and buboes; and, at a later period, ulcers on the throat and mouth, and *corona venerea*. The woman had ulcers on the genitals, condylomata, ulcerated throat and *corona venerea*. Both were treated by several physicians with various preparations of mercury and with iodine; they had, however, not attended carefully to the treatment, and the woman especially had been constantly exposed, during the use of the remedies, to the influence of very cold spring weather. At the termination of pregnancy, however, she had no more traces of syphilis. The child was small, poor, weak, and ill-nourished; it had numerous venereal spots, of a copper colour, with branny desquamation, on the outside and inside of the upper part of the thigh, on the forehead, and in the vicinity of the bones of the foot. A perfect cure was obtained in three weeks, by means of Cyrillo's remedy and baths of bran.

Case III. A married pair, both of whom had suffered from all forms of syphilis, which still had left traces on the skull and sternum, had three children in five years. All three came into the world at the full time, but were all extremely small and weak. The first suffered from ophthalmia, which was not recognised as syphilitic, and yielded to simple cleansing remedies, without the use of mercury; the child, however, was slow in growing, and remained weak. The second was born with furunculi of a red-brown colour, and of the size of a walnut; these suppurated and healed up, but fresh ones constantly formed between them, and were at last replaced by purulent boils of large extent, which yielded a quantity of ichorous pus. Antisyphilitic medicines were not used in this case: but the child was treated with great care and cleanliness. It became atrophied, and died when ten months old. The third child was born with pustules over the greatest part of the body. Some of them were like itch pustules; they dried into a brown scurf, and left deep ulcers beneath. The child had also snuffling breath and coryza. Cyrillo's treatment was used with some success; but the child remained weak, frequently suffered from diarrhœa, and at last became ricketty.

Case IV. A weakly female, whose husband had had syphilis several times before marriage, but had always been treated by rational remedies, was delivered of a small child (thirteen inches long), which was in other respects well formed, and not badly nourished. The woman had never had syphilis. The child had three bullæ of pemphigus; and also had, on several parts of its body, large, brown, dry, leathery spots, the remains of flattened and healed bullæ of pemphigus. In three weeks, more bullæ appeared. Antisyphilitic remedies were not employed; the child wasted away, had diarrhœa, and died in the fourth week. After a second pregnancy, the woman was delivered of a small child, well formed and nourished. On the fifth day, pemphigus appeared; but the bladders seemed smaller than in the other case. The child had one-sixteenth of a grain of calomel given twice a day, and the mother was put on a course of sarsaparilla and dulcamara. The pemphigus disappeared in fourteen days, and was not followed by any other cutaneous affection. The child throve regularly, reached the age of thirteen months, and died in consequence of irregularities in diet after weaning.

Case V. A child, whose father and mother had suffered for some years

from virulent gonorrhœa, was seized, on the fifth day after birth, with inflammation and swelling of the eyelids. This rapidly passed into profuse blennorrhœa; and the eyelids exhibited the velvety excrescences peculiar to *ophthalmia neonatorum*. In other respects, the child was free from any appearance of disease, especially from impetiginous eruptions; and this latter circumstance prevented the syphilitic nature of the affection from being recognised. But, notwithstanding the greatest care, intertrigo appeared between the upper parts of the thighs and the genital organs, behind the ears, on the neck, and in the axillæ; it spread with extraordinary rapidity. The excoriations produced by the intertrigo assumed, in spots, the appearance of exulcerated, broad, flat, irregular sores. The ophthalmia was treated with a lotion of nitrate of silver (one grain to eight ounces of solution of opium); the intertrigo was treated by water; and calomel with magnesia were given internally. The child recovered in seventeen days, and afterwards throve well.

Case vi. A woman had had, for seven or eight weeks, chancres on the external genital organs and vagina, as well as condylomata of the arms and perinæum. The external and internal genitals, and the neighbouring parts, being well anointed with lard to prevent infection, she was delivered of a perfectly healthy and well-nourished child, which remained well, but was fed by hand. When the mother had been cured by appropriate treatment, she gave the child the breast; and it remained well as before.

Case vii. A woman, whose husband had had primary, secondary, and tertiary syphilis, before marriage, but had not since manifested any appearances of it, aborted five times successively in the fourth month of pregnancy: the fœtus was always in a putrefied state. In her sixth pregnancy, she went to the full period, and was delivered of a very small, meagre child, free from any appearance of impetigo: it died on the third day. In the mean time, her husband had, under medical advice, used each summer the warm sulphur baths at Salzbrunn. In her seventh pregnancy, she not only reached the full period, but was delivered of a healthy, strong child, which seemed likely to do well. This case corresponds with another, in which a woman, whose husband was syphilitic, had been delivered several times of weakly children, who died early, and had also aborted several times. When married a second time, to a healthy husband, she had no more abortions, and bore healthy children.

Case viii. Two women and a girl, who had several times had syphilis from irregular intercourse, were cured by methodical treatment. They married healthy husbands, and brought sound children into the world.

Case ix. In the village of G., there were thirty-two persons who had lues. Among these, were seven men and their wives: two of the latter were pregnant, and three were suckling their children. All these women soon had secondary symptoms, partly in the form of ulcers in the throat, and partly in the form of impetigo. The children were infected, and had syphilitic ulcers on the lips and tongue. They and their mothers were treated by mercurial inunction, and recovered. The pregnant women underwent the same treatment, and were cured: they went on regularly, and were delivered of well-developed children, who, however, had syphilitic spots. These were removed by Cyrillo's treatment. An unmarried pregnant woman, who had syphilis, rubbed in mercurial ointment; but she aborted in the sixth month. A very scanty diet and irregular mode of living, as well as frequent mental trouble, may have in this case favoured the occurrence of abortion.

Case x. The children above referred to, as having been infected with syphilis during circumcision, had all enjoyed perfect health up to that time. The wounds made in operating formed red, painful, inflamed cicatrices, which became fissured, and formed chancres. Where there were several of these scars close together, the ulcers became confluent. Buboes also ap-

peared—in some cases, even before the chancres. The general health of the children was much disturbed. Calomel and magnesia were given; and *unguentum cinereum* was applied to the buboes. All the patients recovered without any farther symptoms. In the other children, who had pseudo-syphilitic ulcers and buboes after circumcision, the disease was aggravated by mercurial treatment: they were cured by simply applying a digestive ointment to the ulcers.

The subject of the treatment of congenital syphilis was also brought under notice in the discussion at the Academy of Medicine.

M. Depaul stated, as one of the conclusions to his memoir, "that a physician should think himself authorised to prescribe antisyphilitic treatment to a father or mother, even when it is not possible to find traces of the disease in them, but when a child has been born dead, with the lungs in the state described by him."

MM. Cazeaux, Gibert, and Roux, opposed the practice of treating for *latent* syphilis.

M. Moreau had, some years ago, had an officer of the *garde royale* under his care, who had had syphilis. This officer was married: his wife became pregnant, and was delivered of a dead child; this occurred three times in succession. M. Moreau then advised the officer to put himself under a course of antivenereal medicines. The wife again became pregnant, and was delivered of a living, healthy child; and all her children have since lived.

M. Danyau related the case of a lady, who aborted in her first pregnancy, and in the next was delivered of a dead putrid child. He suspected syphilis, principally because the husband had already been affected, though he believed himself now cured. M. Danyau's proposition of an antivenereal course of treatment was rejected; and he had since heard that the lady had given birth to two other children affected with syphilis, of which they died.

M. Ricord observed: "It has been said that antivenereal treatment only has an influence on the evident symptoms; and that it is useless to have recourse to it when these do not exist. And hence it has been asserted, that it is useless to prescribe such treatment for a man or woman, when, being under the influence of the diathesis, though presenting no evident symptoms, they have become the parents of an infected child. But I think that the supporters of this view have forgotten, that the birth of a child with constitutional syphilis is a true manifestation of the existence of the disease in the parents. On the other hand, I am convinced that no one should be satisfied with the mere disappearance of the symptoms under treatment. Can we believe that a patient is thoroughly healed, when the *syphilide* has disappeared in a week? Daily experience has taught us that, though we do not know the quantity of mercury absolutely required to cure a case of lues, we know at least that the longer the treatment is continued in proper proportions, the more certain is the cure. If it does not destroy the diathesis, it prevents, or at least retards, its manifestation for a longer or shorter period. We have seen many cases of parents, who, having been put under a regular course of treatment, had afterwards healthy children; whereas their offspring had previously died before birth, or had shewn symptoms of syphilis soon after birth. And, if the treatment was suspended, the children born were infected. I have always, in these inquiries, examined more particularly into the state of the mother. Paternity may be doubtful; but not maternity. Some persons have hence thought, that I only admit hereditary transmission through the mother: this is incorrect; I only assert that the hereditary influence is here incontestable.

"It would never be right, on account of doubtful syphilitic symptoms in an infant, or on account of doubtful previous symptoms in the parents, to make the latter undergo a troublesome course of treatment, or to do what I have sometimes seen done—to put the father under an antivenereal course, when he perhaps has had a most harmless gonorrhœa twenty years before."

PARTIAL DILATATION AND RUPTURE OF THE LEFT VENTRICLE OF THE HEART: ATTEMPTS AT REPARATION BY COAGULA AND LYMPH.

Dr. M. M. White, of Syracuse, U.S., relates, in the *Boston Medical and Surgical Journal* for March 26, 1851, a case illustrative of the efforts sometimes made by nature to repair injuries of important organs.

The patient was a gentleman, aged 70 years, to whom Dr. White was called on October 5, 1850. Eleven days previously, he had been seized with urgent symptoms of angina pectoris; these lasted for one hour, and did not recur: but considerable tenderness, fulness, and uneasiness, remained about the region of the heart, with inability to lie on the left side. A slight pain was occasionally felt, and continued to recur until the first visit. At this time Dr. White found he had partially fainted, and was slightly convulsed, with momentary loss of consciousness. The impulse of the heart was very feeble; the pulse slow, small, and intermittent; there was great prostration of the vital powers; the countenance was pale and sunken; the extremities were cold; he had profuse perspiration, with difficult and laborious respiration. The violence and urgency of these symptoms subsided in the course of an hour or two; the pulse became regular, yet rose to 130 beats per minute in the course of the day.

On the ensuing day, October 6, he was much better.

He was visited daily until the 14th, during which time the pain and uneasiness about the heart had almost entirely subsided; but the frequency of the pulse continued, varying from 120 to 125 per minute. His general health had so much improved, that he resumed his business at his office. Dr. White did not see him again until Thursday morning, October 24th, when he was called in great haste. The patient was labouring under a severe paroxysm of palpitation of the heart, with a frequent, small, feeble pulse, nearly imperceptible at the wrist; countenance pale and sunken; respiration laborious; dry hacking cough; hoarseness of voice; profuse sweating, and cold extremities; with rapid sinking of the powers of life, threatening immediate dissolution. These symptoms continued most of the day. His appetite now for the first time failed, and there was nausea, with occasional vomiting; flatulence and constipation of the bowels were also present.

Paroxysms of palpitation of the heart, with sinking of the vital powers, continued to recur at irregular intervals for seven or eight days, though with less and less severity, until they nearly ceased, three or four days previous to death. As the paroxysms of palpitation and sinking gradually declined, the action of the heart became more regular. The pulse also became slower, fuller, and more regular. The muscular power gradually improved, so that he was able to raise himself up in bed with comparative ease. The functions of the brain were most perfect through the whole course of his illness. The mind was clear and tranquil, and his spirits buoyant and happy. A peculiarity worthy of remark, was the alternate violent and tranquil respiration. He would doze a few minutes calmly, then start up with a convulsive spring, with hurried and laborious respiration, and then sink down into the same quiet state as before. These alternations continued to recur for the last week or ten days of his life. Ordinarily the heart's action was weak and feeble; and, during a paroxysm of palpitation, its beats were quite distinct. There was dulness on percussion, on a space corresponding to the apex of the heart, of two inches and a half in diameter. The valvular sounds were clear and distinct. The external jugulars were turgid and swollen. The tongue was slightly coated at first, but towards the close became covered with viscid, tenacious mucus and sordes. A strong desire for acid fruit and drinks was present, and continued until near the fatal termination. This occurred suddenly on the evening of the 8th of November.

Post-Mortem Appearances. An examination of the body was made thirty-six hours after death. *Thorax.* On raising the sternum, the *pericar-*

dium was observed to be very greatly distended, and firmly adherent to the diaphragm. It was filled with bloody serum and coagula. At the apex of the left ventricle was a dark livid mass, two inches in diameter, and an inch or more in thickness, beneath the pericardium, composed of layers of coagula and organised lymph, arranged in alternate patches, and having strength sufficient to prevent the escape of blood for months and perhaps years. An opening about the size of a crow quill was traced beneath the external layer, from which the fatal extravasation had taken place. The muscular fibres of the heart were here very thin, and in the centre entirely wanting. The layers of coagula and lymph, together with the firmly-adherent pericardium, gave such support to the weakened portion of the heart, as to preserve its functions for a long time. It is highly probable that a slight effusion of blood took place from time to time, while, by quickly forming coagula, and subsequently lymph, the mischief was repaired; and this was again and again repeated, until the last fatal effusion. The lungs were perfectly sound; but there were two or three quarts of serum in the cavity of the chest. The stomach, liver, spleen, and pancreas, as well as the other organs in the abdomen, were in a normal condition.

TUMOUR COMPRESSING THE RIGHT SIDE OF THE MEDULLA OBLONGATA AND THE NERVES PROCEEDING FROM IT.

This case was related to the Society of Biology in Paris, on March 15, by M. Charcot.

Case. The patient, a woman aged 48, was admitted into the Charity Hospital on February 28. She had been ill three months; and at first was under the care of M. Gubler. He was called to her a fortnight after the appearance of violent pain in the occipito-temporal region. The neck was slightly tender on pressure; the organs of sense were very susceptible; and every movement of the body brought on attempts to vomit, sometimes followed by a discharge. The pupil was much contracted; and there was obstinate constipation, but no distension or tenderness of the abdomen. The tongue was rather white, but moist; the pulse was not frequent; the skin was not hot. There was no pain in the trunk or limbs, nor paralysis, vertigo, or convulsions. M. Gubler diagnosed a superficial circumscribed softening of the grey matter, or rather an intra-cranial tumour. He applied leeches behind each ear, gave a calomel purgative, and ordered chloroform to be applied locally to calm the cephalalgia. Considerable relief ensued: but the patient was removed by her son two days after. She soon began to manifest great hebetude, and weakness in all her limbs, without pain; and at last her speech became very remarkably impaired. The cephalalgia soon became as severe as before. A seton was applied to the neck, and blisters to the thighs, but without effect; and she was admitted into hospital.

On admission, she answered questions pretty readily, but soon shewed how much her intellect was weakened and perverted. She complained of very severe pains in the cerebellar region: the head was constantly turned towards the right shoulder, but there was no rigidity or contraction of the muscles of the neck. All her limbs were relaxed; but she moved her legs and arms without much difficulty, when desired to do so. When pinched, she felt it readily. There was no strabismus, ptosis, or deafness. The pupils were equally dilated. She had never had vertigo, muscæ volitantes, or noises in the ears. There were no signs of paralysis of the facial nerve. She protruded her tongue readily; but the point was immediately carried to the right. She could, however, easily turn it in her mouth, and could turn the point to the left when desired to do so. The movements of deglutition were perfect. The vomiting and constipation continued as long as the patient was in hospital. A kind of coma supervened, and the patient died on March 9th: she never had convulsions.

From the symptoms, it seemed probable that there was a tumour com-

pressing the ninth nerve; but there were no symptoms of syphilis, tubercles, or cancer. On post-mortem examination, a tumour, of the size and shape of a large pigeon's egg, was found on the front of the right lobe of the cerebellum, where it had formed a hollow. It also compressed the right peduncle of the brain, and pushed the medulla oblongata towards the left side. It had flattened the auditory, facial, pneumogastric, glosso-pharyngeal, and especially the hypoglossal nerves on the right side. The fifth pair was also much flattened. The third and sixth nerves were untouched. The tumour was very feebly adherent, and was easily removed by tearing some very loose cellular tissue. It was hard and dry, and grated under the scalpel: it was somewhat mammillated. Examined with the microscope, it presented fibroplastic tissue, with a predominance of the fibrous tissue.

WRAGG AND ARNOLD ON DENGUE, OR BREAK-BONE FEVER.

Two valuable contributions to epidemiology are contained in the *Charleston Medical Journal and Review* of this year; one, in the March number, by Dr. W. T. Wragg, entitled, History of the Break-bone Fever, an epidemic which prevailed in Charleston in the summer of 1850; the other, published in May, by Dr. R. D. Arnold, of Savannah, on the Dengue, or Break-bone Fever, as it appeared in Savannah in the summer and fall of 1850. We propose to lay the substance of these papers before our readers.

About the end of July and the beginning of August, 1850, break-bone fever began to prevail epidemically in Charleston; and the first case seen in Savannah by Dr. Arnold, broke out on the 28th August. In Charleston, up to the 15th or 20th September, it raged in an epidemic form. Persons of all ages and conditions were affected; but there were very few fatal cases, although the disease is estimated to have attacked seven or eight-tenths of the population of Charleston.

Symptoms. The description of the symptoms is taken from Dr. Wragg's memoir.

First Stage. The attack commenced with languor, lassitude, and general uneasiness, with nervous tremors, sometimes lasting for several days. There was very acute pain in the head, sometimes confined to one part, usually the temple, brow, or one or both eyes: sometimes it was general. In several cases, it was very severe in the ears, the angles of the jaws, and along the dental rows of both maxillary bones. There was, in some cases, intense pain and soreness in the balls of the eyes. [Dr. Arnold says, there was injection and watering of the eyes, with intolerance of light, and acute pain on moving the eyeballs: this was evidently owing to the affection of the sclerotic.] There was great pain in the muscles of the back of the neck, running up to the head; and, occasionally, an annoying sense of weariness. The pain in the head was often intermittent, and sometimes darting.

A very distressing symptom, in several cases, was the great pain and oppression in the chest, which materially impaired respiration, and induced a constant and urgent disposition to cough; which, however, was often impossible, from the severe pains produced by the convulsive motion of the chest. In many cases, there was great pain in the shoulders and back, but most generally in the loins and low down towards the sacrum, running round the body, and extending from the umbilicus to the hypogastrium. Sharp pains shot down the thighs and legs, being most intense in the knees.

There was general soreness of the whole flesh, and particularly of the bones; and this was so great, that many patients could find no ease either in the lying, sitting, or standing postures. Between the scalp and skull, the soreness was particularly distressing.

Soon after the onset of pain, sometimes along with or before it, fever appeared, usually ushered in by chill, and accompanied for many hours by a

chilly sensation alternating with flush. Nausea soon came on; and there was often vomiting, principally of the ingesta, with serous and mucous fluid. The nausea was frequently wanting; but was sometimes distressing, continuing even during convalescence. There was often pain in the bowels, and bilious diarrhœa; but sometimes the bowels were costive. The tongue was soon covered with a thick, brown, pasty coating; and there was generally great thirst. Sometimes the tongue was dry and brown, and the thirst intolerable, and the taste lost. The pulse was moderately full and quick, but never very active in force, quickness, or volume; seldom, according to Dr. Arnold, accelerated beyond 100. The skin was at first dry and harsh, but generally became moist, and often covered with free perspiration. In some cases, the heat and dryness were so pungent, that the sensation, experienced on touching the patient's skin, did not leave the hand of the physician for some time.

This stage, in the experience of both writers, varied in duration from a few hours to several days.

Second Stage. In most cases, there was an eruption on the skin. Sometimes it appeared even before the fever began to subside; sometimes it did not appear until all other traces of the disease had left. It was sometimes confined to the head and neck: it often extended over the whole body. It varied much in its character; assuming, in various cases, the appearance of scarlet fever, measles, impetigo, erysipelas, petechiæ, prickly heat, or papular eruption. Hæmorrhage frequently occurred from the nose, gums, tongue, fauces, stomach, and bowels; but was not generally excessive or obstinate. Want of sleep was a distressing symptom: in one case, it lasted about three nights and two days, and was followed by symptoms resembling *mania à potu*. In other cases, where the absence of sleep was less complete, the rest was disturbed by frightful dreams and fancies, not unlike those which characterise the disease just mentioned. When dreaming was not present, the patient tossed and moaned in sleep. The restlessness appeared sometimes to arise from imperfect sleep, sometimes from the soreness of the flesh.

The nervous tremors, which characterised the onset of the attack, in several cases increased, until, in two or three days, and when the fever was gone, the arms and legs would jerk and twitch without control. In children, these nervous jerks often announced the disease; the snap of the muscles could be distinctly heard. Often there were convulsions in children; but these did not occur in adult men, though there were symptoms of approaching delirium. Pregnant women, in all stages of gestation, almost universally escaped abortion. Dr. Wragg heard of only three cases.

In two cases, there was irritation of the urethra, with discharge of pus. One of the patients had never had gonorrhœa; in the other, the disease had been apparently cured. It was difficult to arrest the discharge. Dr. Dumaresq, of New Orleans, records a similar affection, in his account of dengue in that city, in the *Boston Medical and Surgical Journal*. The senses of hearing, smell, and taste, were variously vitiated or impaired.

The duration and severity of the disease varied very much. The fever, in some cases, was scarcely perceptible, or only existed a few hours. In others, it lasted from three to six days; in a few, it became intermittent, and continued two or three weeks. In some cases, the fever appeared to be absent. The patient would suffer for one or two days with pain in the back, head, and limbs, with giddiness, foul tongue, nausea, restlessness, and fatigue; these symptoms would gradually wear off, and be followed by weakness. After a few days, the eruption would come out in the form of heat, boils, carbuncles or abscesses.

Sequelæ. Recovery was sometimes rapid; but the easy transition from disease to health was the exception, and not the rule. Often, at the going off of the fever, the patient became extremely prostrate. There would be a deeply-coated tongue, with a bitter taste in the mouth; or a persistence of

the loss of taste. The pulse would become weak, the skin cool and covered with profuse perspiration, and a general feeling of faintness and sinking come on, almost as insupportable as the acute pain of the first stage. The spirits would be depressed. Many were left with persistent and violent pains in some part, which were relieved only as the appetite and strength were restored. These pains would sometimes last two or three weeks: they were seated in the muscular, ligamentous, cellular, or cutaneous tissues.

Boils, carbuncles, and abscesses, sometimes annoyed the patients for weeks after the other effects of the disease had gone. The boils were very large and numerous, and would cover the face or limbs. Carbuncles were scarcely less common. In one man, Dr. Wragg saw seven at one time on his back, with boils and phlegmonous abscesses in the interspaces; the entire surface of the back and sides being of the brightest crimson colour. In numerous instances, the inflammations about the fingers took the form of whitlow. Abscesses occurred on the neck, arms, thighs, breasts, buttocks, etc.; from some of these half a pint of matter was discharged at once, coming sometimes from the superficial, and sometimes from the deep-seated cellular tissue. In a healthy child, about nine months old, the fever was followed, after some weeks, by extensive impetigo of the face, neck, and shoulders.

The brain gave strong evidences of debility. On the abatement of the disease, the patient, in several cases, fell into a state strongly resembling delirium tremens; and the hallucinations were of the same character, the apparitions being always of the malignant and diabolical kind.

The fever had a great tendency to relapse, on premature exercise, fatigue, or any kind of exposure. Dr. Wragg has seen it occur three times, each time with marked aggravation of the symptoms. A mild first attack, would often be succeeded by others, excessively severe, and of longer duration. Relapses were most severe when the patient had undergone no medical treatment, under the impression that, as the disease was free from danger, it required no medicine.

As the season wore on, typhoid symptoms supervened in patients whose cases had been neglected, especially when due attention had not been paid to the convalescence. One of these cases offered a remarkable specimen of a purely nervous fever; the patient died twenty-eight days after the invasion of the nervous symptoms, and seventy from the first attack. In the same family, another child was only rescued by the timely use of nourishment, tonics, and stimulants, from falling into a similar state. In two other cases, this condition lasted respectively thirty and forty-two days.

Diagnosis. (Dr. Arnold.) From the *climate fever* of the country, the break-bone fever was not readily distinguishable in the earliest stages: but remission or intermission takes place in climate fever within twenty-four hours; while the paroxysm ushering in the dengue was continuous, even if it lasted forty-eight hours. Dr. Arnold often found the break-bone to be followed by climate fever in the same individual; and has attended cases of each, lying alongside of each other.

From *scarlatina* it was distinguished by the duration of the eruption, the absence of anginose affections, and the violence of the preliminary symptoms. The eruption in dengue was the sign for the abatement of the symptoms; while, in scarlatina, the worst symptoms are generally developed after the eruption has appeared. In scarlatina, the skin never breaks out into a perspiration on the first appearance of the eruption: in dengue, after the eruption has been well thrown out, the fever goes off by moisture on the skin. The eruption lasts but two or three days in dengue: in scarlatina, it lasts six or seven; and there is more desquamation of the cuticle in the latter than in the former. In scarlet fever, the eruptive membrane of the mouth participates in the efflorescence; and, as the skin begins to desquamate, the tongue also throws off its cuticle, and appears bright, red, and shining; and the papillæ, deprived of their sheaths, become very prominent. Any redness

of the lips, tongue, and gums, which may occur in dengue, is, as far as Dr. Arnold has observed, less intense than the redness of scarlatina, lasts a much shorter time, and is not followed by throwing off the cuticle. In two cases occurring in children, Dr. Arnold saw œdema follow the desquamation of the cuticle, as in scarlatina.

From *prickly heat*, the eruption is readily distinguished by careful examination. Prickly heat is a distinct papular disease.

Pathology. The want of *post-mortem* examinations prevents much light from being thrown on this subject. Dr. Wragg is of opinion, that break-bone fever is "essentially a cutaneo-nervous disorder": that the skin, irritated by the intense and protracted heat, dryness, and non-electrical condition of the atmosphere, underwent changes in its functions, and consequent disease. He then enters on a comparison of the break-bone fever which he witnessed, with the epidemics of dengue described by former American writers. The latter disease, he says, is the *scarlatina rheumatica* of Dr. Copland: and, after pointing out some points in which the affections seem to differ, he does not think it safe to attempt a final settlement of the question of identity between the dengue and break-bone fever. Believing that the resemblance is not sufficient for them to be classed together, he is unwilling to discard the idea that the diseases strongly resemble each other in many points. Whether the difference between the two diseases consists in anything more than that, in dengue, the impression is originated in the ligamentous tissues, while in break-bone fever it originates in the skin, he does not undertake to decide.[1]

Causes. Drs. Wragg and Arnold concur in pointing out the constitution of the atmosphere as connected with the cause of the epidemic.

The spring, in Charleston, had been remarkably cool. Early in July, the weather became very hot; and, from that time till the beginning of October, the range of the thermometer at midday, in the shade, was not far from 90°, often above. Water was exceedingly scarce. Very little thunder and lightning prevailed. The wind was from the west, and rather diminished than increased moisture. Febrile diseases of the ordinary types were rare; and the atmospheric conditions which seem to favour their occurrence were wanting. It is not a little remarkable, that the summer of 1780, when an epidemic, resembling the break-bone fever, occurred in Philadelphia, was, as appears from the description given by Rush, very similar to that of 1850 in Charleston.

Drs. Arnold and Wragg both believe the disease to have been non-contagious, and adduce several instances, which are, however, only valuable in a negative point of view. That it was epidemic, is proved by its rapid spread, or rather simultaneous appearance in different parts of the same place.

Treatment. Energetic measures were at first adopted; but were soon abandoned, being found to be erroneous. The practice in Charleston was to give a mild aperient, such as Epsom salts in infusion of serpentary, seidlitz powders, etc. Diaphoretic and opiate mixtures were then prescribed; usually carbonate of potash, with laudanum or paregoric, sometimes with camphor and sweet spirits of nitre. At the same time, pediluvia, warm poultices, frictions, etc., were used. Pain in or determination to the head, received marked relief from cold affusions. To compose the patient at night, pediluvia were ordered, and paregoric and sweet spirits of nitre given in hot ptisan. To overcome wakefulness, morphia was given with much advantage. For the early debility, Dr. Wragg gave stimulants freely, not waiting till the

[1] Dr. Arnold makes no hesitation in calling the epidemic which he describes by the name of dengue. Dr. Wragg's pathological reasoning seems fettered by the idea of localisation of the "primary impression" of the morbific agent. That the same miasm, being introduced into the blood, may produce very varied symptoms, is abundantly proved: witness the cutaneous and rheumatic types of scarlet fever. The primary essence of a febrile disease is not always to be found in the most prominent symptom. [Editors L. J. M.]

pain was relieved, but combining stimulants and opiates. Wine whey, wine, brandy toddy, porter, etc., were given freely; and, at short intervals, quinine, with morphine or paregoric. Nausea was occasionally troublesome; but usually yielded to carbonate of potash and laudanum.

The loss of appetite was often a barrier to the early use of nourishment; yet, when the patient could be got to take some simple articles of food, the stomach was relieved, the thirst was lessened, and the tongue got clean. The cases treated early with stimulants, tonics, and nourishment, were those that did best, and had the least tendency to relapse. The latter occurrence seemed almost to take the form of periodicity; and, for this, quinine was the best remedy.

HANNON ON THE ACTION OF METALS IN CHLOROSIS.

It has long been believed by M. Hannon, in common with others, that the iron and manganese given in chlorosis were assimilated; and the soluble salts of iron have been preferred, as being most capable of being absorbed and of uniting with the elements of hæmatosine. M. Hannon now opposes to this opinion some facts worthy of consideration.

He says that lead, copper, and bismuth cure chlorosis as well as iron or manganese, and have succeeded in some cases where iron has failed. The blood has thus recovered its iron under the influence of some other metal. Neither the iron, nor any other metal, combines with the hæmatosine; for he believes that, although the number of blood-corpuscles be diminished, those which remain still contain a sufficient quantity of iron. He gives the following explanation of the manner in which the metals produce their good effects.

During digestion, hydrosulphuric acid is formed, which acts on the compound of iron and manganese contained in the food, and thus removes these metals. This is especially the case in chlorosis, in which there is a singular tendency to the formation of hydrosulphuric acid in the intestines. The way to prevent this effect is to administer a non-poisonous metal, capable of forming an insoluble sulphuret with the hydrosulphuric acid. This property belongs to bismuth, lead, and copper, as well as to iron and manganese. [Abridged from *Gazette Médicale*, August 23, 1851, as quoted from *La Presse Médicale Belge*.]

SPIRÆA ULMARIA, OR MEADOW-SWEET, IN DROPSY.

M. Tessier, of Lyons, has been led, by the observations of M. Obriot, a priest in the department of Haute-Marne, to make experiments on the effects of spiræa ulmaria in certain cases of dropsy. He has published his results in the *Bulletin de Thérapeutique*.

A person in the prison at Perrache had ascites, connected with intestinal irritation. After all other known diuretics had been tried in vain, M. Tessier prescribed a quart of the decoction of spiræa daily. From the third day, the patient passed much more urine than before. At the end of sixteen days, the medicine was suspended, and the urine immediately became scanty. It was resumed, and continued for six weeks; and the ascitic effusion was absorbed without the production of any debility. In a case of hydarthrosis of the knees, the decoction of spiræa seemed to aid materially the action of vesicants, by increasing the renal excretion. In a young woman affected with heart-disease, it produced abundant diuresis, without lowering the circulation like digitalis. A young man accidentally took some of the decoction, in mistake for a pectoral ptisan. Four days after, he spontaneously remarked, that he had passed an enormous quantity of urine for forty-eight hours after. His condition became improved.

M. Tessier believes that meadow-sweet possesses diuretic properties; that it is also slightly astringent and tonic; that it is agreeable to the taste, and

produces no disturbance of the stomach or of the nervous system. All parts of the plant seem to be endowed with the same properties: the flowers are perhaps less active. The spiræa grows in March and April, and flowers in May and June. [*Journal de Médecine et de Chirurgie Pratiques*, June 1851.]

SUB-PERITONEAL RUPTURE OF THE DUODENUM.

The following case is quoted by the *Gazette Médicale* for August 2, 1851, from the *Annales et Bulletin de la Société de Médecine de Gand* for 1850.] It is related by Dr. Burggraeve.

Case. On July 23, 1850, a sailor, aged twenty-four years, of strong constitution, was struck in the region of the liver by a beam. He was thrown violently to the ground; on rising, he was obliged to seek soon for a support. He had immediately severe pain in the bruised part, and vomited a considerable quantity of blood. When admitted into hospital, he complained of intolerable suffering in the epigastric region, and vomited undigested food mixed with bile. There was no external trace of injury beyond a slight abrasion; but the abdomen was tense and resistent in a circumscribed part. The treatment employed was general bleeding, cupping to the epigastrium, and emollient poultices. During all the day he continued to vomit; the rejected matter became more and more bilious; the pain was slightly decreased. He had a feeling of weight at the epigastrium, with thirst and want of sleep; there was no fever.

July 24. The pain was gradually becoming more severe; the abdomen was very tense and resistent under the right false ribs, but not in other parts. Twenty-four leeches were applied. Towards the evening, the pain and vomiting increased; the vomited matters were of a deep green colour.

The subsequent reports show a gradual aggravation of the pain and irritability of the stomach. On the 29th, the pulse became intermittent, the extremities cold, and the vomited matters were of a yellowish brown colour and putrid odour. On the 30th, the patient died.

Autopsy. The organs of the abdomen preserved their proper relations to each other. The intestines were in general of a blackish ecchymotic colour. The liver was slightly injured towards its anterior edge. The stomach was distended. The duodenum was torn for the two anterior thirds of its circumference, about two and a half inches from the pylorus, at the level of the orifice of the pancreatic and hepatic ducts. Under the peritoneum there was an effusion of yellowish matter, mixed with some bile. There was no trace of inflammation.

SURGERY.

LANGIER ON THE TREATMENT OF WHITE SWELLINGS WITH FUNGOSITIES OF THE SYNOVIAL MEMBRANE.

M. Langier criticises the various means which have been proposed for the treatment of white swelling with fungosities of the synovial membrane, and observes, that none of them have a *direct action*,—none act on the vessels themselves which constitute the morbid development from the membrane. The researches of M. Richet on these fungosities have shewn their eminently vascular nature. It is also well known, that the external surface of the synovial membrane is furnished with a richly vascular areolar tissue, which soon participates in the disease by becoming extraordinary developed, from the organisation of the coagulable lymph which it secretes. Hence the synovial membrane acquires a great thickness, from the fungosities and false membranes interiorly, and the thickening of the areolar tissue externally.

From observing the vascular relation established between the fungosities

and the external areolar tissue, M. Langier has derived a new method of treatment. He believes it to be perfectly harmless, to rapidly produce alleviation of the pain, and to diminish immediately and permanently the fungous areolar tissue external to the synovial membrane.

The treatment proposed consists in boldly plunging a lancet to the depth of several lines into the white swelling, at points where the fungous areolar tissue is thickest. Several punctures may be made at the same time. The immediate effect is an abundant local hæmorrhage from each puncture: from sixty to seventy grammes of dark venous blood escape. The fungosity diminishes; it does not disappear completely, but, in place of being elastic and resistant, it becomes supple. This diminution continues for some weeks. The punctures should be repeated, either in the same or in different spots, to obtain a complete and permanent cure. Local bleeding from the vessels of a morbid tissue may well be understood to have great efficacy.

Case I. A young man, in the hospital La Pitié, had for several months had an arthritic affection of the right elbow, with rapid development of fungosities in the synovial membrane. On his admission into hospital, there was an elastic resistance on each side of the olecranon, much resembling the projection of the synovial membrane produced by dropsy of this joint. M. Langier diagnosed the existence of a white swelling, originating in the synovial membrane. There was constant moderate pain, even when the joint was moved. Motion was restricted, but was still possible. The arm could not be completely extended; passive flexion was easy enough; pronation and supination caused most pain; no crepitation of the joint was observed during motion. The region of the elbow was evidently enlarged, especially behind and on each side of the olecranon. Leeches, flying blisters, and compression, were tried without success; as was also the actual cautery. The disease went on increasing, when M. Langier was led to try the effect of the treatment described above. On the first puncture being made, there was an abundant flow of blood; the tumour was diminished, and the pain was relieved. A month after the commencement of this treatment, the patient's elbow had been punctured fifteen times. In all the posterior portion of the swelling, the fungosities were soft and reduced in size; and there was no pain in the joint: but the patient was not yet cured. Abscesses had formed, evidently communicating with the articulation of the head of the radius,—a part not easily accessible to the lancet. The lateral ligament seemed relaxed; there was great mobility from side to side. There was no crepitation. The elbow and fore arm were enlarged; the arm was smaller. The patient had lost flesh, and complained of much weakness. M. Langier does not know whether the limb can be ultimately preserved; but he thinks the favourable change produced by the puncture worthy of attention.

Case II. Another patient, in the same hospital, had necrosis of the right second metacarpal bone, near its phalangeal articulation. Opposite the necrosed part, there was a fungous ulcer, through which the necrosed bone could be felt with a probe. The metacarpo-phalangeal articulation was healthy: but above it, and at its level, there was an evident fungous state of the sub-cutaneous areolar tissue, not connected with the joint. On July 17, M. Langier made a deep puncture in this fungous tissue, which was resistant, elastic, and painful on pressure. Some venous blood escaped; the pain was immediately relieved; and the fungus was diminished. On the 18th, the tissue was soft, and reduced to about half its former size. On July 30, the improvement was still more marked. On the day following the punctures, the hæmorrhage was replaced by a serous exudation, mixed in some parts with a little pus.

M. Langier states his object to be to lead to more trials of his plan. Several interesting questions regarding it he reserves for future discussion. [Abridged from *L'Union Médicale*, 31 July, 1851.]

NEW METHOD OF APPLYING COLLODION FOR PRODUCING OCCLUSION OF THE EYELIDS.

The process of occlusion of the eyelids, by bringing them together and applying collodion over them, presents two inconveniences. If a drop of the collodion reaches the conjunctiva, it produces irritation, always very painful, and especially troublesome if, as is generally the case, the membrane is already inflamed. In the second place, if it be desired to examine the eye before the collodion has spontaneously detached itself, it becomes necessary to remove it with ether or scissors—both delicate and irritating processes, often causing pain and apprehension to the patients.

M. Barrier, of Lyons, employs a process which avoids these difficulties. A thread is placed vertically on the upper eyelid; a small piece of fine linen is then dipped in collodion, and placed on the lid, a little above the root of the eyelashes, so as to fasten down the thread. The same thing is done on the lower lid. To keep the lids closed, it is only necessary to tie the threads in a knot or bow; and it is quite easy to open or separate the eyelids. [*Annales d'Oculistique*, as quoted in *Gazette Médicale*, August 16, 1851.]

LOCAL APPLICATION OF WINE OF SQUILLS IN HYGROMA.

A Spanish journal, *La Union*, reports, in the March number, a case of hygroma cured by the application of compresses wetted with wine of squills. The patient was a woman fifty years old, who had had, for a year, a tumour of the size of a hen's egg on the front of the patella. Dr. Serrano, who was consulted, proposed iodine injection; but, as the patient objected, he was led to employ a remedy which he had already found successful in a case of hydarthrosis of the knee. Cloths dipped in wine of squills were applied, and fixed by means of a bandage; they were frequently renewed. Under this application alone, and without any particular regimen, the tumour gradually and completely disappeared in thirty-six days. Five months after, there was no return.

Hygromas, or collections of fluid in the patellar and anconal bursæ, must be treated by resolvent applications, or by puncture followed by iodine injection. Very severe symptoms have been known to follow the operation of opening them. The wine of squills, proposed by Dr. Serrano, is perhaps not so efficacious as a local application, as the concentrated solution of sal ammoniac, made according to the formula of M. Jobert de Lamballe, in the proportion of from sixty to a hundred and twenty grammes of the salt, to five hundred grammes of lime-water. Compresses, dipped in the solution, are applied, and frequently repeated. It is more likely to be efficacious when the tumour is of recent origin. M. Jobert has obtained some very successful results from its use. [Abridged from *Journal de Médecine et de Chirurgie Pratiques*, June 1851.]

ENORMOUS HYPERTROPHY OF BOTH MAMMÆ: EXTIRPATION.

M. Rouyer, of Saintes, has communicated to the Academy of Medicine in Paris, the history of a case, in which both breasts were enormously hypertrophied. We extract his account, with the remarks made by M. Robert in his report on it, read at the meeting of the Academy on May 6th, from the *Gazette Médicale de Paris* for May 10, 1851.

Case. S. R. menstruated when eighteen years old. Four months after, the menses almost entirely disappeared, without evident cause. The mammæ, which had been but slightly developed, became painful, and began to enlarge: first the left, then the right. The left breast increased to such a size, that it measured eighteen inches from the base to the nipple, thirty-two

inches round its middle part, and twenty-seven round the pedicle. The right breast was very nearly as large. The mammæ were pyriform, of a violet-red colour, and covered by numerous enlarged subcutaneous veins. They were soft on the surface; but more deeply there could be felt a large number of hard knots, from the size of a walnut to that of a hazel-nut, connected by resistant cords.

In 1842, a puncture was made, from which only blood escaped: potash was also applied without effect. M. Bouyer saw the patient in 1844, three years after the commencement of the disease. The general health of the patient was then good; there was slight emaciation. The tumours entirely covered the abdomen, reaching as far as the knees; they were so heavy, as to have made the patient keep her bed for two years.

An operation was regarded as the only resource; and, on June 24, the left breast was removed, the pedicle being compressed between two plates of whalebone, to prevent hæmorrhage. Notwithstanding this precaution, a considerable quantity of blood escaped from two arteries of the size of a goose-quill, situated at the centre of the tumour. Numerous arterial twigs were tied. The edges of the wound were brought together, but not completely; but little fever followed, and the patient was in a most satisfactory state at the end of a week.

Twenty-six days after the first operation, the right breast was removed: it has diminished remarkably in size. No untoward occurrences followed; and the patient was quite well in two months, the menses being re-established, and the whole body gaining flesh.

The left breast weighed 30½ pounds, and the right 20½ pounds. After the operation, the patient weighed 101 pounds; a third part of her weight had therefore been removed. The tumours consisted of a fatty tissue, in which were found glandular portions, not degenerated, but excessively hypertrophied.

M. Robert, in reporting on this case, called attention to what he considered as an etiological connexion between the suppression of the menstrual discharge, and the formation of tumours of the kind described. He regretted that no microscopic examination had been made; but thought that the affection was probably simple hypertrophy of all the anatomical elements of the mammæ.

With regard to the prognosis and treatment, M. Robert believed that, as long as the tumour did not embarrass the patient by its weight, it would be rash to operate; but, when the patient is so much inconvenienced as in M. Bouyer's case, extirpation becomes a matter of necessity.

From the few cases of hypertrophy of the breasts which have been already operated on, we find that, when one is removed, the other diminishes in size. Hence the largest tumour should be removed first; and we should wait a few months before operating on the second, to see whether it will become reduced to such a size as to be compatible with the functions of nutrition and locomotion.

VARICOSE DILATATION OF THE LYMPHATIC VESSELS OF THE PREPUCE.

M. Beau, of the Hospital Saint-Antoine, describes the above-named affection as situated under the mucous membrane on the internal and lateral aspect of the prepuce, in the lateral folds of which it is hence concealed. To see it, it is necessary to render tense the integument of the penis; it then appears under the form of a small round cord, quite transparent, from one to three millimètres in diameter, and one or two centimètres in length. This cord is resistant and hard: it cannot be compressed, nor can the transparent liquid which it contains be squeezed out. Its *dorsal* extremity is situated near the median line of the dorsum of the penis, and terminates insensibly

under the skin, so that it can scarcely be felt. The *frenal* extremity is near the frænum præputii, and ends abruptly in the mucous membrane; but it is not easy to perceive the lymphatic vessel, which is a continuation of the dilated portion. When the cord is pretty long, it presents a sort of intersection, probably denoting the presence of a valve; for, when it is pricked, only that portion on one side of the valve is emptied. The fluid is perfectly limpid: it reappears two or three days after the vessel has been emptied by puncture. The lymphatic varix first appears suddenly, after excessive irritation of the prepuce, as in coitus. It then disappears in a day or two; but returns on a renewal of the cause, and soon again disappears. It at length becomes permanent, and the cord is as large as a pigeon's quill. The affection does not produce any serious consequences.

The treatment varies, according as to whether the disease is intermittent or continuous. In the first case, it will be removed by astringent or tonic lotions. If it is continuous, a needle, armed with a thread, must be introduced into the frenal extremity, and brought out about a centimètre beyond. The pain produced is very slight. In three or four hours, the thread may be removed, sufficient inflammation having been produced. The cord is then swollen, somewhat tender, and opaque. It gradually decreases; and disappears in two or three months. If the thread be introduced at the dorsal extremity, the frenal end still remains dilated, and the operation has to be performed over again. [*Revue Médico-Chir. de Paris*, January 1851, as quoted in *Archives Générales de Médecine*, May 1851.]

OBSTETRICS.

DR. FLEETWOOD CHURCHILL ON OVARIAN IRRITATION.

In the *Dublin Quarterly Journal of Medical Science* for August 1851, Dr. Fleetwood Churchill describes an affection which he terms Ovarian Irritation. It most closely resembles subacute ovaritis, as described by Dr. Tilt; but it presents to Dr. Churchill certain points of difference which entitle it to be considered as a distinct affection.

It occurs in women of all ages within the limits of menstruation, and is most frequent in delicate nervous individuals. The chief symptom is uneasiness, generally amounting to pain, in one or both iliac or inguinal regions, but most frequently in the left. The pain may be a constant dull aching, or it may be acute and paroxysmal; it is greatly aggravated by standing, and generally by walking. In the severer cases, the patient may be quite unable to walk. On making a rectal or vaginal examination, nothing unusual will probably be discovered; but, in some cases, moving the uterus laterally causes uneasiness. There is no painful enlargement of the ovaries, such as is described by Dr. Tilt to exist in subacute ovaritis.

The circumstances under which the attack occurs are thus enumerated by Dr. Churchill. 1. In patients who occasionally suffer from amenorrhœa, it is not uncommon to find ovarian irritation at these periods, and not always altogether confined to them. Whether it be a cause or result of the suppression, is not clear. 2. On the sudden suppression of menstruation, the ovaries may be either affected by irritation, or, more rarely, by acute inflammation. 3. In dysmenorrhœa, there is more or less ovarian irritation, which Dr. Churchill believes to be generally secondary. 4. In menorrhagia, if the attacks be frequent, the ovaries generally become affected. 5. Ovarian irritation often accompanies congestion and erosion of the cervix uteri; but it most frequently comes on after the latter disease has persisted for some time, or after it is nearly or quite cured; but it then very soon subsides. 6. It occurs in hysteria, either with or without irregular menstruation. 7. Dr. Churchill has met with it in a few cases where the uterine and ovarian monthly functions were regularly performed, but the patients were of a highly nervous temperament, delicate, and childless.

When uncomplicated, the disease rarely gives rise to constitutional symptoms. The urinary secretion is mostly scanty, acid, and occasionally mixed with mucus. Many of the subjects are delicate and weak, and the attack keeps them so ; but it does not seem to aggravate their general condition.

Pathology. The absence of tumefaction generally, the negative results of an examination *per vaginam* and *per rectum*, the intermitting and paroxysmal nature of the attack, the absence of all the ordinary results of inflammation (abscess, accumulation of fluid, etc.), even in the severer cases, and the success of a certain line of treatment, appear to Dr. Churchill very strong arguments in favour of the disease being not inflammatory, but neuralgic. In most of these particulars, it differs from the subacute ovaritis of Dr. Tilt. It does not appear to stand in the relation of cause to the menstrual disturbance ; for sometimes it follows the latter ; or there may be even no catamenial derangement at all. It may disturb the menstrual functions in various ways, but it by no means invariably does so.

Causes. All influences—among which the most frequent is probably cold—which disturb the functions of the uterus or ovary, may be considered as causes of ovarian irritation. Excess in sexual intercourse has given rise to it in many cases ; and, in a few, it appears to have arisen from the entire deprivation of that stimulus.

Diagnosis. The relation to the menstrual functions, the symptoms, and the locality of the pain, render the diagnosis generally tolerably easy. It may be mistaken for intestinal irritation ; but the bowels, even if irregular, are free from irritability. From acute ovaritis, it is distinguished by the *tenderness being generally much greater than results from inflammation:* moreover, in acute ovaritis, the organ is always swollen and enlarged. In pelvic abscess, the hard and painful tumefaction is quite plain at the brim of the pelvis.

Treatment. Dr. Churchill has tried leeches, blisters, anodyne liniments, plasters, and enemata, with but partial success. The most efficacious method of treatment he finds to be the application of opium to the upper part of the vaginal surface. He uses it in the form of balls or pessaries, somewhat in the mode of Dr. Simpson's medicated pessaries, each ball containing two grains of opium, half a drachm of white wax, and a drachm and a half of lard. The whole forms a ball about the size of a large marble, and is placed at the upper end of the vagina by means of the speculum, the patient being left in bed for the rest of the day. Relief is very speedy, generally complete ; and, when the pain returns after a few days, a second application removes it. Dr. Churchill has tried this remedy in many cases, with almost invariable success. He has rarely found it necessary to bleed or blister since he first adopted it. He has tried these pessaries in cases of dysmenorrhœa, applying one the day before the catamenia were expected, with decided benefit.

In ovarian irritation, the bowels should be regulated. If the appetite is bad, vegetable bitters may be given, and it is generally useful to combine some alkali with them.

CÆSAREAN SECTION SUCCESSFUL.

Dr. Radford, in the *Provincial Medical and Surgical Journal*, No. xii, 1851, gives the details of a case, in which the Cæsarean section was performed by Mr. Goodman of Manchester, on account of extreme distortion of the pelvis, caused by mollities ossium. The child was extracted alive, and lived for seven months, when it perished from hydrencephaloid disease, arising from diarrhœa. The mother made a tedious but perfect recovery ; again became pregnant, aborted, and died. Dr. Radford adds :

"By the aid of the stethoscope, the incision was made in a direction to avoid cutting into the placenta ; this is very important. When the placenta

is cut upon or into, partial irregular contraction of the uterus happens; and through such an accident, the infant may be lost, as I have already stated. But besides this, the tissue of the uterus is likely to suffer from the force required to extricate it (the infant) from the spasmodic grasp of this organ. Besides, there may be greater risk of hæmorrhage when the placenta is prematurely disruptured or separated. The operation was timely performed in this case.

"There happened several important contingent circumstances, to which I shall briefly advert. The abdominal parietes were so much attenuated as only to allow a very slender hold to be taken by sutures, and were quite unequal to resist the pressure they were subjected to. By the force of the cough, etc., this weak structure was torn through, and the edges being thereby set at liberty, retracted on each side to a considerable extent, and exposed the bowels fully seven to eight inches in one direction, by three to five in the other. Notwithstanding this serious accident, the constitutional disturbance was only trifling in degree, and of short duration.

"The changes which successively took place on the exposed surface of the bowels were truly astonishing. A thin transparent effusion of lymph was first seen laid over the peritoneal coat of the intestines, which entered a little into the depressions formed between their convolutions. This thin gelatinous material gradually became thicker and more opaque, evidently the second step towards cicatrisation. During this wonderful process—for its effects were truly wonderful—innumerable vessels were seen, destined to carry on this great work of reparation. As this went on, there was a progressive and perceptible diminution in the size of the surface; and when completed, there was a cicatrix to be seen, very little different from one which is formed at the healing of a wound whose edges have been kept in juxtaposition.

"Symptoms of strangulation appeared, for the relief of which several expedients were adopted. The protruded portion of the bowel was ineffectually punctured. Nature, however, stepped in, and immediately the symptoms were relieved by the formation of an opening, through which a great quantity of feculent matter and flatus were discharged. This aperture continued throughout the case. Although this disaster protracted the patient's recovery, there is no doubt it had, at the time it happened, a most salutary effect. During the whole period of the case, the bowels were strictly attended to; and their ready obedience to our measures (chiefly enemata) considerably contributed to her recovery.

"The reparative process which happened in this case, and the decidedly conservative constitutional power which this woman had, proved, beyond dispute, that the opinion expressed by Dr. West (*London Medical Gazette*, No. 1210, February 1851, p. 245) is not infallibly true; and, therefore, ought not to influence us, and deter us from the performance of the Cæsarean section. The same restorative power was observed in the other successful case, which is already before the profession."

M. F. MARTIN ON RELAXATION OF THE SYMPHYSES OF THE PELVIS, AND ITS TREATMENT.

Parturition is sometimes followed by persistent relaxation of the various symphyses of the pelvis. As it commonly arises from the patient leaving the horizontal position too soon, as various sympathetic symptoms accompany it, and as other lesions may co-exist with it, it is not surprising that the nature of the affection should have been mistaken, sometimes for engorgement of the neck of the uterus, sometimes for retroversion of that organ. In persons thus affected, standing erect is peculiarly difficult, and sometimes almost impossible. In spite of using crutches, they feel severe pain in the sacral region, with stiffness in the lower limbs. In general, they are obliged to sit down, after making from ten to twelve steps. This exer-

cise frequently, by causing the two surfaces of the symphysis pubis to play against each other, produces an irritation of the tissues surrounding the urethra, and causes pressing and painful attempts at micturition. The ischia and ilia can also be felt with the hand to have an abnormal degree of mobility. If it be remembered, also, that the impediment to walking and standing commenced near the end of pregnancy, it becomes certain that the permanent relaxation of the pelvic symphyses is the cause of all the symptoms.

M. Martin has observed, that if the iliac bones be kept pressed against the sacrum, the power of walking is almost entirely restored. The apparatus which he uses consists of a large steel band, padded on the inside, embracing the whole circumference of the pelvis, passing over the external iliac fossæ, in the space between the crest of the ilium and the great trochanter. One lady, who could not walk twenty steps without being obliged to sit down twice or three times, was enabled in two days to walk about a large garden without aid.

It must be remembered, that the impediment is often trifling, and not always very easy to be recognised.

In one exceptional case, the band could not be left off. M. Martin advised the patient to wear it throughout her next pregnancy; and to remain in bed with it on for two months after her confinement. This was done; and in two years, she could easily walk a great distance without it. [*Bulletin Général de Thérapeutique*, as quoted in *Gazette Médicale*, July 26, 1851.]

DR. SAMUEL EDWARDS ON DYSMENORRHŒA.

In a paper communicated to the *Provincial Medical and Surgical Journal*, April 30, 1851, by Dr. Samuel Edwards, it is stated that dysmenorrhœa may be always found to depend on either—"1. A naturally contracted os, or cervix uteri, especially at its os internum; 2. A contracted or strictured condition of the passage through the neck of the uterus, from previous inflammation and ulceration; 3. Inflammatory congestion of the substance and lining membrane of the body or neck of the uterus, and sometimes of both, with or without ulceration, giving rise to temporary obstruction of the passage; or, 4. Obstruction of the passage from tumours, or other morbid growths."

Obstruction in some shape or other is looked on as an essential cause; but those who have inquired into the subject only superficially may be inclined to doubt this; for in some cases of dysmenorrhœa, room has been found to pass a bougie of moderate size. A case of this kind occurred to Dr. Edwards. The bougie passed readily on the first trial, but, on examining immediately before the expected period, the passage was found congested and swollen, so that the same bougie could not be made to pass, nor yet a much smaller one, without causing bleeding and much pain.

Dr. Edwards adduces cases illustrative of the various morbid causes above alluded to, and the results of what he considers the most successful modes of treatment. These include, with reference to the particular morbid condition, dilatation of the uterine passage with a bougie, probe, or catheter; scarification of the cervix (very seldom necessary) to relieve engorgement, followed by free pencilling with the solid caustic; insertion of a probe smeared with a mixture of caustic and extract of conium, combined with injection of alum and tannin, when rendered necessary by the presence of leucorrhœa; and the internal administration of blue-pill, henbane, and rhubarb-pill, or extract of colocynth, along with various forms of iron, quina, bitter infusion, strychnine, and muriatic acid, to combat dyspeptic symptoms, and restore the general health.

In one case treated by Mr. Paulson of Mansfield, in which intractable vomiting had been present for years, and unsuccessfully treated as an affec-

tion of the stomach, speedy relief both of the dysmenorrhœa and vomiting followed the dilatation of the cervix uteri with the bougie ; and the patient conceived for the first time. "The introduction of the probe," says Dr. Edwards, "acted as a stimulant, changing the perverted action of the mucous membrane, and promoted interstitial absorption, thereby diminishing the size of the cervix, and increasing the patency of the passage."

In another case, Dr. Edwards says: "There was no symptom which led me to infer uterine disease, and I looked upon it, in all probability, as one of a naturally contracted os and uterine passage, especially as she had been affected with the dysmenorrhœa from the first of her menstrual life. The speculum disclosed this to be a correct view. The vagina and cervix were healthy, but the os it was difficult to find, the only appearance of it being the merest depression; no probe that I could get would enter it in the slightest degree, with all the pressure I dare exert. Under these circumstances, a slight incision was made at the point mentioned, by means of a spear-shaped lancet, and I was then able to pass up a very small metallic bougie about half an inch. On April 26th, I again passed up the same bougie, and, after some little trouble, was able to introduce it up somewhat higher, viz.,—to the extent of nearly an inch. This operation was repeated every fourth or fifth day, with an increasing sized bougie, until the 15th of May, when menstruation again came on. It was attended this time with decidedly less pain; still it was considerable, but not so persistent. On May 22nd, I passed up a small sponge tent, but it produced so much pain that I was compelled to withdraw it. The bougies were consequently continued every three or four days, and kept in for ten minutes at a time, sometimes longer. On May 28th, I find it recorded that the whole of the uterine passage was larger, and that I could pass a small instrument at least two inches. On June the 10th, the catamenia again commenced; the pains were considerably lessened, and only lasted five or six hours. Her health was much improved. Up to August the 30th, the bougie has been occasionally employed; two periods have passed over with but trifling inconvenience, and she considers herself well."

The following observations, in reference to two other cases, the first occurring in his own, and the second in the practice of Dr. Wardell, are quoted at length, in consideration of their practical importance.

"The above case is clearly an illustration of the first cause; and the obstruction which existed both in the os and uterine passage, together with the result of treatment specially devoted to the overcoming of that defect, incontestably prove that in this case, at any rate, obstruction was the sole cause of the dysmenorrhœa. There was no disease in the passage, or any disorder of the general health, which could account for it; but on the obstruction being lessened, the pains were immediately diminished in severity. This was the first case which ever came under my notice, that required the use of any cutting instrument; but it was rendered necessary by the condition of the os uteri, which would not allow any probe which I had to enter it. After the enlargement of the uterine aperture, I was enabled to pass a small bougie half an inch, thereby showing that that was the narrowest part. Professor Simpson, of Edinburgh, informs me that he has long put on one side bougies and tents for the more potent means of incising the cervix uteri. I must confess that, theoretically, I am disposed to view the incision of the uterine passage as an operation of no very trifling importance, for two cases have been reported to me in which the operation had been performed; in one the hæmorrhage was extreme, and very alarming, in the other the incisions got well, and left the passage as impervious as before. To render incision successful, it does appear to me, therefore, that the bougie should be also had recourse to subsequently to the operation for some time, and therefore, on the score of the repetition of a delicate manipulation, the one is no better than the other; besides, it would be wise to anticipate a little, and reflect

how would this mutilated cervix and os dilate on the approach of labour, should the subject of the operation become pregnant! I have now treated very many cases of dysmenorrhœa successfully by means simply of the bougie, aided by the employment of caustic; and the success I have met with induces me to persevere in a plan that is not open to the objections which incision exhibits. This latter could only be applicable to cases arising from the first and second causes; for where disease exists in the uterine passage, it could only act as a temporary remedy. We must overcome, likewise, this disordered condition of the part, at the same time that a permanent passage is maintained; and this, my experience teaches me, is best obtained by the tent or bougie,—the latter of which I almost exclusively make use of,—the judicious application of caustic, and properly directed *general* treatment."

And again; Dr. Wardell's case "is an illustration of the second cause spoken of, viz., a contracted or strictured condition of the passage through the neck of the uterus, from previous inflammation or ulceration. Previous to the diseased condition of the womb, there was no dysmenorrhœa, but during the course of treatment it came on, and increased considerably after the ulceration was cured. The appearance of the os and its surrounding surface, induces one to ask,—How far the effect of the deep cauterization with the potassæ hydras may have been the cause of the contracted condition of the passage? My own impression is, that it was; and reasoning from its effects in other parts of the body, I think we are justified in the conclusion. I have applied the solid nitrate of silver around the cervix, and oftentimes up the uterine passage, without occasioning such a result in the slightest degree; and I take this opportunity of again repeating, (with considerably increased experience,) that which I urged in a paper read before the Provincial Medical and Surgical Association, at Bristol in 1847, and which was printed in the *Journal* of September 8th of that year, viz., 'in the generality of cases that have occurred to me, the nitrate of silver has answered all the purposes of an efficient caustic, and that I cannot but view the actual cautery, the Vienna paste, the pernitrate and acid nitrate of mercury, as well as nitric acid applications, as of too violent a character for ordinary use to that portion of the body.' Since that time I have never met with a single case of ulceration, engorgement, or induration of the uterus, that I have not overcome by means of the lancet, *lunar caustic*, and last, but decidedly not least, by *general* treatment. I am convinced that by some practitioners on uterine diseases in the present day, too narrow a view is taken of them; the diseased womb is looked upon as if it were isolated from the rest of the body,—as if it had no connections—no sympathies. The fact is too often lost sight of, that its morbid states may be, and I believe often are, the result of a morbid condition of the general system. The adoption of specialities at the present time, however valuable in some respects, has an injurious tendency in others. A physician who has directed his attention exclusively to diseases of a particular part, or who has chained himself down to one particular mode of investigation, is often apt, as I remarked before, to take too narrow a view of disease; and when general symptoms exist in the patient who applies to him, which he cannot well account for, from his limited practical knowledge, he is led unconsciously to distort them to his purpose, and fixes upon his "hobby-horse" (whatever it may be) as the seat of his patient's malady. The local disease is consequently attacked, whilst the depraved state of the system, which frequently gives rise to it, is neglected. Simple ulceration of the womb is, I am more and more satisfied, oftentimes an effect of a disordered condition of the general system, and should be met equally by general remedies, as by the application of local ones; the judicious adoption of the former will occasionally obviate the necessity of the latter, and when this is indispensable, the *general* treatment will generally shorten the period of the requirement of the *local*."

RETENTION OF THE CATAMENIA—DEATH FROM EFFUSION INTO THE PERITONEUM THROUGH THE FALLOPIAN TUBES.

Drs. Marchand and Massé relate the following case in the *Journal de Médecine de la Loire-Inferieure*, tome xxvi, Nos. 131 and 132. We quote it from the *Archives Générales de Médecine* for July 1851.

Case. A young woman, aged twenty-two, who had never menstruated, had suffered since the age of thirteen or fourteen from pains in the hypogastrium and loins. The pains recurred each month at the same period, and continued three or four days. During some years the abdomen had been tense, and, for some time, the enlargement and the pain had gradually and considerably increased: the general health was however very good. On examination, it was ascertained that the external orifice of the vagina was closed by a membrane, behind which the menstrual fluid was retained. This membrane was laid open by a crucial incision; and, after some blood had been forcibly ejected to some distance, there escaped two or three quarts of a black inodorous fluid, without clots. Compression was made on the abdomen. For three days, the menstrual fluid continued to escape without pain, to the amount of four or five quarts: the abdomen diminished in size, and the patient seemed to be going on well, when she was seized, on the fifth day, with subacute peritonitis, of which she died nine days after the operation.

Autopsy. The whole of the peritoneum beneath the transversalis muscle was in a state of inflammation. The convolutions of the intestines, slightly adherent to each other, were covered with false membranes, the serous membrane beneath being of a deep red colour, especially in the vicinity of the pelvis, where, and in the iliac fossæ, there was some pus or sero-purulent fluid. The uterus was longer than natural, about the size of a fist; the cavity of the neck was also dilated. The vagina was enormously dilated, especially towards the upper portion. The vaginal and uterine mucous membrane were tinged with blood. The Fallopian tubes presented different appearances in their uterine and in their ovarian portions. The uterine part was normal; while the ovarian or abdominal end was distended with black blood, and resembled a varicose vein of the size, at least, of the little finger. The dark blood which they contained was very fluid, and could be very easily pressed out in drops through the fimbriated end of the tube. There were some drops of the dark blood on the portions of the peritoneum in contact with the Fallopian tubes; and at these points were the most evident traces of peritonitis.

MATERIA MEDICA AND PHARMACY.

MUCILAGE OF PINUS BALSAMIA.

Dr. Cleveland, in a paper (*New York Register*, Sept. 1, 1851) on the American indigenous plants yielding mucilage, remarks: "The twigs of the fir balsam, when of but one or two years' growth, contain a large amount of mucilage, which, as it is combined with the balsam, is superior to that obtained from other sources for pectoral complaints, and those of the kidneys, bladder, or urinary passages, or of the stomach, as well as gleet, leucorrhœa, etc. This is to be prepared by selecting the extremities of the limbs of young trees, and after carefully stripping off all the leaves, the bark is to be separated from the wood, and steeped in hot or cold water."

CANTHARADINE OINTMENT.

This may be prepared by rubbing together equal parts of the ethereal solution and lard or mutton suet. Frictions made with this ointment induce vesication in a few hours. It is much used in Prussia.

Mr. Trant in the Chair.

Case of Gout in the Stomach treated by the Internal Administration of Ether and Chloroform. By Charles E. Bagot, M.D. The patient was T. Ll——, Esq., aged 42, formerly an officer in Her Majesty's service. He was rather a small man, very thin, and of a nervous temperament. His constitution was delicate, and probably somewhat impaired by hardships encountered whilst stationed in Canada. About two years previous to this illness, he had had a slight attack of gout in one of his feet, and since that period he had passed rather a slothful life.

He was lying on his left side, with his knees drawn up, suffering from pain referred to the epigastrium and cardiac region. There was great tenderness on pressure over the seat of the pain, also considerable hardness, exactly corresponding to the position of the stomach; the intense agony under which he laboured was of the true spasmodic character met with in cases of gout attacking this organ, a certain amount of pain being constant, with a violent spasm recurring at short intervals. He had frequent vomiting, also several attacks of chill, none of which amounted to a rigor, and he also complained of slight cramps in the hands and legs. He was restless, with cold surface; pulse 60, small and weak; tongue clean, and perfectly cold. He had been confined to bed the previous day with gout in his knee; his suffering had not been very severe, and he had, at eleven o'clock at night, partaken of a red herring and a glass of hot punch, after which he had fallen into a sound sleep, which continued up to six in the morning. At that hour he awoke in violent agony, and immediately discharged the contents of his stomach; the pain in the knee-joint having entirely disappeared. Dr. Bagot saw him at nine a.m., three hours from the commencement of the attack, at which time it would be difficult to imagine anything more unpromising than his case.

Dr. Bagot covered the abdomen with sinapisms, and had his legs and feet rolled up in large pieces of flannel wrung out of hot water, containing a quantity of mustard and salt, which were frequently renewed. He immediately administered eighty drops of tincture of opium, with a drachm of ether; but not finding the slightest relief afforded by the laudanum, he substituted chloroform in combination with the ether. He considered that the terchloride of formyle would have an advantage, from its being not only antispasmodic, but also stimulating and diaphoretic. The most marked relief followed its exhibition. For three hours this mode of treatment was followed, at the end of which time signs of reaction appeared. The dose of ether having been from half a drachm to a drachm, and that of chloroform from twelve to eighteen drops, a close approximation to the entire quantity of each would be ʒx of ether and ℈vij of chloroform. During this time his thirst was very great, and he took frequent draughts of cold water, which seemed to accumulate in his stomach, and be thrown off at intervals, this vomiting not being attended with either an increase or diminution of the pain, and not followed by any particular exhaustion. As soon as reaction had fairly set in, he administered two terebinthinate enemata, which came away without any fæces. At three o'clock reaction, which had been very slow, was fully established, his body having become warm, and his tongue much nearer to a natural temperature, though yet rather cool. The pain in the stomach was much relieved, but the vomiting was now more troublesome, and his

thirst very great; he was also much annoyed by windy eructations; the hardness in the region of the stomach was persistent; pulse fuller. A grain of calomel, rubbed up with a little white sugar, was now given every half hour. At six o'clock, the vomiting had in a great measure subsided, a little warm whey having remained on his stomach. He was also freer from pain than he had been at three p.m.; pulse as before, 60 in a minute, and fuller. The calomel was continued every hour. At eleven p.m., he was much better; his bowels were well acted on. The calomel was continued at intervals of three hours; and sinapism was applied on the epigastrium, and his feet kept hot through the night. He gradually recovered, the gout appearing again in the same knee next day but one, where it continued to give considerable pain for about thirty hours. A little dull pain continued for a day or two in the epigastrium, but the hardness remained for some time, and disappeared very gradually.

April 19, 1851.

Mr. Trant in the Chair.

Case of Disease of the Head of the Tibia. By Dr. Nolan. The patient was a girl, aged about 17 or 18, on whom Dr. Nolan performed amputation. The diseased part consisted of large cells, about an inch in diameter, filled with bloody fluid. The disease extended into the interior of the tibia and all round it; the fibula was beginning to be affected, and a few inches above the ankle, on the front of the tibia, a tumour, about the size of a nutmeg, was seen, the disease beginning there also; the knee-joint and cartilages were all of a yellowish hue; the capsular ligament was thickened and yellowish, and the synovial fluid red, and the fluid in the bursæ around the joint of the same character as that in the tumour. The shaft of the femur seemed healthy, as well as the muscular structures.

Case of Ligature of the External Iliac Artery. By Charles Halpin, M.D. Private M. M., a hatter by trade, aged 21, belonging to the 35th regiment, was admitted to detachment hospital on the 13th of August, 1850. He was labouring under gonorrhœa virulenta, with bubo in the right groin. There was also an ulcer on the dorsum of the glans penis. He had been ailing between four and five days. A poultice was applied to the groin, and solution of nitras argenti to the sore on the penis, and he was ordered ʒj of sulphate of magnesia, with one-sixth of a grain of tartrate of antimony three times daily. He was treated by mercurials and opium, and subsequently by quinine, up to September 10, when he appeared almost fit for discharge. At nine p.m., he had a smart hæmorrhage from a fistulous point of the ulcer in the groin. A compress of lint, with moderate pressure, arrested it completely.

Sept. 11*th*. In the evening, about an ounce of blood came away.

Sept. 12*th*. At half-past twelve p.m. considerable hæmorrhage set in, evidently from the femoral artery; it gushed out with extreme violence on removing the compress. In consultation with Dr. Roe, it was decided to put a ligature on the external iliac artery; but this proceeding was deferred until four p.m. In the interim, the bleeding was repressed by a firm compress, retained by relays of men, who relieved each other at intervals. A semilunar incision was made above, in the direction of Poupart's ligament; a ligature was placed on the external iliac, about two inches above Poupart's ligament; the slight make of the patient, and the empty condition of his bowels, favoured the operation, which was performed in about three minutes. There was not half an ounce of blood lost. All hæmorrhage ceased instantly, as did all pulsation in the limb; the leg was wrapped in warm flannel. At six p.m., the limb had recovered its temperature; slight smarting pain in the track of the incision. He had an anodyne draught at bed-time.

Sept. 14*th*. About an ounce of venous blood came away from the site of the bubo about two a.m. He had some pain along the course of the vessels as far as the knee.

Sept. 15*th*. After having passed a quiet night, at twenty minutes past five A.M., about six ounces of venous blood came away from the site of the bubo ; the bleeding ceased spontaneously, but recurred about twelve hours afterwards, to the extent of ten ounces, and ceased as before.

Sept. 16*th*. Forty-five minutes past two P.M. Hæmorrhage having returned, Drs. Roe and Halpin opened a tumour that had formed, within the last twelve hours, in connexion with the bubo and site of the hæmorrhage, and a large quantity of coagulum turned out. A considerable discharge of blood took place, apparently from the point at which the profunda femoris is given off. From the sloughy condition of the parts, it was impracticable to apply a ligature ; a compress of sponge, etc., was applied, which controlled the bleeding. The pulse was rapid and tremulous ; about thirty ounces of blood, it was estimated, were lost this day.

Sept. 20*th*. Hæmorrhage, evidently arterial, occurred at ten A.M. All dressings were removed ; the bleeding, which had ceased, proceeded apparently from the site of the ligature ; he complained of *intense pain* along the inner side of the thigh and leg. He died at two P.M., hæmorrhage having returned a few minutes previously.

A *post-mortem* examination was made on the 21st of September, nineteen hours after death. The peritoneum, which had not been wounded in the operation, was found adherent to the cæcum ; it was easily torn in separating it from this part. The artery was exposed from the bifurcation of the aorta to the middle of the thigh. The ligature applied to the external iliac was retained by some portion of the external coat only ; the artery had not been disturbed to a greater extent than permitted the needle to pass under and between it and the vein. About two inches below Poupart's ligament, there was an *aneurism* of the femoral artery, capable of containing a small chestnut. The origin of the profunda femoris was implicated in this aneurism. The femoral vein was destroyed for about three inches of its course, below Poupart's ligament. The ulceration connected with the bubo, reaching the aneurismal sac, eroding its coats, originated the hæmorrhage on the 10th instant, which terminated in the death of the patient on the 20th ; but the blood which came away on the 14th, 15th, and 16th, and which had all the character of venous blood, probably descended through the iliac vein, and escaped by the femoral vein, which had been destroyed by ulceration.

Remarkable Case of Biliary Calculus. By Dr. Benson. The calculus was four inches and a half in circumference, and in the lesser size three inches and a half. It was altogether the size of a walnut, and had passed through the rectum of a man aged 56.

Strangulated Femoral Hernia. By Mr. Ellis. The patient, a female, aged 60, of delicate constitution, who had had several children, was admitted into Jervis-street Hospital, on Friday, March 2nd. She had suffered from reducible hernia for several years. The strangulation had existed from the previous Tuesday, and the symptoms were not those of acute strangulation. The tumour was oval, elastic in the centre, and œdematous at its circumference; there was pain at the epigastrium; not much thirst; occasional vomiting of bilious matter; the abdomen was not much tumefied, nor very tender on pressure. The taxis, ice, and enemata, were tried without effect. The operation was therefore determined on. It was commenced by an incision of an L shape. The superficial fascia was thin; there was no fascia propria; the sac was so thin, that the omentum could be seen through it. No fluid escaped on incising the sac. The omentum adhered to the sac, and its under surface adhered to a knuckle of intestine. The stricture at Gimbernat's ligament was so tight, that the nail could not be introduced; and it required a good deal of force to pass the director, on which the bistoury was introduced, and the stricture divided. On passing in the finger, a band was then felt, which was divided, and the intestine was returned without any

difficulty; after the adhesions were broken up, the omentum was also returned.

Very little alteration in the symptoms took place after the operation. There was no action from the bowels, On Sunday morning, there were symptoms of sinking; and the patient died at six o'clock that evening, fifty-two hours after the operation.

On a *post-mortem* examination, the omentum was found to be adherent to be adherent to the peritoneum of the anterior wall of the abdomen; the knuckle of intestine then came into view, which had protruded through a well-defined circular hole in the omentum, and was *there* strangulated.

Cases of Strangulated Hernia. By Dr. Macdonnell. Dr. Macdonnell related the heads of a case of this kind, in which he had operated three or four months since in the Richmond Hospital. Dr. M. was sent for at a late hour to see the patient, whom he found labouring under severe symptoms of strangulation. There was a large, very tense, and painful scrotal hernia; an old reducible hernia having become strangulated about forty-eight hours before. There was a sunken expression of countenance, frequent vomiting, hiccup, small and rapid pulse, tympanitic and tender abdomen, and constipation since the strangulation. The taxis having been already perseveringly tried without success, he proceeded to operate. Nothing worthy of note occurred till the sac was opened. It contained nearly a foot of tensely distended small intestine. A stricture was discovered, and divided at the situation of the internal abdominal ring. To his great surprise, he found that he could not return the intestine. The stricture was then dilated, so as to permit the forefinger to pass freely into the cavity of the abdomen. Still every effort to return the intestine *en masse*, piece by piece, or even to empty the contents of the intestine, completely failed. Finally, the attempt at reduction was given up, under the impression that the intestine was still strictured by some internal band beyond the reach of the finger. The patient died within twenty-four hours after the operation; and, on examination, the explanation of the above-mentioned singular circumstance was found in the fact, that the intestine had been turned round and round on itself, so as completely to obliterate its calibre at the internal abdominal ring. This accounted for the impossibility of emptying the intestine of its contents, and showed that, without untwisting it, the intestine could only have been returned *en masse*, which would have required, such was the quantity and distension of the protruded part, an opening several inches wide.

MISCELLANEOUS INTELLIGENCE.

Dr. Cormack's Letter on Homœopathy, to the Provincial Association. In our last number, we inserted full reports of the speeches delivered at Brighton, upon the occasion of the unanimous repudiation of the present prevailing professional laxity and charlatanry, in connexion with the homœopathic quackery. We had not then room for Dr. Cormack's letter; by the publication of which the course of action so cordially adopted was first definitely suggested. The letter originally appeared in the *Provincial Medical and Surgical Journal* for 6th August, and was also published as a pamphlet, with additional matter, in the form of an appendix. The pamphlet is out of print.

"Our Relations with Homœopathy. *To the Editor of the Provincial Medical and Surgical Journal.* Putney, July 29, 1851. Sir,—While, with you, I recognise the greatness of the benefit conferred on legitimate medicine by the recent acts of the Scottish Colleges, I cannot help feeling that we ought to do more than, as individuals, yield to them our concurrence and applause. We ought not, I think, to allow our annual meeting at Brighton to pass without issuing a deliverance upon the subject of homœo-

pathy, as explicit as those which have come to us from beyond the Tweed ; and there is one point upon which it appears to me that even more plainness of expression is required.

"To adopt resolutions setting forth that the homœopathic dogma and the doctrine of infinitesimal doses have no truthful basis, and are, in fact, mere nonsensical delusions, may be quite proper, inasmuch as some honest but weak and undisciplined minds have been seduced by the hardy assertions and false reasoning by which these errors have been supported. But something more is required, if it be true, as I think it is, that this fashionable quackery is so susceptible of adaptation to the most contradictory prejudices of shallow men and women, as to have become a sort of Protean deceit, able to lure lucre by every imaginable wile from the sick and the silly. The worst part of homœopathy is, in my opinion, the DISHONESTY of the majority of those who live by it. When patients are once secured, they are, I think, very rarely treated in accordance with the principles of Hahnemann ; but are retained by the combination of every current medical novelty which may at the time be most in favour with the moneyed throng of quack-fanciers. I have not been able to hear of any one who honestly relies on homœopathy for the cure of disease ; but I can point to many calling themselves homœopathic practitioners, who attempt to relieve the symptoms of disease by the same means which we would adopt, and to others, who retain their *clientelle* fully as much by practising hydropathy, Mesmerism, and miscellaneous tricks, as by giving the globules. If homœopathy were honestly practised, it might be amicably dealt with ; but as it is truly a combination of any and every available charlatanic trick, it cannot be effectively opposed as a distinct medical heresy, and therefore all that remains for us, as men of science and men of integrity, is to give notice, that we exclude from all professional intercourse practitioners who are in any way engaged in using or upholding a system which we think bears upon its very face fraud as well as absurdity.

"I have heard it urged in extenuation of the fall of some medical men, that they had large starving families, and that they had met with distressing pecuniary reverses. It has often been said to me that if they treated disease to the best of their ability, there was no great crime in their sailing so far with the fashionable current as to call themselves homœopathic, and to give globules as placebos. From my heart I compassionate these persons ; for I know that want has distorted and destroyed the moral sense even in good men ; but, while in some cases we pardon the transgressors, let us not be tolerant of the transgression. It behoves us, quickly and decidedly, to draw a broad line between medicine and homœopathy, so as to encourage and strengthen the hands of many in our impoverished and overstocked profession, who, though tempted, have not yet bartered principle for pelf.

"The Provincial Medical and Surgical Association has now the power, and the near opportunity, of drawing this much-needed line of demarcation :— *Let the Association declare that the names of homœopathic practitioners and of those who hold professional intercourse with them, cannot be on its list of members.* The promulgation of this law would enlighten the public. It would also deter some too-facile consulting physicians from meeting the homœopathic quacks "simply for diagnosis"; and it would make it impossible for operating surgeons to say they did not mean to insult the profession, "that they only went to give a surgical opinion" or "perform an operation". When it is known that such unworthy proceedings are of daily occurrence in London ; and when we see Fellows of our metropolitan Colleges eagerly seeking as the patrons of their hospitals Lord Carlisle, Lord Robert Grosvenor, and other noblemen who are notorious abettors of homœopathic charities, is it wonderful that the public mind has become poisoned, and unable to discriminate between legitimate medicine and fraudulent practice ? When we see Fellows of both London Colleges so demeaning themselves, how

can the colleges serve the cause of truth? In these circumstances, it is doubly the duty of our great Association to come forward; and when we meet at Brighton, let the fact of membership be made a more distinctive test of professional morality than any now existing out of Scotland. I am, Sir, your obedient servant, JOHN ROSE CORMACK."

HOMŒOPATHIC REJOINDER TO THE BRIGHTON RESOLUTIONS. "ASSOCIATION FOR THE PROTECTION OF HOMŒOPATHIC STUDENTS AND PRACTITIONERS. At a meeting of the committee, held on the 1st of September, in consequence of the recently published resolutions of the Provincial Medical and Surgical Association, and other allopathic bodies, regarding homœopathy, it was resolved,

"1. That homœopathy is thoroughly reconcileable with science and common sense, is in accordance with the experience of some thousands of medical men, and deserves the study of practitioners and the confidence of the public.

"2. That the framers of the hostile resolutions referred to, and other prejudiced opponents, are totally ignorant of homœopathy, avowedly refusing to study its principles (in the writings of Hahnemann and others), and to witness its practice in the homœopathic hospitals and dispensaries, to which they have been repeatedly and cordially invited.

"3. That, notwithstanding the difference in their treatment of disease, there can be nothing derogatory in homœopathists and allopathists (equals in education, science, and social position) consulting together at the request of patients and their friends as to the nature of the malady.

"4. That the resolutions of the Provincial Medical and Surgical Association, representing, as they do, the opinions of only a small fraction of the allopathic body, are in themselves, and for the reasons given above, utterly valueless.

"WM. MACDONALD, M.D., F.R.C. P.E., Professor of Civil and Natural History in the University of St. Andrew's.
JAMES CHAPMAN, M.A., Cantab. M.D.
EDWARD HAMILTON, M.D., F.L.S.
DAVID WILSON, L.R C.S.E.
THOMAS SEADAM, M.R.C.S.
ROBERT E. DUDGEON, M.D., Secretary.

82, Glocester-place, Portman-square, London, Sept. 1, 1851."

THE BRIGHTON RESOLUTIONS, of which the above is a parody, we subjoin for the sake of comparision.

1. That it is the opinion of this Association, that homœopathy as propounded by Hahnemann, and practised by his followers, is so utterly opposed to science and common sense, as well as so completely at variance with the experience of the Medical Profession, that it ought to be in no way or degree practised or countenanced by any regularly educated medical practitioner.
2. That homœopathic practitioners, through the press, the platform, and the pulpit, have endeavoured to heap contempt upon the practice of Medicine and Surgery as followed by members of this Association, and by the profession at large.
3. That for these reasons it is derogatory to the honour of members of this Association to hold any kind of professional intercourse with homœopathic practitioners.
4. That there are three classes of practitioners who ought not to be members of this Association, viz.—1st, real homœopathic practitioners; 2nd, those who practise homœopathy in combination with other systems of treatment; and 3rd, those who under various pretences meet

in consultation, or hold professional intercourse with those who practise homœopathy.

5. That a Committee of seven be appointed to frame laws in accordance with these Resolutions, to be submitted to the next annual meeting of the Association.
6. That the thanks of the Association are eminently due and are hereby given to the Presidents and Fellows of the Royal Colleges of Physicians and of Surgeons of Edinburgh, for their determined stand against homœopathic delusions and impostures.
7. That the thanks of the Association are also due and are hereby given to the Universities of Edinburgh and St. Andrew's, for their resolution to refuse their diplomas to practitioners of homœopathy; but the Association feels imperatively called on to express its disapproval of any School of Medicine which retains among its teachers any one who holds homœopathic opinions.
8. That these Resolutions be printed, and transmitted to all the Medical Licensing Bodies and Medical Schools in the United Kingdom; and that they likewise be inserted in the *Times* newspaper, the *Morning Post*, the *North British Advertiser*, *Saunders's News Letter*, all the British and Irish Medical Periodicals, and in such other Journals as the Council may sanction upon the recommendation of the Branch Associations.

Homœopathy Repudiated in Guernsey, and the Resolutions of the Provincial Medical and Surgical Association Approved. *To the Editor of the Lancet*, Sir,—The inclosed has been sent to the Committee on Irregular Practice of the Provincial Medical and Surgical Association. It is far too important a document to be merely laid before a few individuals, and presented twelve months hence at the next general meeting of our Association. Looking at the signatures attached to this address, I feel, therefore, that it is my duty, not only to communicate it to my colleagues in the committee, but to request the favour of your publishing it to the profession in the pages of the *Lancet*. Allow me to add, that since the Brighton meeting I have received upwards of a hundred letters, approving very heartily of the course then adopted in describing the three classes of practitioners who ought not to be allowed to be members of our Society. I entertain the hope that other bodies will act in a similar manner; and that, ere another year has elapsed, there may be a broad line drawn between homœopathic charlatanry and rational medicine. I am, Sir, your obedient servant,

Putney, Sept. 13, 1851. John Rose Cormack, M.D.

The following is the communication referred to by Dr. Cormack:—

"*To the Committee on Irregular Practice of the Provincial Medical and Surgical Association.*

"Guernsey, Sept. 10, 1851.

"Gentlemen,—We, the undersigned medical practitioners of the island of Guernsey, beg to offer our warm congratulations and sincere thanks to the Provincial Medical and Surgical Association in general, and to you, as their Committee, in particular, for the manly and straightforward Resolutions unanimously adopted at a meeting of that body held at Brighton on the 14th ultimo.

"We likewise desire to express our cordial approval of the uncompromising tone of the speeches delivered on that occasion, when, in our humble opinion, the principles of truth, honesty, and morality, were enunciated, the science of medicine vindicated, and the injurious tendency of homœopathy—its hollowness, absurdity, and dishonesty—demonstrated by clear, comprehensive, and irrefragable facts.

"We would fain hope that the dignified manner in which the Association has responded to the movement of the Universities of Edinburgh and St.

Andrew's, to expose and discard homœopaths, will be followed by the English and Irish Colleges, and thus enable the United Kingdom to set as bright an example in checking error and upholding truth in medicine, as it has recently done in religion.

"We derive additional satisfaction in addressing the Provincial Medical and Surgical Association, from having throughout firmly, advisedly, and conscientiously resisted all attempts to induce us to hold intercourse with homœopathic practitioners, or to countenance a system, the offspring of quackery, the refuge of imposture, and the nursling of dupes.

"We now calmly await the course of events, satisfied that truth and honesty will prevail, and that homœopaths, who seek to be considered as regular practitioners, and pertinaciously shelter themselves under the *ægis* of medical institutions, will ultimately be exposed and repudiated.

"We have the honour to be, gentlemen, your obedient servants,

"John Mauger, M.R.C.S.Eng.

J. Baines, M.R.C.S.Eng."

Dr. J. Y. Simpson and Mesmerism. *To the Editor of The Lancet.* Sir,—During the last few months, I have been more than once, directly or indirectly, alluded to in your leading and other articles in tones of reprehension, and have been broadly accused of committing professional faults which I never committed, and of holding opinions which I never held.

Sometimes your editorial accusations have been in the form of extracts from the writings of others; sometimes they have consisted of observations offered by yourself.[1] I have not of late answered any of these accusations, partly because the task of doing so is always a disagreeable task, and partly because I fear and feel that I am getting too old and callous to care about such things.

In your journal of Saturday last, there is a renewed attack upon me in an editorial article, in which I am held up by you as a believer in animal magnetism; and, at the urgent request of an esteemed London medical friend,

[1] Thus, for example, two or three months ago, you stated, in one of your editorial articles, that an Edinburgh physician (and the allusion was intended to apply to me) had come up from Edinburgh as far as London, to hold a consultation with a homœopathist physician at Brighton, but that I found professional feeling so "hot" upon the subject, that I wisely returned. So far was this from being the fact, that I wrote from Edinburgh immediately on receiving the letter from Brighton, and stated that I was engaged to visit professionally, as soon as I could possibly leave Edinburgh, two chronic cases, the one in London and the other in Paris; that I would thus pass and re-pass near to Brighton, but that I could not meet the practitioner, as he was known to be a homœopathist. Let me add, that I believe professional opinion is "hotter", and in a healthier state upon this subject in Edinburgh than in London. When in London, on the occasion referred to, I was told by one of your first surgeons, that he was attending the foot of a noble duke, whilst a celebrated homœopathist was attending to his grace's stomach and constitution.

Whatever laxity may have existed on the question, here or elsewhere, in past times, there exists none now in Edinburgh, since the Colleges have taken up the subject, and pronounced upon it.

upon whose judgment I place very great reliance, I at last unwillingly take up my pen to say that, on this, as on various other former occasions, your accusation is erroneous.

I do not believe, and never did believe, in animal magnetism. During the last ten or fifteen years, I have repeatedly seen experiments made upon the subject, and I have repeatedly made them myself. In the course of them, I have witnessed very interesting physiological and psychological results, such as the production of deep sleep, fixture and rigidity of muscles, lesions and perversions of sense, etc.: but I have no belief whatever that these effects are the effects of any power, force, agency, or entity, such as is understood by the term animal magnetism, passing from the so-called "Mesmeriser" to the so-called "Mesmerised". On the contrary, these experiments have firmly convinced me, as they have convinced others who have seen them, that these, and other phenomena of the like kind, are merely effects produced by the mind of the "Mesmerised" upon his or her own economy; that they are only self-mental acts, if I may so speak, and that they are as independent of any "Mesmeric" influence as are the phenomena of common sleep, or common dreaming, or common hysteria.

If you, or any of your readers, have, perchance, any desire to know more explicitly my opinions on the subject, you will find them stated at greater length in the May number of the *Monthly Journal of Medical Science*, in a discussion on the subject of "Electro-Biology", before the Edinburgh Medico-Chirurgical Society. In that report it is, *inter alia*, mentioned, that (to quote the words of the report) "Dr. Simpson stated that he totally disbelieved in any of the so-called higher phenomena of animal magnetism,—as lucidity, transference of the senses, clairvoyance, etc. If a person could see with the tips of his fingers, or the pit of his stomach, as was averred, it would be an enormous fact, and would require an enormous amount of proof to substantiate it as a fact. But the evidence adduced was generally of a very imperfect kind, and melted down before accurate inquiry. He had such a conviction of this, that he offered to place in the President's hands £100, which he would give to Dr. Macdonald for the scheme for which he (Dr. M.) was lecturing, if Dr. Macdonald could bring any clairvoyant who could read a line of Shakspeare, or two or three words out of the dictionary, which Dr. S. would shut up in a box. If there was any truth in clairvoyance, why should not a clairvoyant be able to gain for Dr. Macdonald this sum of money." (*Monthly Journal* for May, p. 487.)

Now, to show you the sincerity of my belief, let me put this same proposition in another shape: I will, if you will allow me, place five such boxes or packets (each of them containing a line of Shakspeare) in your hands, and in the hands of a small committee of medical men, whom you and I shall conjointly agree upon, and who with you, shall be judges, and make all the necessary arrangements; and I now offer, through you, £500, for the reading of these included five lines by any clairvoyant. Further, as my pen is in my hand, let me name at once, on my part, your fellow-citizens, Dr. Sharpey, Dr. Locock, Dr. Williams, Dr. Todd, and Dr. Carpenter, or any two or more of them, to adjudge the matter with an equal number named by you.

Perhaps you will agree with me in thinking, that in settling a question of this nature, such a test and trial is better than any other five hundred arguments. Yours, etc., J. Y. Simpson.

Queen-street, Edinburgh, Sept. 15, 1851.

P.S. Is it necessary, after the preceding statement, to add, that you are again in error in reference to the miscalled "Mesmeric soirées". The object of the experiments comprised in this designation is to show, that many striking effects can be produced by the influence of the will of an individual, acting on another, independently of any magnetic, Mesmeric, or other supposed agency. These experiments are, therefore, directly and entirely opposed to the so-called doctrines of "Mesmerism".

Homœopathy at Manchester. The following paragraph we quote from the *Manchester Guardian* of September 20. We learn from various sources, that the profession in Manchester is distinguished for its uncompromising opposition, not only to homœopathy, but also to all other forms of unprofessional conduct. The false gloss put on some facts, and the misstatement of others, by the *Guardian*, is worthy of notice. We would also call attention to the great muster of parsons in the list of quack-fanciers. The clergy have always been famous for their support of charlatans. Old Burton wrote, about a century ago—"Many poor country vicars, for want of other means, are driven to their shifts—to turn mountebanks, quacksalvers, and empirics."

The following is the paragraph from the *Manchester Guardian:* "Homœopathic Students and the Medical Colleges. On Thursday morning, a meeting was held at the Homœopathic Institution, Bloom-street, to form a society for the protection of homœopathic students and practitioners against the proceedings of the medical colleges, which have lately refused to grant diplomas to students proposing to adopt the homœopathic practice, or have demanded the return of diplomas already granted, by practitioners who have adopted that mode of treatment. There were about thirty gentlemen present, and the chair was taken by Mr. W. R. Johnson. Mr. Phillips, M.R.C.S., in explaining the reason for which the meeting had been called, said that homœopathy first came prominently before the public in 1844, when Dr. Henderson, a professor of the University of Edinburgh, was led to investigate it, in order that he might be able to expose its fallacy. Instead, however, of finding it a system of quackery, as he had expected, he became convinced of its truth. About the beginning of the present year, the College of Physicians of Edinburgh, spurred on by the *Lancet*, a paper noted for the abusiveness of its language, had passed resolutions condemnatory of the practice of homœopathy. The University of St. Andrew's, too, stirred up by the same journal, had appeared in the field. Dr. Hale, of Norwich, had passed his examination, and received a degree from that university. By and bye, it came to the knowledge of some members of the university that Dr. Hale was practising homœopathy, and the return of his diploma was demanded by the senate. Dr. Hale did not return his diploma; but the ill-feeling excited against him by other professional men in Norwich, had compelled him to leave that town. The next case was that of Mr. Pope, who applied in April or May last for a degree from the University of Edinburgh. He had passed his examination with credit, when he was asked by Dr. Christison whether it was true that he intended to practise homœopathy. Mr. Pope replied that he intended to investigate that mode of practice, as he was not convinced whether it was or was not based on true science. His degree was refused to him, unless he became convinced of the falsehood of homœopathy. The *Lancet* had also succeeded in causing steps to be taken against homœopathy, which more immediately concerned the practitioners of Manchester. Within the last week or two, the Provincial Medical Society had passed resolutions condemnatory of the practice of homœopathy, and the surgeons had adopted them within the last week. The Medico-ethical Society of Manchester, too, had enlisted themselves in the cause, having addressed a memorial to the council of the Royal College of Surgeons, praying that the names of all members practising homœopathy, should be at once erased from the lists of the College. Under these circumstances, the homœopathic practitioners of Manchester thought that it was time that something should be done, and that they should protest against the steps taken to put them down. He moved—

"'That this meeting views with regret the course adopted by the colleges and other bodies to put down homœopathy, and denies and protests against the right of any corporate body or association constituting but a minority of the medical profession, to dictate to others what course of treatment should be adopted in their practice.'

"Mr. W. Armitage seconded the resolution, contending that, if there were free trade in food, there ought also to be free trade in physic.—The Rev. Mr. Durnford supported the resolution, which was unanimously agreed to.—Dr. Walker contended that homœopathists must obtain a royal charter or a legal enactment to put them on a level in the eyes of the public with their allopathic enemies. He moved—

"'That the course pursued by the universities, etc., towards homœopathic practitioners and students of medicine leaves them no other means of redress than the seeking to obtain a charter of incorporation of a college, which shall be empowered to confer degrees, and grant licenses to practise medicine.' It was seconded by Mr. Henry Dixon, and unanimously adopted.—Mr. W. P. Harrison, M.R.C.S.E., characterised the proceedings of the medical colleges as arbitrary and tyrannical, and moved—

'"That a branch of the General Association for the protection of Homœopathic Students and Practitioners be herewith organised, and that the following gentlemen be requested to act as a committee, with power to add to their number:—Mr. E. Phillips, M.R.C.S., chairman of committee; Dr. Robert Walker, L.R.C.S., Ed.; Dr. J. M'Dowall; Mr. W. P. Harrison, M.R.C.S.L.A.C.; Mr. W. Scholefield, M.R.C.S.; Mr. C. C. Tuckey, M.B.M.R.C.S.J.; Dr. Knowles, Mr. A. Pope, Mr. W. R. Johnson, Mr. G. Wildes, Rev. R. Durnford, Rev. Canon Slade, Rev. R. Fletcher, Ald. J. J. Parker, Rev. J. Gwyther, Rev. C. F. Smith, Rev. A. A. Bagshawe, Mr. W. M'Call.' Mr. C. C. Tuckey seconded the resolution.—The chairman, in putting it, stated that an association had been formed in London for the purpose of taking up this question in a firm and proper manner, which would no doubt terminate in the obtaining of a charter for a college, and that the society to be formed here was intended to act in conjunction with it. The resolution was unanimously agreed to, after which thanks were voted to the chairman, and the proceedings terminated."

[The steps now being taken to purge the medical profession from impostors, may probably give temporary buoyancy to quackery by the pretext which it affords for the raising of a mock cry of "persecution"; but let us remember that the question with us as honest men is, *not one of policy but of principle;* and that we must, at all hazards, make it impossible for the public to confound regular practitioners with quacks, even though disguised by diplomas obtained or retained by illegitimate means. Ed. Lond. J. Med.]

Homœopathy in High Places. It appears that Sir James Clark and Dr. Locock, (like many other orthodox physicians,) prescribe belladonna as a prophylactic against scarlet fever:—not, however, in infinitesimal doses. This proceeding, the *Lancet* states, is exulted in—why we know not—by one of the quack publications. There is a statement, however, quoted by the *Lancet* from the same quack paper, which, if true, is more important. We are quite aware of the culpable laxity which has prevailed regarding meeting with homœopaths; and, therefore, it is quite necessary for "those in high places" to state at least what they intend to do for the future. Even in Edinburgh, where homœopathic quacks cannot now be met professionally by Fellows of the Colleges, it was not always so. The following is the passage referred to: "The two eminent physicians (Sir James Clark and Dr. Locock) mentioned by our correspondent, have distinguished themselves by their gentlemanly forbearance, and their courteous demeanour towards their homœopathic brethren. Neither of them has ever made any difficulty of meeting in consultation, at the request of the patient, any homœopathic practitioner, not for the treatment, but for an opinion of disease."

The Branding of Deserters. We observe by a memorandum issued by the Horse Guards, dated August 19th, and published in *The Times*, that the medical officers are ordered in future to brand deserters with the letter D. This degrading service has hitherto been performed by the drummers. We trust no army surgeon will be so mean as to obey. No office is humi-

liating if performed in the cause of humanity; but the branding of deserters is evidently the execution of a savage sentence, which is quite incompatable with the character of a gentleman, and with the honour of our profession.

The Jenner Monument Committee. We are glad to learn that the Committee is now formed, and ready to receive subscriptions. The names, we understand, will be immediately published. In the mean time, it may interest our readers to learn that numerous additional letters of approval and adhesion have been received.[1] Had space permitted, we should have laid several of these interesting communications before our readers, as they have been kindly forwarded to us for that purpose: but in the present state of our pages, already so much occupied with matters of general intelligence, we are obliged at present to select one only from the many now before us.

Letter from Dr. Knox, *of Strangford, Ireland.*

Strangford, Downshire, Ireland, July 17, 1851.

Sir,—I feel much obliged by your application, and in reply beg leave to say, that I shall esteem it a great honour to have my name added to the list of the Committee, who are so laudably engaged in the attempt to raise a memorial worthy of the subject, to the memory of the great and good Dr. Jenner. At the same time, I may be pardoned for saying that it is little creditable to the age we live in, that this task yet remains to be performed.

No man, living or dead, has probably ever conferred a boon so inestimable and universal on suffering humanity; and the object the Committee have in view, surely requires nothing but sufficient publicity, to ensure its entire success. But, besides discharging a heavy debt of gratitude to Jenner's memory, the contemplated movement will, I trust, have the effect of directing anew the public attention to the great and unquestionable value of vaccination. Having in very recent times attempted, however feebly, to defend the doctrines of Jenner against objections, which appeared to me neither very wise nor very forcible, I indulge the hope that a renewed impetus may be given, by the plan the Committee have in view, to the practice of vaccination, which I ardently desire to see, not in partial, but in universal operation. When this shall have been effected, and not till then, shall we have the means of duly estimating what Jenner has done for mankind: and if the result should not be, as in the ardour of his benevolence he anticipated, to eradicate small-pox from the face of the earth, I feel pretty confident in stating, it will become more and more evident that his great discovery will form the best attainable safeguard against the horrors of that loathsome disease, and demonstrate anew the just claims of his memory to the gratitude and respect of the whole human race.

I have the honour to be, very faithfully yours,

E. V. Irving, Esq. Alexander Knox.

Dr. Mayne's Expository Lexicon. Dr. R. G. Mayne, of Leeds, has issued the prospectus of a work to be entitled, *An Expository Lexicon of the Terms, Ancient and Modern, in Medical and General Science; including a complete Medical and Medico-Legal Vocabulary.* From the specimen which we have received, and a portion of which we reprint, we perceive that Dr. Mayne has performed his task in a most luminous and scholarly manner. He presents the correct pronunciation, derivation, definition, and application of the names, analogues, synonymes, and phrases connected with medicine, and employed in Anatomy, Astronomy, Botany, Chemistry, Comparative Anatomy, Conchology, Crystallography, Entomology, Geography, Geology, Geometry, Ichthyology, Materia Medica, Medical Jurisprudence, etc., etc. Dr. Mayne announces that *his work is complete, and ready to go to press whenever the names of two hundred and fifty subscribers are obtained.* It is proposed to bring out the *Lexicon* in two forms; viz. 1. In six quarterly parts, the first to appear one month after this list shall be closed: 2. In one thick 8vo. volume, bound in cloth, price £1 10s.

[1] For copies of some of these letters *vide* London Journ. of Med. July 1851.

When we contemplate the immense labour which Dr. Mayne has so successfully bestowed upon the preparation of this great work, and when we remember that there is no similar work in our language, we do trust that many who read the lines we are now writing, will without delay place their names on Dr. Mayne's list of subscribers, which they can do at Churchill's in London, or by addressing the author at Leeds. We would recommend book-clubs to take it in. A number of individuals would thus have the benefit of perusing it as it appeared in parts; and some one would doubtless at the end of the year be glad to buy it from the club at the usual reduced rate. We would also suggest that Dr. Mayne might be materially assisted by his professional brethren, were they to mention the character of the work to clergymen, coroners, and naturalists, and others for whom it is also particularly adapted.

The following is a portion of one column of the specimen.

ABDOMEN, *ĭnis.* n. (*Abdo*, to hide; because the abdominal viscera are hidden within its cavity.) *Anat.* Name for the largest cavity of the human body; the belly or abdomen. *Comp. Anat.* Applied to the same region in the lower animals. Also termed *Venter.* See *Imus Venter*, *Mirach*, *Nadys*, *Sumen.*

NOTE.—In some dictionaries, *omentum* is added as a part of the derivation, to account for the last syllable of this word. The suggestion originated with Martinius, it is supposed, but was long ago shewn to be erroneous, that syllable being merely a termination of frequent use in the Latin, as *acumen*, from *acuo; foramen*, from *foro*, etc.

ABDOM'INAL. (*Abdōmen*, the belly.) *Anat.* Of, or belonging to, or in some manner connected with the abdomen or belly; ventral. *Abdōmĭnālis, is, e.*

ABDOM'INAL AOR'TA. *Anat.* Term for that portion of the aorta situated below the diaphragm.

ABDOM'INAL APONEURO'SIS. *Anat.* Term for the conjoined tendons of the Oblique and Transverse muscles on the anterior portion of the abdomen or belly.

ABDOM'INAL GAN'GLIA. *Anat.* A name for the semilunar ganglia, from their situation.

ABDOM'INAL RING. *Anat.* Term for the fancied ring-like opening on each side of the abdomen, external and superior to the *pubes*, formed by the separation of the tendinous fibres of the lower portion of the external oblique muscle; transmitting, in the male, the spermatic cord, and in the female, the round ligament. *Annŭlus Abdōmĭnis.*

ABDŌMĬNĀLES. See *Abdominalis.*

ABDOMĬNĀLIS, *is, e.* (*Abdōmen*, the belly.) *Ichthyol.* Of or belonging to the belly or abdomen; ventral; applied to an Order (*Abdominales.* Nom. pl. f.) of fishes which have the ventral fins suspended to the under part of the abdomen, and behind the pectorals, without being attached to the bones of the shoulder: abdom'inal.

ABDOMINOS'COPY. (*Abdōmen*, the belly; *σκοπέω*, to observe.) *Med.* Term for the operation or mode of ascertaining the existence of abdominal disease by percussion mediate or immediate, by inspection, measurement, and manual examination. *Abdōmĭnoscŏpĭa, æ.* f.

THE GLASGOW FACULTY AND INSURANCE COMPANIES. The following resolutions were adopted at a meeting of the Faculty of Physicians and Surgeons of Glasgow, held upon the 1st of September, 1851, in reference to the payment of fees to medical referees by Life Assurance Companies.

I. That this Faculty has long maintained the principle, that medical referees, the ordinary attendants of the parties desiring life assurance, ought to be suitably remunerated for their trouble in replying to the usual queries on behalf of the assuring companies; and that the parties granting the assurance ought to pay this fee, as it is obviously for their safety and guidance that such information is afforded.

II. That in conformity with these views, the Faculty, so long ago as 1st June, 1835, passed a law, requiring every member of their body to refuse replying to these queries unless a specified fee were transmitted alongst with the schedule, and this law has, from that time, been steadily adhered to and acted upon.

III. That in carrying out the above views, the Faculty regret being obliged to record, that till of late, with a few honourable exceptions, they have met with the most uncompromising opposition from the Insurance Companies, especially those of more early establishment; and although, within the last two years, several even of these have made a movement in the right direction, yet this has been so long deferred, and so obviously only a yielding to the pressure of circumstances, as to deprive the concession of much of its value.

IV. In this position of affairs, it has given the Faculty much pleasure to observe some of the more recently established Insurance Companies, not only frankly acknowledging the justice of the principle so long contended for, but spontaneously offering a liberal compensation to the members of the medical profession for the very valuable information and opinions it is not unfrequently in their power to afford; and to such companies the Faculty beg, in this public manner, to offer their best thanks.

V. The Faculty also take this opportunity of recording the sense they entertain of the important services done to the profession, in this matter of remuneration to private referees, by the editors of the *Lancet*, the *Medical Gazette*, and *Medical Times*, to whose intelligent and steady advocacy, they are aware, they mainly owe whatever favourable change that may have taken place in the conduct of the Assurance Companies towards the profession.

VI. The Faculty beg also to state, that whilst in 1835, in their anxiety to have the principle of remuneration established, they were indifferent as to the actual amount conceded; they now feel called upon, in justice to themselves, to intimate to the agents of all Assurance Companies, that the Fellows of their body will not, in time coming, pay attention to any schedule of queries submitted to them with a reference to any species of life assurance, unless such schedule of inquiry be accompanied by the fee of One Guinea, if the sum proposed to be insured exceeds £300, and 10s. 6d. if the sum is £300 or under.

VII. The Faculty order these resolutions to be printed, and copies sent to the editors of the London and Provincial Medical Press, to the agents of the various Insurance Companies, and to the presidents of the Royal Colleges of Edinburgh, and the other medical corporations throughout the kingdom, inviting their concurrence and cooperation.

Extracted from the Records of Faculty, by LAURENCE HILL, Clerk.

The Nairn Hospital. We have much pleasure in inserting the following letter.

To the Editor of the London Journal of Medicine.

Nairn, September 3rd, 1851.

Sir,—Your valuable articles on the Hospitals of London induce me to hope that you may consider the following communication worthy of insertion in your Journal.

The Nairn Town and County Hospital receives the invalided poor (medical and surgical cases) of the small town and county of Nairn: it has already proved a blessing to many. It is the first unendowed charity of the kind which has been established in so comparatively poor and limited a district of Scotland. It is upheld entirely by voluntary subscriptions, collections made in churches, donations of the charitable, and bequests. The history and progress of this hospital are interesting, and show how much good may be done by the perseverance and well-directed energies of a few. I would hope that the example will not be lost in places similarly, or more favourably situated, and equally destitute of the means of relief and comfort to the poor when on the bed of sickness and suffering.

The town of Nairn, with its population of 3,000, in the winter of the year 1842-3, was visited with a very fatal and infectious fever, prevailing principally, as usual, amongst the poor and labouring classes, and much in proportion to their wants, their visits and exertions towards their sick friends and neighbours, and their depraved habits of life: it was then that the idea of a small hospital for the town and county suggested itself, for general purposes; and more particularly as a provision for the recurrence of any similar epidemic. The scheme, however, was considered Utopian by most of the inhabitants, on account of the confined and comparatively poor state of the town and district. Such difficulties, however, did not daunt an energetic and persevering few, whose praiseworthy exertions in due time were crowned with success. They had ere long the gratification to behold the foundation laid of a chaste building, in the Italian style of architecture, capable of containing some thirty-two patients; and on the 12th of August, 1847, it was opened for the reception of patients.

Nairnshire was for many years deeply indebted to the Northern Infirmary at Inverness, for the almost gratuitous admission of her sick poor; and I would here reiterate the generally expressed opinion of the usefulness of this institution, whose benefits extend, not only over the town and county of Inverness, with her far-distant isles, but over the vast counties of Ross, Sutherland, and Caithness. In the above-mentioned emergency at Nairn, and in acute cases generally, the distance of sixteen miles proved often a barrier to the removal to Inverness of our sick poor; and it is a deep cause of thankfulness to them, and an advantage to the community at large, that an asylum is now open, where the sick poor can have every comfort and assistance that they require.

The plan, drawings, and specifications, were given by Messrs. Mackenzie and Matthews, architects, of Aberdeen and Elgin. The plan has been much commended by competent judges, as chaste in style, economical in execution, and most comfortable and commodious in internal arrangement; in fine, a model for a small hospital. Should any party be wishful for the plans, or information regarding them, the Treasurer of the Hospital will be happy to furnish them; and should this communication meet the eye of friends at a distance, or those favourable to the furtherance of this novel and laudable experiment, they may rely on the smallest donation being thankfully received and acknowledged. I am, Sir, your obedient servant,

John Grigor, M.D.

[If Dr. Grigor will kindly furnish us with the plan of his Hospital, and a statement of the expense of building and maintaining it, we will be happy to lay them before our readers.]

OBITUARY.

BADELEY, J. C., M.D., Fellow of the Royal College of Physicians of London, Visiting Inspector of the Essex Lunatic Asylums, on the 22nd September, at his residence in Chelmsford. The circumstances of Dr. Badeley's death are very distressing; and they likewise point out how wrong it is for any one under the influence of pain, to handle dangerous drugs, or to mix a dose, when a slight error may cause a fatal result. We have seen more than one narrow escape, under circumstances precisely similar to those which occurred in this melancholy case. It appears that, in order to relieve a severe attack of tooth-ache, the deceased prepared for himself, and took, a dose of morphia, about 4 A.M. on Monday, 22nd September. Symptoms of narcotic poisoning appeared, and he died at 1 P.M., about nine hours after the accident. Dr. Badeley was widely known, and much respected.

BRIGGS, William, M.D., late of Ambleside, formerly of Liverpool, and also of Kendal, at Cheltenham, on the 18th September.

BRISCOE, Dr., of the 59th Regiment, at midnight on the 22nd July, in consequence of the wreck of the *Pasha*, one of the Oriental Steam Navigation Company's fleet, which, by some as yet unexplained blundering, was allowed to come into collision with another steamer. Both vessels had signalled each other when several miles distant.

BUDD, Thomas P., Esq., Surgeon, formerly of Newton Abbot, at Burra, Adelaide, South Australia, on the 7th April, aged 31.

FAITHORN, John, M.D., of 14, Grosvenor Place, Bath, on 18th August, aged 78.

GIBSON, John, Esq., Surgeon, and formerly Provost of Lanark, N.B., at 25, Bloomgate Street, Lanark, on the 8th September.

KIDD, John, M.D., at his residence, Oxford, on the 17th of September, after a few hours' illness. Dr. Kidd was Regius Professor of Medicine, Tomline's Prælector of Anatomy, Aldrichian Professor of Anatomy, and Radcliffe's Librarian. He was highly esteemed and respected, both in the University and city of Oxford. In 1809, being then a student of Christ Church, Dr. Kidd took the degree of M.A.; in 1801, that of Bachelor of Medicine; and in 1804, he proceeded to the degree of Doctor of Medicine. In 1822, Dr. Kidd succeeded Sir Christopher Pegge, Bart., in the office of Regius Professor of Medicine, to which is annexed Tomline's Prælectorship of Anatomy and the Aldrichian Professorship of Anatomy; and in 1834, he succeeded Dr. Williams as Radcliffe's Librarian. The election of a successor to the latter office rests with the Archbishop of Canterbury, the Lord Chancellor, the Chancellor of the University, the Bishops of London and Winchester, the two principal Secretaries of State, the two Chief Justices, and the Master of the Rolls. Dr. Kidd did good service in his time, as his publications testify, in various departments of mineralogical, chemical, and geological research; and about ten years ago—his last appearance, we believe, as an author—he put forth some observations on medical reform. Dr. Kidd was one of the eminent men selected under the Earl of Bridgewater's will to write one of the well-known Bridgewater Treatises; a work which, we believe, has gone through several editions.

WHITE, Joseph, M.D., late of Banff, N.B., at Montreal, on the 8th July, aged 70. The deceased practised in the town of Banff for nearly thirty years, after having served as Assistant and Full Surgeon in the Navy, having been promoted after only three years' service. In Banff, he acquired considerable local celebrity as an accoucheur. He emigrated to Lower Canada in 1835, and settled at Huntingdon, Goodmanchester, county of Beauharnois.

ORIGINAL COMMUNICATIONS.

ON INJURIES TO THE EYE FROM SHOT, Etc.

By WHITE COOPER, Esq., Ophthalmic Surgeon to St. Mary's Hospital, etc.

There is a class of injuries to which sportsmen are especially liable, and which medical men are sometimes called upon to treat under circumstances the reverse of favourable. Upon these I propose to offer a few observations.

Cover shooting is a frequent source of injuries to the eye, from the circumstance of small shot being very liable to glance from the branches of trees in unexpected directions, and also from the eagerness of some sportsmen, who cannot resist a tempting shot, regardless of the proximity of others, whereby many persons have been blinded for life. Fragments of copper caps are another source of injury to these organs, though less frequently so than formerly, from the superior make of the caps themselves, and of the gun-locks; and, lastly, the eyes may be punctured or lacerated by thorns.

Injuries from Shot. The external effects produced upon the eyeball by a shot-pellet are, according to my observation, three in number. If the shot be spent, it will bruise and not penetrate the eye, causing considerable ecchymosis externally, and not unfrequently paralysis of the retina. If the eye be struck obliquely by the round pellet, it will glance off, cutting a little furrow which marks its course; but if the eye be struck point blank, or if the shot has been flattened or jagged by previous collision, the tunics will probably be penetrated, and the shot will lodge in the interior of the globe. The peculiarly tough structure of the sclerotic offers great resistance to the progress of a shot; hence, it frequently glances off altogether, if the outer side of the eye be struck, or lodges in the orbit, if the inner side. Those cases, in which a grain of shot pierces the eye, (except when fired at a very short distance), appear to be most frequent when the lid is struck in the first instance; as, for example, by a shot glancing downwards from the branch of a tree. Much, however, will depend on the angle of incidence and on

the velocity, whether the sclerotic be penetrated or not. The following is an illustration of the first description of injury.

Case. A man, æt. 32, was acting as "marker" to a party of sportsmen, and had ascended a tree to obtain a good view. A covey of partridges rose between him and the gentlemen, who were distant about one hundred yards, and on their firing at the birds, several shot struck about him, and one hit his left eye: the pain was at the moment acute, and the sight greatly impaired. He came under my notice two days afterwards, and I found considerable ecchymosis over two-thirds of the sclerotic, but no breach of surface. The frequent application of cold and astringent collyria speedily removed all traces of the blow; and the sight was gradually recovered.

Of injuries arising from over-eagerness, three examples have been seen by me; but as the main points were similar in all, the brief recital of one case will suffice.

Case. A party were beating a wood for pheasants, and in the excitement of several birds rising, a gentleman shot at one, without observing that another sportsman was in the line of fire. Three shot struck his face, and his left eye received one. As a wound in the eye was visible, great alarm was created, and medical assistance was promptly obtained. The impression was, that the shot had lodged in the globe, and such was the belief when the case was seen by me, some days subsequently. On careful examination, however, the groove which marked the course of the shot was clearly discernible: the eye had been struck about a line from the margin of the cornea, and there was quite the appearance, under a lens, of a piece having been chipped out. This was so far satisfactory, showing that the shot was not, as supposed, buried in the eye, and a fine probe, which traced the bottom of the wound in the sclerotic, rendered this certain. There was rather a smart attack of inflammation, but the case eventually did perfectly well.

When the eye has been struck by a shot, there is generally considerable ecchymosis, and the patient is much frightened; but our prognosis may be favourable if no shot-hole is visible, or if, by the assistance of a lens, the little groove above described can be discerned, though perhaps obscured by the effused blood; if, however, vision has been extinguished by the blow paralysing the retina, a cautious opinion, as to the restoration of vision, is advisable. The following case is interesting, from the severe effects produced by a small particle of gravel forcibly propelled against the eye; effects resembling those attendant on a shot-wound, which, for a time, it was believed by the patient to be.

Case. On the 18th of July, 1851, I was requested by Dr. Archibald Cockburn of Kensington, to visit a gentleman who had met with an accident on the previous day. He was playing at cricket with his sons, and a small fragment of gravel was struck up either by the bat or ball, and driven against his right eye with such force, that vision was instantly extinguished. The agony was intense, and the gentleman felt convinced that he had been shot. The most judicious treatment had been adopted by Dr. Cockburn; but, in spite of leeches, fomentations, etc., the pain continued, though in a less degree, and the patient passed a feverish and restless night.

On examination, much ecchymosis and considerable inflammation,

involving the sclerotic and iris, was apparent; the pupil was dilated and motionless, and the iris tremulous. Just at the junction of the cornea with the sclerotic at the inner side, a cut about a line in length was visible; and a gap at the ciliary margin of the iris at the same spot indicated that that membrane had been torn from its attachment. The pupil was displaced downwards and outwards, and a hand held up could be scarcely discerned.

Active antiphlogistic treatment was adopted, and every endeavour made by inunction and internal administration, to bring the patient under the influence of mercury. No effect, however, was produced, and the following report from Dr. Cockburn leads me to fear that the result of the case will be unsatisfactory. "I saw little of him after you went out of town, as he got impatient and used the eye freely, and went out against my warnings. He was never salivated, though he took a good deal of calomel. The eye was not improved, and he could barely distinguish my figure in the room; the pupil remained very dilated and angular."

When a shot penetrates the eye and lodges in the globe, the consequences cannot fail to be most serious. The following case occurred in the practice of Dr. Butter of Plymouth.

Case. A gentleman, aged 50, was struck by a shot in the left eye, and instantly lost the sight. His sufferings during the succeeding fortnight were not great, but then, and from time to time, during the four years and a half which preceded his application to Dr. Butter, the most agonising pain would shoot, like a flash of lightning, through his left eye and his head; and his sufferings, together with the disturbance produced in the vision of the other eye, led him to seek relief from operative measures. On the 9th of September, 1831, Dr. Butter extracted the lens of the injured eye, and found it to consist of calcareous matter and bone; some gritty matter was also syringed out, but no relief was afforded, and on the 23rd of February, 1833, Dr. B. proceeded to make another attempt to extract the shot. A portion of sclerotica was removed with scissors, and an aperture made sufficiently large to allow of the exploration with a probe of the cavity of the eye, the vitreous humour being evacuated; still no shot was found, nor was there alleviation of suffering; and, as a last resource, it was determined to extirpate the eye, which severe operation was performed on the 23rd of the following September. On the parts which had been removed being examined, a duck-shot was found impacted so firmly in the optic nerve, just at its junction with the retina, that some force was required to detach it. Ultimately, the case did well.

If the shot can be seen in the anterior chamber, there can be no hesitation as to the propriety of extracting it by an incision through the lower part of the cornea; but if it be hidden in the globe, all unnecessary poking or probing is to be strongly deprecated; no possible advantage can result from stirring up the vitreous humour with a probe in the hope of finding the shot, and such a proceeding cannot fail to deprive the patient of the faint chance of recovery he otherwise has. Under such circumstances, the room should be darkened, and the most absolute quiet enjoined; the head should be well elevated, and not allowed to move; the eye should be equally motionless, and the sound eye ought to be closed with a strip of plaster, to prevent

the other opening from sympathy; rags dipped in cold water should be applied to it; the bowels should be freely opened, and depletion practised according to the age and constitution of the patient.

Shots may lodge in the orbit: and when there, they give rise to distressing neuralgia, and have even caused symptoms of inflammation of the brain. The following case, which came under my notice some years ago, is remarkable, as showing by what a small body death may be caused, when the bones of the orbit are penetrated.

Case. Some children, in the neighbourhood of St. Bartholomew's Hospital, were playing with a sixpenny brass cannon, and to increase the report, had loaded it with a small piece of tobacco-pipe, scarcely bigger than a duck-shot. A little girl was standing a few paces from the muzzle of this toy, and when it was fired, she fell, and was carried into the hospital—dead. I was a student at the time, and have a vivid recollection of the embarrassment felt to account for the fatal result, as no wound was apparent; at length a speck of blood was noticed at the inner corner of one of the eyes, and on close examination, an insignificant puncture was discovered just within the lids. *Post-mortem* examination showed that the missile had struck that spot, glanced along the eyeball, and passing through the roof of the orbit, had buried itself deep in the substance of the brain.

Injuries from Fragments of Copper Caps. Fragments of copper cap will sometimes strike the eye and inflict serious wounds, of which I have seen several examples. Such cases were of frequent occurrence from imperfection in the construction of these implements when first invented, but they are less numerous now, and more frequently arise from exploding caps with a hammer, than from their legitimate use.

A young gentleman, aged 14, at one of the large public schools, was amusing himself and some schoolfellows with exploding copper caps by striking them with a hammer. A fragment struck his left eye, cut through the upper lid, and inflicted a formidable wound on the globe, immediately above the cornea. Medical assistance was obtained, but the youth concealed the truth, and stated that the wound was caused by a fall. The truth became known some months afterwards; and then the question arose, as to whether the fragment of the cap had remained in the eye or not, especially as a yellowish object was indistinctly visible in the wound. I saw him in June 1848, when the condition was as follows;—the globe was reduced in size about one-fourth, soft and boggy; the iris tremulous; the pupil was dilated and motionless, and vision was so far extinguished that there was barely perception of light. The wound in the sclerotic was filled by semitransparent material, through which a yellowish substance was perceptible. My first impression was that this was metallic; but on careful examination, with a lens and by a probe, I satisfied myself that such was not the case, and that it was merely coloured lymph. Although the eye had been acutely inflamed at the time of the accident, it had become quiet, and had been free from pain for some weeks. This circumstance, combined with the result of the examination, led me to conclude that the fragment of copper was not in the eye; restoration of vision was, however, hopeless.

Mr. Crompton, of Manchester, has detailed[1] the symptoms resulting from the presence of a fragment of copper in the eye, and my experience entirely accords with that gentleman's. The wound is generally clearly incised, heals rapidly, and for a period, varying from a few days to a month after the accident, the patients appear in a fair way of recovery; but at the expiration of that time, they are commonly suddenly seized with most acute pain in the eye, attended with extensive chemosis, swelling and redness of the lids, and frequently haziness of the cornea. The pain and acute symptoms may gradually subside, but will surely recur again and again, until the eye is brought into a state of chronic irritation, most distressing to bear, and not unfrequently leading to sympathetic irritation in the other eye, which may extend to destruction of vision.

The following is the plan of proceeding adopted by Mr. Barton, in whose practice seven cases occurred. It is equally applicable to a pellet of shot, or a fragment of copper cap, rolling loose in the eye.

The patient being placed in a convenient position, a large flap of the lower part of the cornea is to be cut as in the operation of extraction, but it must then be snipped off with a pair of scissors. The operation being acutely painful, and the eye irritable, chloroform may be advantageously employed. A linseed meal poultice is to be applied, and we may pretty confidently expect to find the foreign body in the poultice in the course of a few days; of course collapse of the globe is the consequence of the operation, but the disfigurement may be remedied by an artificial eye.

A shot becomes discoloured, and a fragment of iron is oxidised by remaining for some time in the eye, but the copper undergoes no change, and its edges continue as sharp and angular as at the moment of its entrance.

In the case above mentioned, the diminution in the size of the globe was a marked feature; and this is a common result of laceration of the sclerotic by a shot or a fragment of metal. The consistency of the vitreous humour is gradually lost at the same time that it becomes diminished in quantity. The colour of the iris is altered, and the membrane becomes tremulous; the globe shrinks to from one-fourth to one-third of its natural size, and as a visual organ the eye is rendered useless. If, however, the cornea be penetrated by a fragment of metal, it may fall into the anterior chamber, of which a case was related by me in the *Lancet* of 30th December, 1843; or it may pass through the iris, produce cataract by opening the capsule of the crystalline, and lodge deep in the eye. Dr. Mackenzie has repeatedly seen grains of powder propelled through the cornea into the lens, so as to cause cataract; and one case was very remarkable. A grain of powder, propelled through the cornea, traversed the lower part of the iris, in which it left a considerable opening, and striking the lens, produced cataract. Gradually the opaque substance cleared away behind the false pupil, and vision was restored. The natural pupil remained much longer cataractous, but at length it also cleared, and the patient saw well with a cataract glass.

A very remarkable case of recovery from a gun-shot wound of the

[1] London Medical Gazette, vol. xxi, p. 175.

eye is related by Professor Stœber of Strasburg, in the third volume of the *Annales d' Oculistique.*

Case. A child, seven years of age, was stealing fruit in a garden, when the owner fired at him, and wounded his right eye. The man was brought before the authorities, and declared in his defence, that the gun was only loaded with salt. Two experienced surgeons, after making an examination of the eye, reported that the wound had been more probably caused by salt than by lead. The man therefore escaped with a fine of twenty-five francs. Nearly a year afterwards, a foreign body was observed under the lower lid, on depressing which, a round black substance was discovered. The child was then brought to Professor Stœber, who found that the body in question was evidently a grain of shot, and that it was freely moveable between the conjunctiva and sclerotic, at the lower and outer part of the eyeball. There was a mark of a wound at the lower and outer border of the cornea, and corresponding to this, a circular lacerated opening in the iris. The pupil was immoveable, and vision was reduced to the mere perception of light.

The mother stated, that the eye frequently became red and painful, especially at changes of weather; and Professor Stœber considering that this irritability arose from the presence of the shot, decided to remove it, but was utterly foiled on several occasions by the restlessness of the child. The shot remained; nevertheless the eye gradually recovered, and sight returned to such a degree that very small objects could be discerned, though it never became as strong as the sight of the other eye. This case is highly instructive, showing that an amaurosis, nearly complete, and of more than two years' duration, can be removed by the unaided efforts of nature, notwithstanding the presence of a foreign body, which might have been expected to have kept up perpetual irritation. Such a result, though scarcely to be hoped for, offers encouragement in similar cases.

When there is a wound in the upper eyelid from any missile, it is important to ascertain whether the eye has been injured, a circumstance which may be overlooked by the attention being confined to the more conspicuous laceration. There may be a fragment left under the lid, or a wound in the upper part of the sclerotic, or even a fragment sticking in the coats of the eye. Demours mentions a case of this sort, where a double grain of shot passed into the sclerotic and remained fixed, one grain being without and the other within. The proper mode of proceeding is to direct the patient to look on the ground, and then to raise the lid by drawing up the integuments with the point of the finger towards the brow: a view of the sclerotic may thus be obtained; but if there be reason to suspect the presence of a foreign body between the eye and the lid, the latter should if possible be everted, or if this cannot be done, a stream of tepid water should be thrown under the lid by means of a syringe, whereby the substance will most probably be washed out.

Injuries from Thorns. These are far from uncommon in the country. If the thorn has penetrated the sclerotic, it should, if entire, be carefully drawn out; but if it has been broken, it becomes much more difficult to remove. I have had one such case, and the plan adopted

with success was as follows: having bound up the sound eye, and fixed the other with the points of the fingers of my right hand, a slight superficial incision was made with a sharp cataract needle on each side of the thorn, then with a pair of fine forceps it was grasped and smartly twitched out: the eye did perfectly well. A common consequence of a thorn striking through the cornea, is traumatic cataract; and it is singular to observe the rapidity with which opacity of the lens takes place. The injury is often followed by instant blindness; but that cannot arise from the mere injury to the lens, though I have seen it distinctly turbid one hour after it had been pierced by a thorn. This injury is attended with more pain than a gun-shot wound, and the subsequent inflammation is often of great severity.

Case. Mr. Thompson, residing near Ashbourne in Derbyshire, was struck by a thorn in the left eye on the 24th of February 1851, and instantly lost his sight. His right eye had been rendered blind twelve years previously by a wound from a fragment of iron. Severe inflammation followed both accidents; but though it was subdued in the eye last injured by the judicious measures adopted by Mr. Gregory, of Youlgrave, the patient continued blind. He was placed under my care last July, his condition being as follows:—the right pupil was blocked up with a mass of lymph strongly adherent to its margin, and it was drawn upwards and inwards; from the concavity of the iris, it was clear that the lens was no longer in existence. The left eye presented adhesions of the pupil to a soft capsulo-lenticular cataract. On the ninth of July, I opened the capsule in this eye, disturbing the lens but little; and not the slightest inflammation followed.

Professor Jäger, of Vienna, was then staying with me, and on the 20th of July he operated at my request on the right eye of Mr. Thompson; making a free incision through the sclerotic, he then introduced a pair of fine forceps, acted on by a spring, behind the iris, the opaque and very tough capsule, and seized and drew it out. For five days the progress of the case was everything that could be desired, but on the evening of the sixth day, violent inflammation set in, and in spite of the most active treatment, the pupil became closed again with lymph. Mr. T. returned into the country, and I did not see him until the 1st of October. On examination, it appeared that the cataract had entirely disappeared from the left eye, and there was vision through a small opening in the capsule. This was enlarged on the following day with a cutting needle, and he can now see very satisfactorily. It is proposed to make a central aperture through the lymph occupying the pupil of the right eye, when the organ is in a fit state for the operation.

A case once came under my notice, where the *hook* of an artificial fly had caught in the conjunctiva of the eye and had passed through the lid, just at the outer canthus: clumsy attempts had been made to extricate it, and a very awkward lacerated wound was the result. What should be the proper mode of proceeding in such a case? Obviously to push the hook forward until the barb is fairly exposed, then to snap it off with pliers or forceps above the barb. The shaft can then be withdrawn with ease.

There is one point with reference to wounds through the cornea to

which it is proper to direct attention. The immediate consequence of opening the anterior chamber is escape of the aqueous humour, whereby the iris, losing its support, falls forward, and is exceedingly liable to become entangled in, or adherent to, the wound, whereby the pupil becomes distorted, diminished in size, and incapable of performing its proper movements. Should this speedily ensue, the iris may often be disengaged by placing the patient before a window, and suddenly opening the eye; the natural action induced is powerful contraction of the iris, which draws it out of the wound. It is recommended by many writers to push the protruded part back with a probe; but so far as my experience extends, the bruising of the membrane by this proceeding is highly objectionable, as tending to excite iritis. The exposure to light three or four times, and belladonna subsequently, are at least safer, and probably quite as effectual as the other plan. An elegant mode of keeping the pupil dilated, is by rubbing upon the brow a solution of four grains of sulphate of atropine in half an ounce of glycerine. This is a more cleanly application than extract of belladonna; and it does not dry so readily.

In conclusion, I venture to offer the following remarks. If a surgeon be called to an injury of the eye, the organ should be carefully and gently cleansed from all blood and coagula, and once for all, fairly and thoroughly examined. This can be done with ease, and little pain at first; but if delayed till inflammation has set in, it will become both difficult and hazardous. If there be a foreign body in the eye, no time should be lost in extracting it if possible; if not, the patient should be kept quiet in bed, subjected to the strictest antiphlogistic discipline, and carefully watched. It should never be forgotten that the integrity of the organ depends on the *prevention* of inflammation, and that this is chiefly to be accomplished by the measures adopted within the first three days after the accident. The condition of the lids will be the criterion of the state of the eye; so long as they remain free from tumefaction and natural in appearance, all is going well; but not so, if a little puffiness appear at the internal angle, and gradually steal over the upper lid. There will then be some uneasiness in the eye, and the patient will complain of annoyance from scalding tears. If active measures have not been before adopted, not a moment should now be lost in resorting to them. Time is precious, inflammation is commencing, and every effort should be made to arrest its progress. The patient, if robust, should be bled from the arm, cupped from the mastoid process, or leeches may be applied there or to the temple. The cold wet rags must give place to frequent fomentations with hot water, and mercury, combined with a sedative, should be administered.

Such are the main features of treatment; but too much attention cannot be paid to the apparently minor points of absolute quiet, strict discipline, gentle handling, and little interference with the eye by opening it unnecessarily; and lastly, general careful watching on the part of the surgeon, that if mischief be threatened, it may be arrested at the very outset.

19, Berkeley Square, October 1851.

ON THE OBSTETRIC USE OF ERGOT OF RYE.

By GEORGE E. ELY, M.D.

(*Read before the Western Medical and Surgical Society of London, March* 7, 1851.)

In the brief remarks which I am about to submit, on the employment of Ergot of Rye in Parturition, I propose to offer the conclusions to which experience has led me, and do not profess to furnish either novel facts, or exact deductions from numerical details. Having been busily occupied in this department of practice for the last sixteen years, during which time I have personally delivered nearly 3,000 women, I have had ample opportunities for testing the maxims of my old preceptor, Dr. John Thatcher, of Edinburgh, on this point, and have never found them fail me. So little title to originality have I to boast of, that it would not have occurred to me to write at all on the subject, did not the cases which I read in the journals, and those which I occasionally see, convince me that many practitioners hold very loose opinions on the properties of the remedy, expecting from it more than it can perform, and exhibiting it when it can be potent only for evil. If a labour prove tedious, no matter in what stage of its progress, no matter what the cause of delay—and in spite even of faulty presentation—ergot appears by some to be given. In fact, *this* appears to be their only rule:—if labour is not terminated in half an hour after their arrival, a dose of ergot is to be administered. I have known it given,—by those who are well educated, and in other departments skilful,—in primiparæ, long before dilatation of the os uteri; and that even when the breech has presented. And I have known it to be given, with the head above the brim of the pelvis, the latter being deformed so much as to have made craniotomy necessary in former labours. Others, again, not knowing its proper adaptation, have denied it all power. Others, judging from the mischief arising from its improper administration, decline its use altogether, from a fear of its ill effects. But while, given wrongly, the consequences to mother and child may be most disastrous; if given rightly, it will often render operations with the forceps, or turning, unnecessary; and in some descriptions of hæmorrhage, may be the means of averting even death itself.

A consideration of the *action* of ergot, will render distinct and evident its nature as an obstetric instrument; and thus its powers, uses, and unsuitabilities, may be at once deduced. We may thus, also, see how and why it has occasionally been productive of ill effects on the mother or the child. I am not competent to enlarge on the minute physiological theory of its action. I speak as a man who professes medicine only as a practitioner; not, however, meaning hereby to undervalue a branch of science of which he confesses himself not a master.

The effect, then, of ergot of rye, given during labour, is to produce, in about twenty minutes after its administration, *propulsive contraction* of the uterus; differing from the natural expulsive pains in this re-

spect, that the intervals of ease will be either altogether absent, or very incomplete. Occasionally, if there is but little opposition, it will be a very powerful and continuous pain; or, on the other hand, it will be a quiet, tonic, slow, and steady propulsion, causing little or no expression of suffering, and lasting some time.

We see, then, immediately and exactly, the sort of case to which it is *suited*, and the sort of case in which it is *needed*. We see also how, when it is improperly administered, the serious consequences which have been ascribed to its use may really ensue. They must be, in a word, cases in which *a few strong expulsive pains* are required, and will be safe. The required pains must be *few;* for many ergotic pains, not having intervals, might rupture the uterus, or asphyxiate the child. It must be a case where *strong* expulsion is not undesirable, for the contractions resulting from ergot may be very strong.

In the first place, then, there must be no disproportion between the maternal pelvis and the fœtal head, for here a few pains and a short time cannot suffice. Therefore ergot is not to be used in any difficulty case. It must not be given before the os uteri is well dilated. It cannot, therefore, be suitable in the *early* stages of labour at all; far less, when the very cause of delay resides in rigidity of the os. It must not be given unless the vagina and perinæum are soft, moist, and well relaxed:—it can, then, be very rarely safe in primiparæ, especially if advanced in life. It cannot be applicable, unless the presentation is entirely favourable.

These rules appear so self-evident as to make it idle to repeat them. Yet I have seen them grossly transgressed; and I have often read in the journals, cases in which the authors narrate the exhibition of ergot under such circumstances as are deprecated above, without appearing at all aware of any impropriety in their treatment. If it is given in a case rendered tedious by the difficulty, nature will sometimes, fortunately, prove insensible to the action of the drug. But if not, the uterus will be roused to a violence of action, which will in all probability end in rupture: or if it should by fearful efforts accomplish delivery, the convulsive rigors which follow are tokens of the imminent risk which has been run.

When there is rigidity of the os uteri and soft parts, results so fatal may not occur; but the patient will become exhausted by misplaced and ineffectual attempts at expulsion; the rigidity and dryness will increase; a feverish state will be produced; and, after the subsidence of ergotic pain, natural pains will be slow in returning. And such are cases in which I have seen ergot fatal to children, whose vitality has not been proof against the long-continued and unremitting compression.

Probably none will be found so mad as to administer ergot in presentation of the *upper* extremity. But neither is it applicable to a foot or breech presentation; for here it is often only after the slow, gradual, and dilating passage of the hips, that we can hope to extricate the head sufficiently speedily to save the child. Even where the *head* is the presenting part, malposition will often forbid the use of ergot; as that would frequently be an infringement of the maxim,—that *few* pains must be requisite for the completion of labour.

I must also confirm that which Dr. Hardy, of Dublin, in an interesting and important paper on this subject, has stated; that ergot will sometimes produce very serious depression of the pulse, where the patient has already been weakened by very great hæmorrhage, or previous profuse diarrhœa.

After what I have said, few words will suffice for pointing out in what cases ergot is a suitable means. And if from those in which it may be given safely, we subtract those in which it is not required, very few will remain. I myself so seldom require it, that I have never carried any about with me. Doubtless, there are many cases where no possible harm could arise from its administration, and where the suspense of the patient, and the time of the accoucheur, may be unobjectionably spared by employing it; but my own custom on such occasions is, to submit to the tediousness and inconvenience, and exhibit simply "tincture of time". Herein, every one must act as he thinks right.

But when, in a woman who has already been a mother, the head has rested on the perinæum for two or three hours, waiting only for the final extruding pain, it is folly to withhold what will then be so speedy, so safe, and so welcome an interference. And I have known that, occasionally, in elderly women, where only *one* pain is wanted, that one pain *will* not come; and either ergot must be given, or the forceps at last applied.

In cases where, in the last stage of labour, the expulsive pains are feeble and infrequent, serious hæmorrhage will very often follow; and this untoward sequence is almost always to be prevented by the exhibition of ergot, in the manner proposed by Dewees, and so ably expounded by Dr. Beatty, of Dublin.

But the case in which ergot is most strikingly beneficial, and I may say most necessary, is that of partial presentation of the placenta. Here, until the os uteri is considerably dilated, the hæmorrhage can only be stayed by the plug, which will do so effectually. But when the os is tolerably open, thin, and soft, the yielding surface of the membranes will not afford a counter-pressure to the plug, which is then no longer efficient. They may also give way without our knowledge, and then we shall have internal hæmorrhage. If we now rupture the membranes, the descent of the head will so compress the lacerated vessels, as to place the patient in safety. But we cannot depend upon the continuance of sufficient contraction of the uterus to keep up this compression; and the intervals of pain will permit a considerable draining. Here, then, if the symptoms are urgent, there would be no remedy but turning; a measure painful and exhausting to the mother, hazardous to the child, and perhaps difficult to the operator. But ergot supplies, as I can aver, an admirable and a competent aid. Let a full dose be given, and the membranes ruptured, and the happy results will be, a cessation of hæmorrhage and a speedy delivery; or, at all events, such a degree of tonic contraction of the uterus will ensue, as will keep the patient out of danger.

Dr. Ramsbotham recommends the administration of ergot as a preliminary step in the induction of premature labour. In the few cases of this kind which I have treated, I have derived no assistance from

it; and I do not think that the non-parturient womb is very susceptible of its stimulus. Nor can I say that I have found the ergot very effective, when given after delivery, in atonic hæmorrhage; although I willingly defer to the contrary opinion held by many distinguished accoucheurs.

Rochester, February 1851.

ON THE RELATIONS OF UTERINE TO CONSTITUTIONAL DISORDER.

By F. W. MACKENZIE., M.D., Physician to the Paddington Free Dispensary for the Diseases of Women and Children, Fellow of University College, etc.

Of those who have devoted themselves to the study and investigation of morbid phenomena, we may recognize two principal classes. The one, looking more especially to the alterations of structure which are occasioned by disease, endeavour to deduce from them and the study of their specific characters, anatomical, chemical, and physical, the laws which regulate their development, and the principles which should guide us in their prevention and cure. The other, looking beyond the mere structural changes themselves, seek to determine their mode of origin and formation by an examination of their causes, the circumstances by which they have been preceded, and the order and sequence of morbid actions. Each of these methods of inquiry has its advantages, whilst both are conducive to the extension of medical science; and while it would be invidious to draw any parallel between their respective merits, we may at least admit the importance of that which, by teaching us the incipient phenomena of disease, enables us to anticipate and avert those ulterior changes of structure which, when met with, are but little amenable to the resources of our art.

But in such investigations, it is necessary to carry our inquiries beyond those limits which custom or system has arbitrarily assigned to particular diseases. It is necessary to study closely the first deviations from health; to trace morbid actions from their more determinate to their more primitive conditions; and to note the order and succession of changes by which constitutional disorder becomes localised, and local disorder passes into organic disease. For it is too evident, that morbid action may have commenced before sensibility warns us of its existence, and that the mere perception of pain or uneasiness, or, indeed, of any sensible deviation from what is normal in a part, cannot be regarded as the commencement of disease. This may have begun long antecedently; and inquiry in such cases will often show that it had been attended by appropriate symptoms, which, if carefully sought

for and recognised in other instances, would enable us to avert those consequences which would otherwise ensue.

In the prosecution of this subject, much may be gained from physiology, for it is to the point at which physiological actions become pathological, that our inquiries should be mainly directed. Much, again, is to be learnt by collecting the histories of individual cases; and this should comprehend, not only their immediate symptoms and causes, but their remote antecedents also. By studying the particular circumstances or combination of events, which may have preceded or given rise to any particular lesion, we are enabled to anticipate its occurrence whenever similar circumstances cooperate; and this knowledge is eminently equivalent to power; with such power, medicine may claim to rank foremost among those sciences which have contributed most largely to the happiness and welfare of mankind. The knowledge of the past becomes our guide and security for the future; and in proportion as we have diligently watched and followed and correctly interpreted the workings of nature, are we enabled to direct, to modify, or control them, and thus to minister most successfully to the wants and necessities of our fellow creatures.

The relations which subsist between uterine and constitutional disorder have not, as it appears to me, been satisfactorily determined, nor have they received, perhaps, that degree of attention which the importance of the subject merits. According to the most recent doctrines which have been put forward, uterine disorder is sufficient to take the initiative in all those morbid conditions, constitutional as well as local, which are met with in the progress of uterine disease; and consistently with this view, the rule of practice has been to direct measures primarily and specifically to the uterine organs. The precise nature of the uterine malady has not, indeed, been clearly settled;—by one it is considered as congestive, by another as inflammatory and ulcerative, by a third as neuralgic, and by a fourth as a kind of mechanical displacement; but all agree in regarding it as of primary importance, and as the *fons et origo* of any coexisting disorders. Whether, however, such views are correct, or, at all events to the extent which has been contended for by some, may, I think, admit of reasonable doubt. I do not deny that uterine disease, when fully established, may react injuriously upon the constitution, or that some organs may suffer in the general reaction more than others; but if our inquiries are directed to the early history and mode of origin of such diseases, we shall find, I think, many reasons for believing that this is constitutional rather than local; that, whilst irritative disorder has preceded vascular disease, that this has mainly resulted from constitutional causes, and that it is less the reaction of the uterine malady upon a healthy than upon a disordered constitution, which gives rise to those complex and often intractable maladies which are sometimes met with in connexion with uterine diseases. The question involved in this inquiry is one of considerable practical importance; for if, on the one hand, it should appear that uterine disorders are for the most part local and isolated affections, and arise irrespective of general causes, it must follow that treatment of a local character, if not exclusively, must be chiefly required, and that the constitutional disorder will cease with

the uterine. If, on the other hand, it is true that uterine is generally preceded by constitutional derangement, and is mainly dependent upon it; then it must equally follow, that treatment, to be successful, must be addressed principally to the latter, and more subordinately to the former.

Those who have adopted the first of these views, and who look to uterine derangement as being for the most part idiopathic, and as initiating other disorders, and who regard the cervix uteri as the chief seat of the majority of uterine diseases, would seem to attach primary importance to the physical appearances which it presents under difficult circumstances, and have associated with many of them the presence of inflammation. In some instances however, it is possible that they may have interpreted these according to preconceived views of their nature. I say this, because the significance of certain appearances presented by the cervix in different cases has not as yet been clearly determined. In regard to the diagnostic characters of inflammation, there is confessedly much difference of opinion, and there is still more as to those of ulceration. But in determining the nature of any physical changes which may be met with in an organ, it is necessary to take into consideration the general and local symptoms with which they are attended, in order to arrive at correct conclusions, for the mere anatomical characters of inflammation may be present without inflammation actually existing. Now, on this point, the cases under consideration possess no kind of uniformity. I have met with some in which inflammation and ulceration had been diagnosed after ocular examination, in which there was neither local pain, uneasiness, or functional disorder, or any febrile or constitutional derangement. In some instances, it is admitted that the general health has been perfectly good, where the cervix has presented the so-called appearances of inflammation; and they have been met with after death in persons who had died of other diseases, and who had never experienced any uterine pain, derangement, or uneasiness. Now such facts are calculated to shake our confidence in the inflammatory nature of *some* of these appearances of the cervix. I do not doubt the necessity or the importance of making an ocular examination of the uterine organs in cases of doubtful disease; but in estimating the character of the appearances which are observed, we should proceed with much caution, and with a due attention to the general and local symptoms which are met with in each case. In this country the subject of the physical characters of inflammation has been very carefully investigated by Dr. Yellowley, in an essay on the vascular appearances of the stomach, published in the *Medico-Chirurgical Transactions*, and he has shown that all the characters of true inflammation may be met with when no such disease could have existed. They were found in an intense degree in the mucous membrane of the stomach in healthy criminals who were executed in the prime of life, and in patients who had died of other diseases, quite unconnected with any affection of the stomach. He observes also very truly, "that in judging of the existence of external inflammation in the living body, it is not by mere redness or turgescence of vessels that the opinion is guided, but by those circumstances in conjunction principally with pain, heat, and

swelling. It does not therefore appear to be less necessary, he observes, for the purpose of enabling us to judge of the existence of internal inflammation, that *something unequivocal in the symptoms* should be superadded to the *appearances* submitted to our consideration, than that there should be assistance required in judging of external affections in addition to mere colour or vascularity." The conclusions which Dr. Yellowley has arrived at on this subject have generally been assented to by the pathologists of this country, who avail themselves of his investigations in deciding upon the inflammatory nature of the physical appearances which are met with in different organs. The uterus can be no exception to their truth; and bearing them in mind, we may venture to doubt whether the appearances which have been attributed to inflammation of the cervix may not in some cases have another origin, and be indicative of other pathological conditions.

Again, in accounting for the origin, and the supposed frequency of these inflammatory lesions, we are referred by some writers to the anatomical and physiological characters of the uterine organs, to the vascularity of the cervix, the presence of cellular tissue in it, and the peculiar functions which these organs are destined to fulfil. But surely in such views there must be some fallacy. It is scarcely consistent with the usual providence of nature, to suppose that such susceptibility to disease should be the necessary consequence of the due performance of the ordinary functions of an organ; and when a writer gravely tells us that the function of parturition cannot take place without inevitably, in many, if not in all cases, being accompanied by erosion, laceration, and contusion of the lining membrane of the cervix, we are tempted to inquire if this can really be so; and whether this can truly be said of the organ—the contemplation of which of old inspired Galen with such wonder and admiration, and which Swammerdam, many centuries afterwards, described as the *miraculum naturæ*. I do not think that all can participate in such views; there must be many who believe that the uterine organs have been constructed so as to be adequate to the proper performance of their allotted functions, and who are disposed to look elsewhere, than to their anatomical and physiological characters, for an explanation of the source of their morbid actions.

But, on the other hand, it is a well-established fact, that local diseases may arise exclusively from derangement of the general health—from morbid conditions of the blood—irritative disorder of organs which have extensive sympathies and abnormal states of the nervous and ganglionic centres. This principle was strongly inculcated by Abernethy, is in harmony with the doctrines of Hunter, and has been practically recognized by a host of English practitioners. A due appreciation of it has, moreover, led to very valuable results in practice. It has taught us to look beyond the mere appearance of things; to trace morbid actions up to their remote origin or source; and thus to arrive at more rational and successful modes of treatment. Upon this principle, we are often able to connect local diseases with causes with which at first they would appear to have but little connexion, and the application of this doctrine is daily becoming more extended, as our knowledge of the nervous system and of physiology generally is ad-

vanced. "I must confess," says Sir Benjamin Brodie, "that, in proportion as I have acquired a more extended experience in my profession, I have found more and more reason to believe that local diseases, in the strict sense of the term, are comparatively rare. Local causes may operate so as to render one organ more liable to disease than another; but everything tends to prove, that in the great majority of cases there is a morbid condition, either of the circulating fluid or of the nervous system, antecedent to the manifestation of disease in any particular structure. Moreover, even in those cases in which a disease may be distinctly traced to some kind of mechanical injury, the character which it assumes depends as much on the state of the general health as on the injury itself."[1] By substituting for the general terms here employed, those which are significant of the particular diseases under consideration, we have in this passage those opinions clearly expressed, which it is the principal object of this paper to elucidate.

In considering how far this purpose could be best attained, and the relations of uterine to constitutional disorder most correctly determined, it has occurred to me to take a given number of uterine cases, to tabulate their principal antecedents and concomitants, and to observe their order, connection, and sequence. The subjoined table has been framed upon this plan; but I am aware that in constructing it I have not attained that degree of accuracy in its details which could be wished, and which is so necessary in inquiries of this kind. In questioning patients as to their state of health antecedently to any particular malady, it is extremely difficult to obtain from them satisfactory information. On casual inquiry, they will often say that they had been perfectly well, when, on further questioning, they will admit that they had been far otherwise. In soliciting information from patients respecting their maladies, I am also aware that the inquirer is apt to put questions which are calculated to elicit partial information, and such as may be favourable to certain preconceived views. This error I have also endeavoured to guard against in taking the histories of the cases from which this table is constructed, and I have sought to obtain the real facts connected with them, without being influenced by any particular bias. Indeed, when I commenced these inquiries, I had none whatever; and any opinions I may now entertain on the subject of uterine diseases, have entirely resulted from a consideration of facts which have come under my observation. Some of these I have endeavoured to analyse and embody in the subjoined table, in the hope that they may serve to throw some additional light upon the pathology and early history of uterine disorders. I have selected a hundred cases, because that number appeared to me to be sufficient to form a basis for comparison. I could have extended the number, but it did not appear to me that my object would have been materially advanced by doing so.

[*Table*

No.	Name.	Age	Uterine Disorder.	Antecedents.	Concomitants.
1	E. S.	69	Carcinoma, metrorrhagia	Long continued mental anxiety, dyspeptic symptoms, nervous derangemt.	Gastro-hepatic and intestinal disorder, asthenia
2	I. O.	21	Dysmenorrhœa, leucorrhœa	General ill health, nervous depression & weakness, dyspeptic symptoms	Dyspepsia, with marked hepatic and intestinal derangement
3	C. G.	40	Carcinoma, metrorrhagia	Severe trouble, mental uneasiness, marked dyspepsia, nervous prostratn.	Anæmia in a marked form, with gastro-intestinal disorder
4	H. P.	45	Hysteralgia	Mental anxiety and trouble, dyspepsia, and gastrodynia	Well-marked dyspeptic symptoms, and spinal irritation
5	S. S.	39	Metrorrhagia abortus	Great ment. uneasiness, agitation, dyspeptic symp.	Anæmia and derangement of digestive organs
6	S. C.	25	Leucorrhœa, dysmenorrhœa	Over fatigue, disturbed sleep, nervous prostration, dyspepsia	Anæmia, spinal irritation, hysteria, dyspeptic symptoms
7	M. L.	17	Leucorrhœa	Weakness, nerv. prost., and dyspeptic symptoms	Anæmia, gastro-hepatic derangement
8	E. S.	25	Profuse leucorrhœa, dysmenorrhœa	Much mental uneasiness, languor, and general weakness, dyspept. sympt.	Anæmia and general derangement of the digestive system
9	S. G.	38	Hysteralgia, leucorrhœa, dysmenorrhœa	Mental uneasiness, dyspeptic sympts., gen. weakness, ill health, rheumat.	Anæmia, gastro-intestinal derangement, nervous headaches
10	A. W.	34	Leucorrhœa	Bad health generally, dyspepsia	Nervous debility and dyspepsia
11	M. S.	49	Metrorrhagia, carcinoma	Severe & long continued mental anxiety, dyspepsia	Anæmia, severe dyspepsia, spinal irritation
12	M. M.	36	Leucorrhœa	General weakness and ill health, dyspepsia	Anæmia, dyspept. symptoms, severe gastrodynia
13	M. C.	26	Leucorrhœa, menorrhagia	Derangement of the digestive organs.	Derangement of the digestive organs
14	J. W.	21	Leucorrhœa	Hæmorrhage post part., gastro-intestinal disorder	Anæmia, asthenia, gastro-intestinal disorder
15	C. W.	36	Leucorrhœa, menorrhagia	Long-continued dyspepsia.	General derangement of the digestive organs
16	E. S.	22	Hysteralgia, leucorrhœa	Dyspepsia, much intestinal derangement	Anæmia, spinal irritat., gastro-intestinal disorder
17	S. K.	25	Hysteralgia, irreg. menstruation, leucorrhœa	Weakness, nervous depression, and dyspepsia	Anæmia, disorder of the stomach and digestive organs
18	E. C.	23	Leucorrhœa, amenorrhœa	Over fatigue, physical exhaust., dyspeptic symp.	Anæmia, gen. debility, gastro-intestinal disorder
19	C. B.	33	Leucorrhœa, hysteralgia	Protracted suckling in the case of two children, dyspep. symps., weakness	Anæmia and severe dyspepsia
20	M.A.H	31	Leucorrhœa	Bleeding and salivation for pleurisy, hæmorrhage post partum, dyspepsia	Well-marked anæmia, gastro-intestinal disorder
21	M.A.P.	24	Leucorrhæa	Anxiety, trouble, dyspep.	Anæmia, dyspepsia
22	R. L.	22	Amenorrhœa	Residence in a damp and unhealthy situation, gen. debility and dyspepsia	Anæmia, feverishness, dyspeptic derangement, bronchocele
23	E. E.	21	Metrorrhagia hysteralgia	Labour two months ago, the digestive organs subsequently disordered	Anæmia, marked disorder of the stomach and digestive organs
24	M. W.	36	Irritable uterus	Difficult labour, attended and followed for some time by hæmorrhage, extreme weakness, dyspeps.	Anæmia in a severe form, great derangement of the stomach and digestive organs

No.	Name.	Age	Uterine Disorder.	Antecedents.	Concomitants.
25	M.A.H	31	Leucorrhœa	General ill health and weakness, dyspepsia	Anæmia, disorder of the stomach & digestive orgs.
26	M.A.B.	15	Amenorrhœa	General weakness and nervous prostration	Well-marked anæmia, disord. stom. & digest. org.
27	E. M.	30	Leucorrhœa, hysteralgia	Several labours attended with much loss of blood, gen. weakness, prostration	Anæmia, dyspepsia, piles, and hæmatemesis
28	M.A.M	23	Leucorrhœa	Weakness, nervous symptoms, dyspepsia	Anæmia, considerable disorder of the stomach, and digestive organs
29	C. P.	30	Uterine hæmorrhage at the 7th month of preg.	Anxiety and uneasiness of mind, dyspeptic symptoms	Sickness and great disorder of the stomach and digestive organs
30	M. R.	17	Amenorrhœa	Weakness and dyspepsia, much disorder of the stomach and bowels	Anæmia, great disorder of the stomach and digestive organs generally
31	A. S.	40	Irregular menstration and leucorrhœa	General ill health, prostration, disordered stomach and bowels	Anæmia, diarrhœa, much chylopoietic derangement
32	E. J.	44	Hysteralgia, leucorrhœa	A very severe illness, weakness, nervous symptoms, dyspepsia	Anæmia, asthenia, and dyspepsia
33	E. J.	51	Leucorrhœa	Much trouble & anxiety, bad living, tongue long disordered	Weakness, dyspepsia, nervousness
34	E. K.	44	Metrorrhagia	Severe attack of cholera, subsequently pregnancy, attended with much weakness and gastro-intestinal disorder	Extreme anæmia, marked disorder of the stomach and digestive organs, nervous symptoms
35	S. Y.	50	Leucorrhœa	Much anxiety of mind, dyspepsia	Bad gen. health, disordered stomach, nervous symptoms, rheumatism
36	E. W.	25	Hysteralgia, leucorrhœa	Weakness, languor and nervousness, bad health, much disorder of stomach and bowels	Anæmia, great disorder of the stomach and digestive organs
37	S. M.	30	Hysteralgia, leucorrhœa	Mental anxiety, over fatigue, languor, weakness, and depression	Anæmia, disorder of stomach and digestive organs, spinal irritation
38	M. M.	21	Scanty menstruation, leucorrhœa	Bad general health, nervous symptoms, weakness, bad morning tongue	Anæmia, disorder of stomach and digestive organs
39	S. S.	20	Leucorrhœa	Weakness, nervous symptoms, dyspepsia	Anæmia, disord. stom., and digestive organs
40	E. M.	27	Hysteralgia, leucorrhœa	Dyspepsia	Anæmia, disord. stom., and digestive organs
41	M. T.	25	Leucorrhœa	Rheumatic complaints	Anæmia, rheumatism
42	J. S.	35	Hæmorrhage post partum	Mental excitement, rheumatism	Anæmia, and rheumatism
43	A. D.	40	Suppres. mens., hysteralgia, leucorrhœa	Acute disorder of stomach and digestive orgs. prior to menstruation	Great derangement of the stomach and digestive organs
44	M. S.	37	Hysteralgia, leucorrhœa	Weakness, nervous symptoms, and dyspepsia	Anæmia, disorder of stomach & digest. organs
45	J. J.	38	Suppres. mensium	Irregular menstruation, four very difficult labours, each attended with considerable flooding, mental anxiety, and indigestion	Anæmia, much disorder of the stomach and digestive organs

No.	Name.	Age	Uterine Disorder.	Antecedents.	Concomitants.
46	A. B.	18	Suppressio mensium	Irregular menstruation, general weakness and prostration, dyspepsia	Anæmia, much disorder of the stomach and digestive organs
47	M.A.N	18	Amenorrhœa, leucorrhœa, hysteralgia	Always had indifferent health, had small-pox at 12, has never been well since; weakness, and a bad tongue on awaking	Anæmia, great disorder of the stomach and digestive organs
48	M. C.	53	Leucorrhœa	Dyspeptic symptoms, rheumatic attacks, weakness, and gen. ill health	Anæmia, disorder of digestive organs, rheumatism
49	M. B.	21	Menorrhagia	Disorder of the stomach & digest. organs brought on by sea-sickness	Very great disorder of the stomach and digestive organs generally
50	J. V.	38	Metrorrhagia, fibrous enlarge. of uterus reaching to umbilicus	Considerable mental anxiety, constitutional weakness, occasioned by cholera, dyspeptic symps.	Marked anæmia, disorder of stomach and digestive organs
51	S. W.	34	Hysteralgia, dysmenorrhœa, leucorrhœa	Protracted suckling, weakness, dyspepsia	Anæmia, disorder of stomach and digestive organs
52	M. A.	32	Hysteralgia, menorrhagia, leucorrhœa	Bad general health, weakness, dyspepsia	Anæmia, disorder of the digestive organs generally, spinal irritation
53	M-A-W	23	Hysteralgia, suppres. mens., leucorrhœa	Protracted suckling, general weakness and prostration, dyspeptic symptoms	Anæmia, much disorder of the digestive organs generally
54	E. L.	25	Hysteralgia, dysmenorrhœa, leucorrhœa	Much mental anxiety, bad general health, weakness, and dyspepsia	Anæmia, disordered stomach and digestive organs, spinal irritation
55	A. H.	38	Irreg. menstruation, profuse leucorrhœa	Anxiety and trouble	Anæmia, general weakness and prostration, disorder of digestive organs
56	J. T.	38	Irregular menstruation, profuse leucorrhœa	Mental uneasiness, long residence in a tropical climate, general prostration, and dyspepsia	Marked anæmia, and great disorder of the digestive organs
57	P.W.	35	Hysteralgia	Mental uneasiness, much disorder of the stomach and bowels	Asthenia, depression, great disord. of stomach & digest. orgns., spinal irrit.
58	C. W.	31	Hysteralgia, dysmenorrhœa, leucorrhœa	Mental anxiety and trouble, five very difficult labours, preceded by much disorder of digest. organs	Anæmia, spinal irritation, great disorder of the digestive organs
59	E. S.	23	Irregular menstruation, leucorrhœa	Never had good health, menstruated at 18, previously to which, and subsequently, the digestive organs have been disordered; 16 months ago was much frightened, uterine ailments have been much aggravated since	Anæmia, dyspeptic symptoms, intestinal disorder, spinal irritation
60	S. M.	20	Hysteralgia, irreg. menstru., leucorrhœa	Anxiety and mental excitement, dyspeptic symptoms	Anæmia, disordered stomach and digestive organs, spinal irritation
61	S. H.	32	Metrorrhagia, miscarriage	Anxiety, dyspeptic symptoms, weakness, and nervous depression	Anæmia, disorder of the digestive organs

No.	Name.	Age	Uterine Disorder.	Antecedents.	Concomitants.
62	M.A.H	30	Dysmenorrhœa, leucorrhœa	Bad general health, depression, dyspepsia	Anæmia, disor. of digest. orgs., gen. weakness and depress., spinal irritation
63	R. G.	24	Metrorrhagia	Two months after labour, attended and preceded by much mental anxiety, dyspepsia	Anæmia, disorder of the digestive organs
64	L. F.	36	Hysteralgia, dysmenorrhœa, leucorrhœa	General health very bad, anxiety & trouble, dyspepsia, weakness, depression	Anæmia, disorder of digestive organs, spinal irritation
65	M.A.B.	17	Amenorrhœa	Bad health, anxiety, great fatigue, dyspepsia, weakness, and depression	Great disorder of digestive system, intense anæmia, nervous symptoms, and spinal irritation
66	E. M	21	Hysteralgia, leucorrhœa	Weak, low, and generally out of health	Anæmia, disorder of digest. organs, & spinal irrit.
67	A. B.	36	Irregular and painful menstruation	Bad general health, anxiety & trouble, weakness and depression	Anæmia, great derangement of the digestive organs, and prostration
68	S. W.	27	Profuse leucorrhœa and dysmenorrhœa	Very bad health, dyspepsia	Anæmia, dyspepsia, dysuria
69	E. P.	28	Menorrhagia, leucorrhœa	Great weakness & very bad health, anxiety of mind and dyspepsia	Anæmiated, disorder of digestive organs, spinal irritation
70	M. N.	43	Hysteralgia, dysmenorrhœa	Very bad health, much ment. anxiety, dyspepsia, very difficult labour	Anæmia, disorder of digestive organs, spinal irritation
71	E. E.	27	Hysteralgia, irreg. menstrua., leucorrhœa	Weakness and depression	Anæmia, disorder of digestive organs
72	S. W.	45	Hysteralgia, leucorrhœa	Great anxiety, very bad health, and severe labour	Anæmia, disorder of digest. organs, spinal irrit.
73	S. N.	26	Hysteralgia, irreg. menstrua., dysmenorrhœa	Bad health, dyspepsia	Anæmia and disorder of the digestive organs
74	S. W.	33	Hysteralgia, profuse leucorrhœa, dysmenorrhæa	Great mental anxiety, hæmorrhages after labours, general prostration	Anæmia, disorder of digestive organs, spinal irritation, hysteria
75	E. N.	28	Hysteralgia, dysmenorrhœa	Much anxiety, bad health, dyspepsia	Anæmia, disorder of digest. organs, spinal irritat.
76	A. A.	23	Amenorrhœa	Weakness, gen. deprsn. disorder of digest. organs	Anæmia, marked disorder of digestive organs
77	J. C.	29	Profuse leucorrhœa, dysmenor.	Excessive fatigue, depression, and dyspepsia	Anæmia, disorder of digestive organs
78	E. H.	26	Hysteralgia, irreg. menstrua., profuse leucor.	Bad general health	Anæmia, asthenia, disorder of digestive organs
79	M.A.H	37	Hysteralgia, fibrous enlargement of cervix	Mental anxiety, weakness, and depression	Anæmia, dyspepsia, spinal irritation
80	C. G.	27	Irreg. & painful menstruation, leucorrhœa	Very bad health, weakness, and gastric disorder	Anæmia, derangement of digestive organs very marked
81	S. H.		Scanty & painful menstrua., profuse leucorrhœa	Scrofulous disease, general prostration	Anæmia, gastrodynia, and dyspepsia
82	E. H.	17	Amenorrhœa	Weak, nervous, and generally out of health	Anæmia, disorder of digestive organs

No.	Name.	Age	Uterine Disorder.	Antecedents.	Concomitants.
83	E. A.	31	Irregular menstruation, hysteralgia, leucorrhœa	Over fatigue, mental agitation, dyspepsia	Derangement of the digestive organs
84	L. C.	43	Hysteralgia, dysmenorrhœa	Mental anxiety, hysteria, dyspepsia, weakness	Anæmia, hysteria, dyspepsia, spinal irritation
85	S. D.	27	Leucorrhœa	Bad health, weakness, and dyspepsia	Anæmia, disorder of the digestive organs
86	M.A.H	26	Scanty & painful menstruation	Bad health	Anæmia, marked dyspepsia
87	S. S.	35	Irreg. & painful menstruation, leucorrhœa	Bad health, weakness, and nervous symptoms	Anæmia, disorder of digestive organs, nervous symptoms
88	M. G.	37	Hysteralgia, dysmenorrhœa, leucorrhœa	Weakness, depression, and gastric disorder	Anæmia, and derangement of digestive organs
89	M.A. B	34	Hysteralgia, leucorrhœa	Severe labour, preceded by bad health and gastric disorder	Asthenia, general disorder of digestive organs
90	M.A. B	34	Profuse and persistent menorrhagia, recurring frequently for years, fibrous enlargement of the neck and body of the uterus	Long continued derangement of the stomach and digestive organs; severe flooding after labour	Anæmia, considerable disorder of the stomach and digestive organs, nervous symptoms
91	J. K.	18	Irregular, scanty, and painful menstruation	Bad health, and derangement of digestive organs	Anæmia, nervous symptoms, and great disorder of digestive organs.
92	E. W.	25	Dysmenorrhœa, profuse leucorrhœa	Bad health, depression, dyspepsia	Anæmia, nervous symptoms, and disorder of digestive organs
93	A. E.	23	Dysmenorrhœa,	Bad health, dyspepsia	Anæmia, dyspept. symptoms, spinal irritation
94	M.S.R.	40	Metrorrhagia, fibrous enlargm. of neck and body of the uterus	Mental anxiety, weakness and depression, long continued disorder of digestive organs	Anæmia, great derangement of the stomach and digestive organs
95	E. J.	30	Irregular and often excessive menstruation, leucorrhœa	Much mental uneasiness, impaired general health, dyspeptic symptoms	Anæmia, depression, disorder of digestive organs
96	J. J.	24	Dysmenorrhœa, leucorrhœa	Weakness and bad health, dyspepsia	Anæmia, dyspepsia
97	J. I.	26	Hysteralgia, dysmenorrhœa, leucorrhœa	Bad health and debility, depression, dyspepsia, & nervous symptoms	Anæmia, dyspepsia, and nervous symptoms
98	M. O.	26	Irregular and very scanty menstruation	Mental uneasiness, occasioned by leaving home, weakness and nervous symptoms, dyspepsia	Intense anæmia, marked disorder of the stomach and digestive organs
99	M.F.S.	19	Metrorrhagia, leucorrhœa	Weakness, nervous symptoms, dyspepsia	Anæmia, very marked derangemt. of digest. org.
100	M.E.B	27	Menorrhagia and severe leucorrhœa	Previous miscarriage, long continued derangement of digestive organs	Anæmia, and very severe derangement of digestive organs

On analysing this table, it will be found to comprehend thirty-seven cases in which the uterus was morbidly irritable; fifty-two cases of disordered menstruation; sixty-five of leucorrhœa; and seven of organic disease. These affections were variously blended in different cases; and, upon the whole, it may be said to be rare for any uterine disorder to be met with in a perfectly isolated form. Irritable affections, for instance, are generally associated with either menstrual or leucorrhœal disorders. Menstrual disorders seldom occur without leucorrhœal discharges, or some other kind of uterine derangement; whilst leucorrhœa is so frequent a concomitant of all morbid conditions of the uterine organs, whether functional or organic, that it can scarcely be regarded in the light of an idiopathic disease. With regard again to antecedents, the table points to the fact, that in nearly all the cases some derangement of the general health preceded the uterine disorder. The occurrence of languor, weakness, and depression, would show that there had been antecedent disturbance of the nervous system. The digestive organs must have been disordered in the majority of these cases, whilst the symptoms referable to the nervous and muscular systems would tend to show that there was probably some abnormal condition of the circulating fluid. In looking to the concomitant affections, again we observe that a disordered condition of the chylopoietic organs is very frequently, if not invariably, met with; that anæmia presents itself concurrently with uterine derangement in a large proportion of such cases, amounting to nine-tenths of those which are contained in the table. Spinal irritation was met with in thirty-six cases out of the hundred, and would appear to have important relations to uterine disease. The general inference, then, deducible from these facts, is, that uterine disorder is for the most part preceded by constitutional derangement, and that this is more especially referable to the nervous system, the digestive organs, and the blood; and that various morbid conditions in respect of these present themselves, either as complications or concomitants of most uterine affections.

But let it be understood, that however uterine disorder has arisen, it may continue long after the exciting causes shall have passed away; may assume the character and importance of an idiopathic affection; and, as such, be the cause of various secondary disorders. A healthy female, for instance, receives a severe fright during menstruation, which is immediately followed by suppression, and this may continue for some time, even for months: here the disturbing cause was evidently mental, momentary, and transient,—not so the effect; and this, so long as it continues, may be a source of embarrassment to the constitution, and the immediate cause of secondary disease of other organs, which again, by reacting upon the uterus, would tend to perpetuate or maintain a state of irritation which is unfavourable to the return of healthy functional action. But in other cases, uterine derangement originates in causes of a more permanent nature, as in the instance of disorder of the chylopoietic organs; which, whilst on the one hand a prolific cause of it, is on the other, often a persistent malady,—often continuing for years, and that, too, in despite of every available mode of treatment. Now, should the uterine organs fall into a state of irritation or disorder, as a consequence of this, it must follow that such irritation or disorder will be equally protracted and difficult of cure:—nay more,

vascular disease will sooner or later supervene upon such irritative disorder, and thus increase the difficulties of the case, independently of its being aggravated and perpetuated by the continuance of its original cause. These circumstances show the necessity of regarding uterine diseases in a comprehensive manner; but they do not militate against the correctness of the views which I have ventured to express, and which I shall now proceed to illustrate.

THE ORIGIN OF UTERINE DISEASE FROM DISTURBED STATES OF THE NERVOUS SYSTEM must be generally admitted, and every practitioner must be cognisant of cases in which it has arisen from such causes. Severe mental emotion, shock, or affliction, will, it is well known, give rise to painful uterine affections, to interrupted, excessive, or irregular menstruation, miscarriage, or premature labour; and if such consequences follow such causes, it is reasonable to conclude that causes of a similar but less violent nature will equally give rise to slighter but no less certain deviations from normal uterine action. This, indeed, is in reality the case, and many instances of uterine disease may be traced to the continued influence of grief, anxiety, and other uneasy states of mind. But the nervous system may be disturbed in many other ways, by various pursuits, by residence in an unhealthy situation, by insufficiency of food, over fatigue, and other physical causes, which tend to depress the constitution and lower the tone of the nervous system. And here also the uterine organs may suffer; for in whatever way nervous influence is withheld, whether from defective or irregular supply, such parts being inadequately supplied with nervous energy, will either take on irregular actions, or become morbidly susceptible to disturbing influences.

The recent researches of Dr. Robert Lee, in regard to the nerves and ganglia of the uterus, are of extreme interest in a practical point of view, as tending not only to show how great is the amount of nervous energy possessed by that organ, but as serving to explain the cause of that intimate sympathy which exists between it and other organs of the body, a circumstance upon which so much of its physiological as well as pathological conditions depend. It would not be inconsistent with the views of modern physiologists to attribute to those ganglia and nerves important bearings upon the subject of uterine pathology, regarding them as we must as nervous centres, which, under the influence of certain stimuli, give rise to corresponding actions, either conducive to health or disease, according to the character of the impressions which are received. In speaking of the nervous ganglia generally, a recent writer observes, "that they are nervous centres, which probably receive through afferent fibres impressions of which we are unconscious, and reflect these impressional stimuli upon afferent motor fibres; that perhaps motorial stimuli emanate from them; the movements excited by, or through the ganglia, being always involuntary, and affecting chiefly the muscular parts of the viscera, the sanguiferous, and perhaps absorbent vessels, and that in fine, the chief purpose served by the ganglia and ganglionic nerve fibres, is to govern the involuntary, and, for the most part, imperceptible movements of nutrition, so far at least as these movements are not dependent upon the brain and spinal cord."[1]

[1] QUAIN'S Anatomy; Edited by Dr. Sharpey and Mr. Quain, p. ccxxiii.

Consistently with these views, then, it may be assumed, that so long as the uterine ganglia receive, through afferent fibres, impressions of a normal character, so long will normal ganglionic actions ensue, giving rise to healthy uterine action, both in regard to function and structure; whilst on the other hand, impressions of an abnormal character will excite ganglionic actions equally subversive of both. The *modus operandi*, then, of disturbed states of the nervous system, irritative conditions of the nervous centres, and disorders of remote organs, in the causation of uterine disease, is either by the uterine ganglia participating in such states of disorder, or receiving impressions which tend to morbid actions. Regarded, then, in this point of view, we cannot be surprised that the majority of causes which tend to uterine disturbance should have a constitutional rather than a local origin; for whatever impressions are made upon the body, whether through the mind or otherwise, which are capable of being reflected upon the uterine ganglia, and are calculated to excite morbid actions, are so many ways in which uterine disorder or disease may be induced. Examples of this occur in all uneasy states of mind, in irritative disorder of organs with which the uterus has sympathetic relations, and in abnormal conditions of the blood; and if it is the case that uterine disturbance most frequently arises from such causes, it cannot be expected that it should cease, so long as the conditions upon which it depends continue.

In connexion with the nervous system, there is no subject of greater interest or importance than the influence of the mind, or rather of certain uneasy or emotional states of mind, in giving rise to uterine derangements; and there is none which it is more necessary to study and appreciate fully in all its bearings. In regard to pregnant women, the effect of sudden or severe emotion has been often of a very serious nature; such as the death of the *fœtus in utero*, many alarming sensations, and abortion, miscarriage, or premature labour, according to the period of pregnancy. Should the child's life be spared, it has been born deformed, idiotic, maimed, or disfigured, whilst parturition itself has been seriously compromised. These circumstances are, however, well known to the profession, and need not be illustrated by any particular instances. But the effect of severe mental emotion upon the non-pregnant female is often equally serious, although less frequently observed; and there is scarcely a functional disorder of the uterus which may not, and has not been, occasioned by it. Thus Baudelocque reports that sixty-two women were attacked with uterine hæmorrhage, or suppressions, upon the occasion of the explosion of the powder magazine of Grenelle. M. Husson gives the case of a woman who, at several different times, was attacked with menstrual suppressions under the influence of claps of thunder. M. Colombat observed, in July 1830, that the reports arising from the platoon firing and cannon shot produced the same effect in several women. He also states, that a relation, whose menstruation was ordinarily very regular and abundant, was attacked with a sudden suppression, in consequence of a frightful dream, a kind of nightmare. With regard to menorrhagia, again, it is well known, that all circumstances capable of imparting a sudden shock to the ennervation, such as joy, grief, anger, fright, have been its causes: and M. Alibert relates the case of a female who,

whenever she gave way to transports of passion, was attacked with violent hæmorrhage from the uterus (see Meigs *on the Diseases of Females*). I have myself reported cases in which hysteralgia arose from sudden fright.

But the influence of less violent perturbations of mind, of anxiety, grief, affliction, etc., although productive of less marked results, are equally the cause of many uterine maladies; and although such states of mind in themselves do not admit of a direct cure by medicine, it is yet possible to do much by studying the nature, order, and sequence of the morbid actions to which they give rise. In some cases of this kind, the uterine organs would appear to receive a direct impression from the brain of a disturbing character, and uterine derangement to follow, without the intervention of any other organ or agency; and this is especially the case in the instance of sudden shock or emotion. But in other instances, and more particularly where the mental affection has been of a less violent nature, it would seem that other organs were disturbed, either concurrently with the uterus, or altogether independently; and the consequences differ accordingly. In the first of these cases, it will generally happen, that the uterine disorder, and that concurrently produced, will reciprocally react upon one another; and this reciprocal reaction, while it gives increased intensity and persistency to each, will at the same time disturb the constitution in a proportionate degree. In the second case, where the mental uneasiness, etc., is principally or entirely reflected upon some organ, it will often happen that the disorder thus produced will become the immediate cause of uterine derangement, either by a sympathetic or reflected operation; and in this respect it has appeared to me, from many facts which have come under my observation, that the spinal cord, or rather its ganglia, have important relations to uterine pathology. Spinal irritation is, as I believe, a frequent consequence of mental uneasiness, shock, or emotion, and at the same time, when so produced, a frequent cause of uterine disturbance; and it is to spinal irritation thus induced and productive of uterine disorder that I would more particularly wish to draw attention, as exemplifying in one form the relations which exist between uterine and constitutional disorder.

The existence of spinal irritation as a distinct and idiopathic affection, whether dependent upon mental or other causes, has been altogether denied by some writers, while it has been doubted by others. In speaking of it, Dr. Abercrombie remarks, that "it may be doubted whether it conveys any definite notion, or whether it is not to be considered as a gratuitous principle assumed so as to answer to the phenomena, rather than deduced from observation". But, with all the deference and respect due to so high an authority, it must be added, that the truth of the doctrine has been affirmed by many eminent practitioners, and so many facts have been accumulated in support of it, that it is impossible to doubt its reality, however difficult it may be of explanation. I shall, in the first place, state the grounds upon which I consider it entitled to be ranked as a distinct affection, and then those which point to its connexion with mental causes on the one hand, and uterine derangement on the other.

The subject of spinal irritation was first noticed by Mr. Pleyer, of

Malmesbury, in the twelfth volume of the *Quarterly Journal of Science;* and his attention would appear to have been first directed to it, from observing that the symptoms of spinal disease frequently resemble various and dissimilar maladies, and that commonly the function of every organ is impaired whose nerves originate near the seat of disorder. The occurrence of pain in distant parts particularly attracted his attention, and induced frequent examinations of the spinal cord, and the results of his investigations is given in the following words: "After some years' attention, I consider myself enabled to state, that in a great number of diseases, morbid symptoms may be discovered about the origins of the nerves which proceed to the affected parts, or of those spinal branches which unite with them; and that if the spine be examined, more or less pain will commonly be felt by the patient on the application of pressure about or between those vertebræ from which such nerves emerge. If disease is confined to one side of the body, or one arm, or one leg, this tenderness will be felt on the *same side* of the spine *only;* but if central parts, or *both sides* of the body, or both arms or legs, are diseased, tenderness will be felt on *both sides* of the spine. This symptom has been found to attend various other affections. This spinal affection may, perhaps, be considered as the *consequence* of diseases, but of its existence at their *commencement* any person may satisfy himself; and this circumstance, combined with the success which has attended the employment of topical applications to the tender parts about the vertebræ, appear to indicate that the *cause may* exist there."

The correctness of these observations has been attested by many subsequent writers, and more particularly by Dr. Brown, Dr. Darwall, Mr. Teale, and the Messrs. Griffin, the latter of whom have given us the result of their investigations upon the subject in a work on the functional affections of the spinal cord and ganglionic system of nerves, which contains the most complete and elaborate account of the phenomena resulting from spinal irritation that has yet been published. More recently the matter has been treated of by Dr. Todd, in an article in the *Cyclopædia of Practical Medicine*, and he has endeavoured to show that anatomy affords some support to the doctrine. He particularly insists that it is unfair to deny the previous existence of compression, or irritation of the spinal cord, or of the spinal nerves at their origins, because the anatomist cannot detect any vestige of disease after death; he points out that the spinal cord and the nerves which emerge from it, are surrounded by a venous anastomosis of remarkable complexity, that these veins do not possess valves, that they communicate freely with the superficial veins and with the numerous muscular veins in the region of the back; and from these anatomical considerations he infers, that such a degree of congestion or turgescence of this spinal venous plexus may easily occur as will excite irritation at the origins of the spinal nerves, and that such congestion may exist *ante mortem* without leaving any trace of it *post mortem*. These facts certainly meet many of the objections which present themselves to the reception of spinal irritation as a distinct pathological affection. For, if spinal congestion is so ready a consequence of irritation of the cord, the phenomena it presents, and its mode of causation, do not essentially differ from the usual consequences of irritative

disorder of other organs. The doctrine of venous congestion, as explanatory of the phenomena of spinal irritation, accords well with many pathological facts which have been observed in connexion with it. Thus it is most frequently met with in persons who are weak and anæmiated, in those whose general health has been impaired, and thus in those in whom the circulation must be languid and favourable to the occurrence of venous congestion. It is at the same time most successfully treated by measures which improve the health, the tone of the nervous system, and the vigour of the circulation.

But, notwithstanding these circumstances, there are many who deny the existence of spinal irritation as a distinct pathological affection, and regard it, when present, rather as an accident or a casualty than as an independent lesion; and it must be admitted that it is difficult to establish the affirmative of this question; first, because the exact nature of spinal irritation has not, as yet, been satisfactorily determined; and secondly, because *post-mortem* examinations have not hitherto thrown any light upon it. But these objections do not appear to me to be by any means fatal to the doctrine; for there are many diseases, and more especially of the nervous system, the reality of which cannot be doubted, the nature of which is yet obscure, and in regard to which *post-mortem* investigations have elucidated nothing. Let us look, for instance, to tetanus, hydrophobia, and some forms of epilepsy. This spinal affection, moreover, is admitted to be functional, to be one which does not lead to fatal consequences, and therefore one the nature of which cannot be determined by *post-mortem* inquiries. But admitting these difficulties, it may be replied, that the history of these cases, their symptoms, and more particularly the effect of remedies, point conclusively to the reality of spinal irritation as a distinct pathological condition. A female, perhaps in delicate health, receives a sudden fright or shock, which is followed, either immediately or remotely, by uterine symptoms. The spinal column is examined, and tenderness found in the lumbar or sacral region: possibly no other organic lesion is discoverable: and in this case the application of a sinapism or of some other counter-irritant to the tender portion of the spine is followed by a cessation of the uterine symptoms, without any other kind of treatment. Here it must be obvious, that some state of the spinal cord existed, upon which the uterine malady depended, unless, indeed, such an occurrence were rare and accidental. But that it is not so, is proved by the frequency with which such cases are met with; and of which I subjoin the following as examples.

Case. Mary Ann Davies, aged 20, a healthy young woman, rather more than eight months advanced in pregnancy, received a sudden fright, on the 18th September; labour pains came on shortly afterwards, and, at half-past two the next morning, she was safely delivered of a living child. She went on very well after her labour for the first twenty-four hours, but afterwards became feverish, her digestive organs disordered, and she was seized with severe pain in the uterus, which had continued for many hours persistently before I saw her. On examining the spine, there was well-marked tenderness in the lumbar and sacral region. A sinapism was directed to be applied to this part, and the uterine pain disappeared shortly afterwards. The only medicine given was an alterative dose of blue pill.

Case. Ann Keane, aged 20, had nearly reached her full period of pregnancy, when she was frightened: no particular symptoms occurred for some days, but on the eighth day uterine hæmorrhage took place; this was not found on examination to be connected with placental presentation, nor had the labour apparently commenced. After continuing for six hours rather profusely, it ceased; and twenty-four hours afterwards labour came on, and she was in about eight hours safely delivered of a healthy child without any particular loss of blood. Some hours after this, she complained of much uterine uneasiness, and on examining the spine, it was found very tender in the sacral region. The uterine pain disappeared on applying a sinapism, and there appeared to be no other cause for it or the hæmorrhage than the irritable state of the spine.

Case. Harriet Benjou, aged 19, applied at the Paddington Free Dispensary, suffering from amenorrhœa and leucorrhœa; the former was brought on by a fright, and since the suppression she had suffered from headache and nervous symptoms, with much derangement of the stomach and digestive organs. On examining the spine, there was decided tenderness in the lumbar and sacral regions; tartar emetic ointment was directed to be rubbed over the tender part, and, after four or five applications, a good deal of cutaneous irritation was produced, which was immediately followed by cessation of the leucorrhœa.

Mr. Teale, in his treatise on neuralgic diseases, gives several cases of an analogous though more general character, of which the following may be quoted.

Case. Mr. L., aged 26, complained of a feeling of indisposition, having suffered for a few days from stiffness in the neck and pain at the back of the head, extending laterally to the ears and upwards over the back part of the scalp; he perspired much at night; felt languid and unable to attend to business; about four weeks before, he was exposed to wet and cold, and had ever since been affected with these symptoms. On pressing the spine, there was tenderness over the first cervical vertebra, but no pain was produced by firm pressure upon any other part of the spine. Leeches were applied to the neck; and it was stated that the pains in the scalp were immediately relieved on their application.

Case. In another case, a lady, a week after her confinement, complained of pain in the head, occurring in the afternoons in a violent degree. It was described as a dull aching pain, principally seated in the occipital region, but extending from that part over the parietal bones; towards the temples, and in the neighbourhood of each ear, there was a small space more acutely painful than the rest. There were also pains darting over the scalp and along the upper part of the neck. She complained of violent pulsating sensations in the head, accompanied with distressing sounds, which she compared to the beating of hammers. Leeches had been applied to the temples, but without benefit; the spine was examined, and it was found extremely tender over the two upper cervical vertebræ. Leeches were applied to this spot, and it is reported that they gave immediate relief, and that no further return of the paroxysms was experienced.

Such cases as these are sufficiently simple, and for the most part require only that proper measures should be directed to the spine to

effect a cure. But it more frequently happens that spinal irritation is met with in conjunction with disorder of some other organ, which equally tends to keep up uterine derangement, and thus equally requires to be looked for and corrected. In this respect, derangement of the digestive system is a very frequent concomitant, and would appear to have a similarity of origin in many instances. In this case, if the concomitant affection is not duly attended to, any measures directed to the spine will fail of their anticipated benefit. The following cases illustrate this connexion and the results of treatment.

Case. Elizabeth Brown, aged 31, when about four months advanced in pregnancy, received a severe fright, which occasioned her almost to faint away. From the date of this occurrence, she began to feel many uneasy feelings in the stomach and womb, such as she had never had before in any of her six previous pregnancies. At times her sensation was that of extreme distension of the abdomen, as if it would burst; at other times she felt severe uterine pains, with occasional forcing sensations extending to the hips, back, and thighs. The digestive organs were much disordered, the tongue was unpleasant on awaking of a morning, the appetite was uncertain, and the bowels were sometimes costive, and at other times relaxed. On examining the spine, there was well-marked tenderness over the sacral region; indeed, pressure here brought on pain in the uterus. She was directed to apply sinapisms daily to the region of the sacrum, and mild alteratives with aperients were prescribed. In little more than a week her uneasy feelings had all subsided, and there was every probability of her going on favourably with her pregnancy.

Case. Margaret Nadauld was attended, October 1, 1850, suffering intense pain in the uterus and left iliac region. The pain was of a very excruciating character, was increased by the least pressure over the uterus externally, and the slightest touch of the cervix was attended with great suffering. There was a great deal of febrile disturbance, a quick pulse, hot skin, furred tongue, thirst, and disordered bowels. The lower part of the spine was extremely tender, and on pinching up the skin of the left iliac region, the patient evinced much suffering. The history of the case showed that it had originated in a fright, which the patient had had a few days before. She was directed to have a linseed-meal poultice applied over the hypogastrium, and a sinapism to the lower part of the spine. One grain of calomel, and five of Dover's powder, were to be taken every four hours, until three doses had been taken, and on the following morning as much castor oil as would insure a full action of the bowels. The next day, the symptoms were all abated; and, so far as the immediate attack was concerned, the patient considered herself to be convalescent.

Case. Emma Portsmouth, aged 28, unmarried, applied at the Paddington Free Dispensary under the following circumstances. She had been suffering from profuse and almost constant menorrhagia for a period of eight months, during which period, she had been scarcely a week free from some kind of sanguineous discharge from the uterus, and had very often passed clots of blood. At times she had severe uterine pain, and a sensation of bearing down with leucorrhœa, and much pain in the back. These symptoms had been preceded by general weakness and ill health, and much disorder of the stomach and digestive organs. She had also undergone a great deal of anxiety and trouble, to

which she attributed her bad health and uterine maladies. When admitted, she was suffering from the consequences of anæmia in a severe form, very marked dyspeptic symptoms, and the lower part of the spine was exquisitely tender; there was almost constant metrorrhagia and leucorrhœa when this was absent. In the first instance, the treatment adopted was the exhibition of the acidulated muriated tincture of iron, with drachm doses of the solution of the bichloride of mercury; but as in a week she was not materially better, and as the tenderness of the spine was very marked, she was directed to rub the lower part of it freely with the tartar emetic ointment night and morning, until pustulation took place. In a week from this period she is reported to be much better, and I find the following entry: "Is much better, looking better, hæmorrhage less, tongue cleaner, appetite improved, leucorrhœa less, feels stronger." Three days afterwards the following entry was made: "Is much better; no hæmorrhage, leucorrhœa less, no uterine pain, reports that she has very much improved since pustulation has taken place over the spine." This patient entirely recovered under this mode of treatment, but it is unnecessary to give the particulars of the case any further.

Case. Mary Johnstone was attended in November, 1850, suffering from much uterine pain, profuse leucorrhœa, and irregular menstruation. She had been out of health before any uterine symptoms had appeared. She had undergone much anxiety and trouble, the tongue was habitually dry and unpleasant, and she felt low, nervous, and depressed. She had been married two years, but had no children; there was extreme tenderness of the spine in the lumbar region, she was anæmiated, and her digestive organs were much disordered. The tartar emetic ointment was directed to be rubbed over the lower part of the spine night and morning, until pustulation took place, and she was ordered the acidulated muriated tincture of iron, with drachm doses of the solution of the bichloride of mercury three times a day. After pursuing this treatment for four weeks, she is reported to be perfectly well; to have no uterine pain or leucorrhœa, the tongue perfectly clean, and the digestive organs healthy. She especially mentioned, that the uterine pain and leucorrhœa ceased upon pustulation taking place over the tender part of the spine.

These cases appear to me to be sufficient to establish the truth of the doctrine for which I am contending; viz., that spinal irritation exists as an independent affection, and, as such, may be the cause of various secondary uterine disorders. In the first group of cases, we see it connected with symptoms which entirely disappear without any specific treatment, simply by attending to the morbid condition of the spinal cord. In the second, we find it coexisting with chylopoietic disorders, and together with these the cause of various uterine maladies, which again disappear without special treatment, on correcting the spinal affection concurrently with the derangement of the chylopoietic viscera. But it may be supposed that I have attached too much importance to the spinal affection in this latter group, and too little to the gastrointestinal as a cause of uterine disorder; and with the view of meeting this remark, I subjoin two cases, in which every treatment that appeared to be indicated was adopted, and failed, until the spinal affection had been recognised and remedied.

Case. Mrs. R. B., a lady of extremely nervous temperament, was

attended by me in her second confinement on Dec. 12, 1841. The labour was comparatively easy, and over in a few hours: no unfavourable circumstance occurred either during or subsequently to it, and, up to the 18th December, her progress was as satisfactory as could be wished. She began then to suffer from nervous symptoms, her sleep was broken, her tongue and digestive organs were disturbed, and slight febrile symptoms showed themselves. She had also pain and uneasiness in the uterine and left iliac regions; not at first persistent, but rather recurring at intervals: pressure over these parts gave increased pain. Dr. Ferguson, who was consulted on account of these symptoms, attributed them to a mild attack of puerperal fever, observing that he considered that there was congestion of the left ovarian ligament. Eight leeches were applied to this part, and subsequently warm linseed poultices. At the same time, small doses of grey powder and Dover's powder were given at intervals of four or six hours. The local pain and uneasiness were relieved by these measures, and, upon the whole, the case appeared to be going on favourably: but after some days had elapsed, there was still a greater degree of irritability of the constitution observed than is usual, the pulse continued quick, and the digestive organs were still somewhat disordered. Part of these symptoms were attributed to her extremely nervous temperament, and we had every expectation of their subsiding; but instead of this, a week after the treatment had been commenced, we were surprised by a sudden return of all the uterine symptoms, in a severe form; with them the pulse rose, and there was much constitutional disturbance. The abdominal pain was very acute, and aggravated by the least pressure. The sudden return of these symptoms suggested a doubt as to their inflammatory nature, and this was strengthened by the result of my inquiries. It appeared that some weeks before her labour, she had lost a near relative, whose death affected her very painfully; from that time she became subject to uneasy feelings in the left side of the abdomen, and the return of the uterine symptoms appeared to have been immediately caused by her seeing the monthly nurse fall while carrying her infant. The spinal column was examined, and there was extreme tenderness at the commencement of the lumbar vertebræ, and this was so intense that she completely started under the pressure of the finger. These circumstances were reported to Dr. Ferguson, who approved of topical counter-irritation over the tender part of the spine. Nothing but a sinapism was employed, but it succeeded in removing all her symptoms. The uterine pain subsided, as did also the constitutional disturbance, and she rapidly got well. She has since been twice confined, and on each occasion has done well.

Case. Elizabeth Loughborough, aged 25, applied August 6th, 1850, suffering from anæmia and dyspeptic symptoms, together with leucorrhœa; she had acute pain at the epigastrium; the tongue was dry and furred, and her appetite was bad; she had also pain at the back of the head, and felt giddy and faint; she menstruated regularly, but with pain, and she suffered much from leucorrhœa. Her illness had been preceded by mental agitation, and to this she attributed it. For these symptoms she was, in the first place, treated with alterative doses of blue pill, at bed-time; with the citrate of iron, and sesquicarbonate of ammonia, during the day. At the end of a fortnight, she

was not materially better, and still complained of severe pain at the epigastrium. The chlorate and nitrate of potass were now added to her mixture, and they were directed to be taken in effervescence with the citrate of iron. At the end of another week, she was still complaining of the epigastric pain; her digestive organs continued in a very irritable state, and upon the whole she was very little better. An examination was now made of the spine, and exactly corresponding horizontally with the pain at the epigastrium, it was found to be very tender upon pressure. The tartar emetic ointment was ordered to be rubbed over this portion of it, night and morning, until pustulation took place; no change was made in her medicines, and four days subsequently she reported herself to be very much better. The pain at the epigastrium was nearly gone, she felt generally stronger, and the leucorrhœa has almost ceased. From this time she rapidly improved, and was soon convalescent.

It appears to me impossible to reconcile the facts of these cases in any other way than by admitting the doctrine of spinal irritation as a distinct and independent affection; and although post-mortem investigations are wanting to inform us of the precise nature of the affection, the existence of some morbid condition of the cord or its ganglia, in such cases, is conclusively shown by the results of treatment. Nor is this doctrine by any means irreconcilable with well-established physiological facts: it is now, I believe, generally admitted, that the spinal cord is to be regarded rather as a series of nervous centres than a single organ; that from these centres emanate the nervous actions of corresponding parts of the body; and that one or more of these ganglia may be disturbed irrespectively of others. Now in this latter case it will follow, that the disorder of any given portion of the medulla will be principally evinced by disorder in those organs or parts which are supplied with nerves from the particular parts or ganglia which are affected; for as a general rule, it is found that disease of the nervous centres is less indicated by morbid phenomena in the immediate seat of the disease than in those organs or parts to which the nerves arising from them are distributed. This is certainly so in regard to structural diseases of the spinal cord and brain; and in cases where the trunks of nerves have been compressed or disorganised, the effects are less shown at the immediate seat of these lesions, than in those parts to which these filaments are distributed. In the more severe forms of disease, this principle, as observed by Mr. Teale, is readily admitted and recognised; and when, for instance, one half of the body shall have lost its sensibility, and the corresponding muscles their power of action, we look at once to the brain as the immediate seat of the disease. But in the slighter forms of disease of the brain and spinal cord, such as do not obliterate, but merely impair or pervert the functions of the nerves, this important principle, which is as strictly applicable here as in the former case, is too often entirely overlooked; and a numerous class of complaints are regarded as local affections, instead of being considered as actual diseases of that portion of the brain or spinal cord from which the nerves of the part are derived. I might support the correctness of these views by adducing numerous cases which would show how efficacious had been the effect of remedies directed to the spine, where treatment perseveringly ad-

dressed to the seat of pain or uneasiness had been altogether useless. But this would carry me beyond the scope and limits of this paper.

In the next place, I have to consider how far spinal irritation is a consequence of mental uneasiness on the one hand, and the cause of uterine disorder on the other. On looking to the foregoing table, I find that thirty-six cases are referred to in it, in which uterine disease had been preceded by, and was apparently connected with mental causes; and of these it was found that spinal irritation existed in seventeen, in a decided manner; whilst in five only was it met with independently of such causes. It should be added, however, that it may have existed in a larger proportion than this. But as the majority of patients were not so ill as to be confined to bed, the examination of the spine was generally made over their dress, and the result was consequently less accurate than could have been desired. To elucidate the point further, I have made the following analysis of twenty-six cases of spinal irritation, which occurred in connection with uterine disorder, giving their probable causes, and the nature of the concomitant affection.

Spinal Irritation.

Case.	Antecedents.	Concomitant Uterine Malady.
1	Bad health, dyspepsia.	Dysmenorrhœa.
2	Anxiety, hysteria, dyspepsia, and weakness.	Hysteralgia, dysmenorrhœa.
3	Anxiety, asthenia.	Hysteralgia, fibrous tumours.
4	Anxiety, hæmorrhage post partum, great debility.	Hysteralgia, dysmenorrhœa, profuse leucorrhœa.
5	Anxiety, dyspepsia, bad health.	Hysteralgia, dysmenorrhœa.
6	Anxiety, bad health.	Hysteralgia, leucorrhœa.
7	Fright, general weakness.	Acute hysteralgia.
8	Mental emotion, delicate health, pregnancy.	Uterine and ovarian disease, simulating puerperal fever.
9	Mental uneasiness, dyspepsia, bad health.	Hysteralgia, dysmenorrhœa.
10	Anxiety, dyspepsia, bad health.	Menorrhagia, leucorrhœa.
11	Anxiety, bad health, extreme weakness.	Amenorrhœa.
12	Weakness, depression, and general ill health.	Hysteralgia, leucorrhœa.
13	Anxiety and trouble, bad health, weakness, depression, dyspepsia.	Hysteralgia, dysmenorrhœa, leucorrhœa.
14	Mental uneasiness, dyspepsia.	Hysteralgia.
15	Anxiety, dyspep., 5 difficult labours.	Hysteralgia, dysmenorr., leucorr.
16	Anxiety, bad health, dyspepsia.	Hysteralgia, menorrhagia, leucorr.
17	Bad health, weakness, dyspepsia.	Hysteralgia, menorrhagia, leucorr.
18	Weakness, depression, anxiety, and over fatigue.	Hysteralgia, leucorrhœa.
19	Dyspepsia, intestinal derangement.	Hysteralgia, leucorrhœa.
20	Bad general health, weakness.	Dysmenorrhœa, leucorrhœa.
21	Great mental anxiety, dyspepsia.	Carcinoma, metrorrhagia.
22	Mental anxiety, dyspepsia.	Hysteralgia.
23	Fright.	Hysteralgia, leucorr., dysmenorr.
24	Over fatigue, want of sleep, extreme debility, nervous symptoms.	Amenorrhœa.
25	General bad health, dyspepsia, fright.	Hysteralgia, leucorrhœa, irregular menstruation.
26	Mental trouble, excitement, dyspep.	Leucorr., irregular menstruation.

From this table it would appear, that of the twenty-six cases, twenty had been preceded by mental uneasiness, shock, fright, or agitation of some kind. This is a large proportion, but not larger than, I believe, really obtains in the instance of well marked cases of spinal irritation; and the conviction that such causes lead to this affection is so strong on my mind, that I would suggest a careful examination of the spine in all cases where they have preceded uterine symptoms. That such states of mind should affect the medulla spinalis in the manner supposed, is rendered at least probable by what occurs in other cases. As the result of violent or sudden emotion, we know that the functions of the cord throughout may be disturbed; as is shown in the case of chorea, a disease especially of the spinal system, and of which the most frequent exciting cause is sudden fright. Some cases of epilepsy may also be referred to in support of this view; and if it is the fact that violent or sudden mental impressions should give rise to general disturbance of the spinal cord, it appears to me reasonable to conclude that less vivid impressions, such as various uneasy states of mind, should also affect it and give rise to irritation of a more subdued but more persistent character. The influence of such mental causes in tending to the production of functional disorders of the spinal cord, is further rendered probable by other considerations. Thus this affection is for the most part met with in weak, anæmiated, and delicate persons. Dr. Taylor, of Huddersfield, who has paid great attention to it, informs me, that it is his opinion that spinal irritation may arise from any cause which reduces the general strength, and that nothing more than this is necessary for its production. Regarded then in this point of view, mental uneasiness or anxiety would be quite adequate to account for it, by its depressing influence upon the constitution and the general health. Again, it has been conjectured by some who have investigated the subject, that the phenomena immediately depend upon congestion of the spinal venous plexus; a circumstance which would also be favoured by the causes in question, nothing being more calculated to depress the tone of the nervous system, or the vigour of the circulation, and thus to give rise to venous congestion, than continued anxiety or uneasiness of mind.

But, in the last place, the question occurs; If it be admitted that the causes in question can so affect the spinal cord as to give rise to functional disorder of it, can such disorder give rise to uterine derangement, as I have supposed and represented? To this question, I have no hesitation in giving an answer in the affirmative. The cases I have related point in their history to this conclusion, analogy is alike in favour of it, and it is impossible to reconcile the results of treatment with any other view. Nor do I think that any one who has carefully investigated the subject can arrive at any other conclusion. It is quite true, that we cannot always determine whether the uterine or the spinal affection has the priority, because we have not often the opportunity of investigating this point at a sufficiently early period of the case; but some who have had this opportunity, affirm that spinal irritation exists at least from the commencement of such cases. Thus Mr. Player remarks (*Quarterly Journal of Science*, vol. xii, p. 429):— "This spinal affection may perhaps be considered as the *consequence*

of diseases; but of its existence at their commencement any person may satisfy himself, and this circumstance, combined with the success which has attended the employment of topical applications to the tender parts about the vertebræ, appears to indicate that the *cause* of such diseases may exist there."

Very similar views have been expressed by other writers upon this subject. In treating of it in a paper published in the *Midland Medical and Surgical Reporter*, for May 1829, Dr. Darwall enumerates many of the symptoms with which spinal irritation is attended, and observes, that the most common disturbance met with in connexion with it is in the uterine functions,—that he had scarcely seen an instance of it in which this had not occurred. Most commonly, he says, there is menorrhagia; in some few cases the catamenia are diminished, or they are completely suppressed; but whether they are increased or diminished, leucorrhœa almost invariably attends, and is generally more or less profuse, in proportion to the duration of the general disorder. When the catamenia are profuse, they are usually in the earlier part of the period dark-coloured and grumous. At p. 88 of his interesting work on neuralgic diseases, Mr. Teale gives the particulars of a case, in which considerable uterine disturbance coexisted with much derangement of the general health, and more particularly of the chylopoietic organs, in which the spine was tender throughout, and where treatment directed to this condition proved eminently successful. Dr. Griffin informs us, that painful affections of the uterus dependant upon irritation of the lumbar portion of the cord, are of much more frequent occurrence than any previously mentioned; and he refers particularly to hysteralgic affections, to dysmenorrhœa, to menorrhagia, and amenorrhœa. Of dysmenorrhœa, he says, that patients subject to it are also very often the subjects of general irritation of the spine. Menorrhagia and amenorrhœa he describes as less doubtful results of this state, the former being exceedingly common. Mr. Burns, of Glasgow, has written a valuable paper on the subject of spinal irritation, and has especially drawn attention to the connexion which exists between sacral tenderness and painful conditions of the uterus and bladder; and Mr. Tate has published a small volume on the coincidents of spinal tenderness with hysteria generally, and has given several cases illustrative of the benefit which has resulted from counter-irritation over the spine by means of the tartar emetic ointment.

With regard to the particular forms of uterine derangement which are met with in connexion with this affection, I find, on referring to the twenty-six cases which I have tabulated, that—

Hysteralgic affections occurred in 18	Amenorrhœa in 2
Dysmenorrhœa in 9	Leucorrhœa in 13
Menorrhagia in 4	Menstruation was irregular in .. 2

But these affections were variously associated in different individuals: a fact which of itself would almost point to a constitutional origin. The predominance of hysteralgia is very striking, and has been noticed in general terms by other writers. It also favours an opinion which I formerly ventured to express upon more general data, that impressions made upon the uterine organs, from or through the cerebro-spinal system, rather give rise to painful and uneasy conditions, whilst those received from or through the medium of the ganglionic system

of nerves, rather give rise to functional disorders in regard to nutrition and secretion. It is, however, necessary to bear in mind, that the causes of uterine disease are, for the most part, of a complex nature; that the cerebro-spinal and the ganglionic system of nerves are often concurrently disturbed, and that they thus reciprocally react upon the uterine organs, so as to give rise to very mixed and complex forms of derangement.

But spinal irritation, although I believe it to have important relations to uterine pathology, must not be supposed to constitute the sole medium by which nervous derangement is conducive to uterine disease; nor is it a consequence solely of such mental conditions as have been referred to. It may arise from depression of the general health, impoverished states of the blood, and various local irritations reflected upon the medulla. And uterine disorder may arise altogether independently of spinal irritation or mental influences. Whatever indeed tends to depress, disturb, or to embarrass the actions of the nervous system, will either directly or remotely produce it. For it is an admitted axiom, that the healthy performance of every organic function is dependent in a great measure upon the integrity of this system, the due generation of nervous energy, and its proper distribution to the several organs of the body. But none are so liable to suffer from a defective or irregular distribution as the uterine;—there are none which sympathize more largely with the constitution or the nervous system in its several physiological and pathological conditions. It is upon the uterine organs that all the impressions made upon the female organism, whether physical or mental, are either directly or indirectly reflected; and none are influenced so powerfully by the various affections and passions of the mind. Can it then be doubted, that in the mental phenomena, or rather in painful and uneasy states of mind, whether emotional or intellectual, we have a powerful and frequently operative source of uterine derangement, which it is important to recognise and to appreciate?

Nor can it be denied, that there are circumstances of an extrinsic character, which bear closely upon the subject under consideration,—circumstances which are connected with the social condition of the female, which give force and intensity to the operation of causes which might otherwise be harmless. It cannot for instance be doubted, that in the restraints, the refinements, and the education to which the female constitution is subjected as society is constituted, there are to be found important elements tending to the causation of disease. No class or grade of society possesses an immunity from social evils, whatever may be its social advantages. The more developed is the mind, and the more refined are the feelings, the greater will be the susceptibility of both to the influence of disturbing causes, and these are to be met with to a prolific extent in the anxieties and cares, the troubles, the disappointments, and perturbations of mind to which each in his social capacity is subject, and from which no class is exempt. It is true that the troubles of one person are not exactly the troubles of another, nor do those of one grade of society correspond exactly with those of another; but upon the whole, the actual amount of good and evil, of suffering and enjoyment, is pretty equally distri-

buted; and accordingly we observe a great similarity in the diseases which prevail among different classes of the community, however opposite may have been the stations of different individuals, and however different may have been the causes, whether physical or moral, which may have co-operated to produce them.

But it may further be affirmed, that the treatment of uterine diseases cannot be successfully carried out if these circumstances are disregarded, or if the relations which subsist between the nervous and the uterine systems, in their physiological and pathological conditions, are overlooked. Mental affections are not, of course, susceptible of direct cure by medicine, but the physical disorders they give rise to frequently are, if properly investigated and treated; and in this investigation, it is necessary to study attentively the order and sequence of the morbid actions which ensue. In this order and sequence, the affection of the spinal cord, which I have been considering, claims our especial attention, not only as forming an intermediate link between psychical and uterine affections, but as constituting, in many cases, a distinct pathological condition, calculated in itself to react injuriously upon the uterine organs, and the removal of which is absolutely necessary for that of the uterine malady. The treatment, moreover, of this condition, is sufficiently simple and successful when properly recognised. It comprehends little more than regularly repeated friction over the spinal column; counter irritation, more or less active, over the tender portion, continued for longer or shorter periods, according to the persistency or acuteness of the spinal irritation; while in extreme cases, a few leeches may be usefully applied to the seat of irritation when this is very acute. These measures, together with moderate and regular daily exercise, attention to diet and regimen, and such general hygienic measures as are calculated to improve the general health, appear to me to comprehend all that is necessary for the cure of spinal irritation considered as an abstract affection. Some writers have recommended cupping and continued recumbency, but I have never met with a case in which the free abstraction of blood would have been justifiable; neither should I anticipate any benefit from continued recumbency. On the other hand, regular exercise has appeared to have been of the utmost service, and more especially when combined with change of air and scene, and such circumstances as operate agreeably on the mind.

The benefit which I have seen result in the treatment of uterine affections, connected with irritable states of the spine, from such simple measures as I have mentioned, leads me to regard the spinal affection as being in many cases an original lesion, and to differ from those who look upon it as being merely subordinate, or incidental to the uterine. And when writers speak of the derangements of the nervous system, of the various pains which are felt in the abdominal and pelvic viscera, of the sensations which are complained of in their neighbourhood, and point to remote disorders as the direct consequence of uterine irritation, and the symptoms by which uterine disease is denoted, I would venture to inquire whether they are not sometimes confounding with the uterine affection one which in its nature and origin is perfectly distinct? I am, I confess, led to adopt the affirmative of this question, when I find that the history of these cases points in nearly

all to an antecedent disturbance of the nervous system; and I am strengthened in this view, when I observe the symptoms of uterine disease in some cases to disappear without any specific treatment, by simply directing remedies to the spinal cord and the nervous system generally. On the other hand, I am not induced to relinquish this opinion on finding that such measures sometimes fail of their intended object, because I know that the causes of spinal irritation are at the same time those of various associated disorders of other organs, which, together with that of the spinal cord, originate and maintain a state of uterine irritation and disorder. But I am above all convinced of the truth of the position which I have assumed, when I meet with cases in which these affections have co-existed with uterine derangement, and have been supposed to be dependent upon it, and where, conformably with this view, it has been sought to remedy them by the constant, repeated, and persistent, but unsuccessful employment of measures specifically directed to the uterine organs, for periods varying from one to two years, and this, too, by practitioners of authority and eminence.

(To be continued.)

Chester Place, Hyde Park Gardens, October 1851.

THE FIRST OF OCTOBER 1851.

By AN OCTOGENARIAN.

The first of October is an interesting day to the medical profession: on it the different schools are opened, at which such acquirements and knowledge are to be obtained as will qualify the pupil to pass his examination at Apothecaries' Hall, at the College of Surgeons, or at the College of Physicians; and the public journals have announced more than twenty well-provided lecture-rooms, at colleges, hospitals, halls, and private institutions, where the necessary instruction may be acquired.

Anterior to the year 1815, few medical schools existed, and those were very incomplete, with the exception of those founded for anatomical and surgical teaching; but even upon these the attendance was not compulsory, and many persons practised as physicians, surgeons, and apothecaries, who had never attended a single course of lectures, or witnessed one dissection. In the year 1814, at the seven London Hospitals, namely, St. Bartholomew's, St. Thomas's, St. George's, Guy's, the London, Middlesex, and Westminster, there were only thirty-eight physician's pupils; in less than twenty years after the Apothecaries' Act passed, they increased to three hundred and twenty-six, and are now still more numerous.

The first important incentive to a more careful and appropriate medical education was effected by the privilege, granted by Parliament to the Society of Apothecaries in London, of electing a Court of Examiners, to inquire into the competency to practise medicine of all future apothecaries throughout England and Wales. This bill passed

through Parliament in the year 1815, but so little did the upper ranks of society estimate the value of a sound medical education, that after being, with great difficulty, got through the House of Commons, it at last passed the Lords by the paltry majority of ONE.

Some years afterwards, when, as one of the consequences of this Act, it became necessary to render the study and practice of anatomy more easy and unobjectionable, and when a bill was brought into Parliament to effect this desirable object, the measure was strongly opposed, and more than one honourable member urged as a most cogent reason against it,—that though a knowledge of practical anatomy was indeed required by surgeons who had operations to perform, yet, for physicians and apothecaries, a sufficient knowledge of anatomy might be gained from plates, from wax and terra-cotta models, from skeletons, and such preparations and dried specimens as were always to be found in museums and repositories.

Even in our own days, woefully deficient is the encouragement bestowed upon the medical man; and if there were not some redeeming exceptions, some cheering moments of comfort, his course would indeed be gloomy and overpowering; for he must often feel that his worth and his usefulness are unacknowledged, his fatigues and his anxieties unheeded, and his unselfishness and disregard of lucre derided and abused. The man—the individual—indeed, is often greatly beloved and respected; but the profession—the great body of practitioners — holds not that honoured rank in public estimation which it so justly merits. While labouring and toiling in the divine employment of striving to diminish the woes of his afflicted fellow-creatures, it cannot fail to mortify the honourable pride of an honourable practitioner to witness how much the palpable absurdities and deceptions of homœopathy are patronized by noblemen and influential commoners; how wonderfully strange it is, that clergymen should combine with infidels and atheists in practising Mesmerism; and that government itself does not disdain to derive a large revenue from quackery,—quackery, the very essence of which is falsehood, and which can only be sustained by the publication of advertisements and books of the most obscene, prurient, and disgusting character that can be imagined.

And yet, surrounded as it is with difficulties and discomforts, the art and science of medicine has steadily pursued a course which has placed it in a very high state of elevation. Let us then take a retrospective view of what medical practice was a hundred years ago, and we shall not be ashamed of what it is now.

Dr. Hulse, a physician of great eminence and reputation in the reign of Queen Anne and her two successors, was in 1738 appointed physician-in-ordinary to King George II, and was created a baronet. He died April 10, 1759, aged 74. His practice was very large and lucrative, and Dr. Heberden bears testimony to his "judgment and sagacity". Dr. Heberden likewise mentions his partiality to the bark,[1]—the Peruvian bark,—which he had "prescribed for forty years, more than any other physician out of England, and as much as any one in it".

[1] Transactions of the Royal College of Physicians, vol. ii, p. 15.

Among the many distinguished patients of Sir Edward Hulse, one of the most celebrated was the Earl of Orford, more generally known as Sir Robert Walpole, who died March 18th, 1745, after a very painful illness, and who gave his own "solemn injunction" to be opened after death by Mr. Ranby, "in order that he, who could no longer survive to profit mankind, might be the means of conveying to them what good he could after his death."

Ranby's narrative is neither erudite nor attractive; yet his statement of facts contains materials which could hardly fail to excite inquiry and discussion, especially among those who were exercising, in its various departments, the practice of medicine; so that if the noble lord's solemn injunction did not immediately effect all the good that in his dying moments he perhaps expected, yet it was doubtless one of the quiet contributory streams which began the improvements in medical and surgical science, and which will continue to move on

"——— in omne volubilis ævum."

The narrative[1] states, that in the spring of the year 1744 Lord Orford had an attack of intermittent fever, for which, by the advice of Sir Edward Hulse, he took the bark with good effect, and retired for a short time to Richmond-park. Here, one day after dinner, he was suddenly "seized with great pain in the head, giddiness, violent sense of sickness, and frequent inclination to vomit"; in addition to which, he suffered "intense pain in the back, and passed coffee-coloured urine". It might be expected that such a series of symptoms would have been considered sufficient evidences of a distinct and alarming attack of disease, but it was hastily and inconsiderately attributed to "a return of the intermittent fever, attended with some nephritic symptoms", and the bark was again prescribed, "some regard being had to these nephritic symptoms".

It may well be supposed that the symptoms here mentioned did not yield to the bark; the "hard and full pulse" was therefore attacked by venesection, and "he was bled in the arm even to three times" before this alarming symptom gave way, and the coffee-coloured urine ceased to be discharged. His lordship's medical attendants appear to have contented themselves with *conjecturing*, for it was only conjecture, that some concreted matter in the kidneys had passed into the bladder, and it was expected that what had thus passed into the bladder would be speedily expelled through the urinary passages; "but as these expectations were entirely fruitless, a doubt began to prevail whether it were anything more than a gravelly affair, accompanied by some symptoms produced by intermitting fever"; and this inconclusive reasoning being allowed to have more weight than it merited, the use of the bark was returned to and persevered in, under different forms, for six months.

The quietude which this severe attack made necessary, and the abstaining from *much* wine,—"for he was so abstemious as to drink only a little sack",—kept Lord Orford's complaints within some bounds for a considerable space of time; but in attempting to make a visit in an "extremely easy chariot", he felt an unusual irritation to

[1] A Narrative of the Last Illness, etc. By JOHN RANBY, Principal Serjeant Surgeon to the King, and F.R.S.

make water, and the urine was tinged with blood; and this irritation and bloody urine continued to distress him, unless in a state of absolute rest. It may easily be imagined that a surgeon would, under such circumstances, suspect stone in the bladder, and Mr. Ranby expressed his opinion that this was the case. But physicians and surgeons did not conduct themselves towards each other in those days as they do now; and "as the blood that came away was judged absolutely by the physician to proceed from the kidneys, this symptom was deemed of no material consequence", and his lordship was allowed to return to Norfolk, no attempt having been made to ascertain what was the actual state of the bladder.

With, upon the whole, little difficulty, he reached Houghton in July, and remained there under the care of Dr. Hepburn till November: he kept himself very quiet and retired, took largely of marshmallow tea, and other demulcents, and avoided much exercise or exertion. Several times, however, when using gentle carriage exercise, he was much distressed with pain and irritation, and occasionally tinges of blood were observable in the urine: these symptoms were sometimes mitigated by taking manna in cream of tartar whey; indeed, Dr. Hepburn's treatment was soothing and judicious.

Lord Orford returned to town in November, but his journey was performed with great difficulty, occupying the space of four days. On the last day, in travelling twenty miles only, he suffered excessive torture; "he was obliged to alight from his chariot at least twenty times, and every time subjected to a discharge of almost pure blood, with excessive pain". Sir Edward being again called in, "and having heard all the particulars from his lordship's own mouth", gave it as his opinion, "that the seat of the whole disorder was in the kidneys, insomuch as the bladder being furnished with but few blood-vessels, could not supply any great quantity of blood; and besides, that almost all discharges of blood proceeded from the kidneys."

Ranby expresses his regret at differing in opinion from a physician of so great experience, but he "was sufficiently convinced that the stone in the bladder was the sole cause of all this tragedy". This opinion, however, was strangely slighted, especially as in a former illness, ten years ago, a small stone had passed through the urethra; and in Norfolk, while under Dr. Hepburn's care, much gravel and one or two small stones had in the same manner passed away.

Under these circumstances, "a soft and diluting method" was prescribed and persevered in for about three weeks, when Dr. Jurin,[1] the inventor of a lithontriptic medicine, was called in as consulting physician with Sir Edward Hulse. "*Searching*" was now proposed, but Dr. Jurin was so well convinced that there was a stone in the bladder, as to render the introduction of a sound unnecessary. At this consultation it was determined that a dram of the doctor's *lixivium lithontripticum*, made into a draught, or rather a potion (for it amounted to seven ounces), should be taken three times a day. The dose of the

[1] Dr. Jurin distinguished himself early in the last century as an advocate for the newly introduced inoculation of the small-pox. He was a very eminent physician, and became President of the College. The exact composition of his lithontriptic is not generally known, but the principal and most efficacious ingredient was the caustic potash.

lixivium was gradually increased, and between the 15th December and the 4th of February, "six and thirty ounces of this lixivium were taken", variously combined with stomachics, cordials, etc., as seemed necessary. The effect of this remedy appears to have been considerable in disuniting the calculous concretions, but at a grievous expense to the mucous membrane, and indeed, to the entire structure of the bladder. Frequent discharges of pieces of calculus, more or less cemented together, excessive pain, and profuse hæmorrhages, harassed the poor sufferer most cruelly. "On the 9th of January particularly he had a more than ordinary flux of blood, attended with greater pain than he had ever yet felt, at the end of the penis. . . . . In the evening he voided as much gritty matter as would cover a shilling, of the colour of common house sand, and looking as if wrought together with gum-water." "February 4.—About nine he discharged a great quantity of blood, and soon after complained of an intolerable pain in the penis. Mr. Ranby extracted from the urethra a stone exceeding the dimensions of the largest kidney bean. About one, he felt a strong irritation to make water, which was followed by a large discharge of blood, a good deal of it coagulated, in which were found eleven pieces of stones, some of them smooth and rounded on one side, and scraggy on the other; some sharp and pointed on all sides, as having been inner parts; but not one of these that did not evidently appear to have been a part of some larger stone. These fragments were whitish, but in the stones which were entire the parts of the joinings were streaked with yellow veins, resembling in some measure Mosaic pavement". These discharges of blood and portions of calculus continued through the day, but in the evening "an extraordinary coagulation of blood was discharged, but there could not be discovered any concreted substance, till the coagulum had been dissolved in a large basin of water, when about fifteen pieces presented themselves, one of which was a stone, near entire, and almost as big as the great one in the morning". This seems to have been the last evacuation of calculi; but the hæmorrhage continued profuse, and the patient was reduced to a most extreme state of lassitude and debility, in spite of the bark, which was again prescribed in various forms, but with, of course, little or no advantage. The fragments of calculus of all sizes exceeded forty in number.

Dr. Crowe was now called in, who appears to have agreed in opinion with Sir Edward, that the blood discharged was supplied by the kidneys, "it being in reality his sentiment, that all discharges of blood through the urethra flowed, not from the bladder, but entirely from the kidneys". Dr. Crowe did not recommend any particular mode of treatment. From this time, though the patient's progress was duly watched, and his pains occasionally relieved by opiates, nothing of importance is recorded, except some ineffectual attempts by Ranby and Cheselden to introduce the catheter. On the 18th of March, 1745, the friendly hand of death released the noble earl from the intense sufferings of a most afflicting disease.

It is a curious circumstance, that the announcement of Lord Orford's death, in the *Gentleman's Magazine*, stated that he had died of inflammation of the lungs.

The *post-mortem* examination, signed by "E. Hulse, J. Ranby, W. Cheselden", states that the bladder "had expanded itself above the

os pubis at least four inches: on cutting into the cavity, there issued a quantity of urine, with three large clots of coagulated blood, which no doubt had lain there some time. On separating the bladder from the parts with which it was connected, and dividing it from the neck to the bottom, several inflamed spots were observable, with an inflammation quite round the neck, about the breadth of two inches, and a lodgment in the membrane of several small stones about the size of half a grain of wheat. Its substance was of a very unequal texture, innumerable ridges as thick as the eighth of an inch, and many of them much larger, running across one another through the whole capacity of it, while the spaces between those ridges were as remarkably thin and transparent. The prostate glands were enlarged, and become harder than they commonly are. No defect was discoverable in the kidneys or ureters, though the pelvis was larger than usual." Nothing is said in the *post-mortem* examination about the state of the lungs.

A perusal of this case will not impress the reader with a favourable opinion of the practice of medicine in London anterior to the reign of "good old" King George III. Investigations into the nature, causes, and progress, or the probable results of diseases, seem to have been conducted with little nicety or exactness. The first symptoms of disease were not accurately analysed, and those which presented themselves during its progress were too often overlooked or neglected. Nor was there much discrimination in the choice of remedies; indeed, the virtues and value of the most important articles of the materia medica were neither well ascertained nor duly appreciated; but reliance was placed on old forms and combinations of remedies, which were prescribed rather to the name by which the disease was called, than to the symptoms by which its nature was to be learned and its management directed. The "judgment and sagacity" of Sir Edward Hulse enabled him to treat ordinary diseases with effect and advantage; but whosoever deals largely in any one course of treatment by the bark or any other remedy, shews little discrimination, or that amount of penetration which is required from an accomplished physician.

The so-called consultations of old were anything but deliberative and confidential: they were rather meetings of formality, at which the authority of one overruled the others; and the surgeons had rarely influence when they visited with physicians. When old Radcliffe was called in, he was the paramount: very few physicians could offer advice when he was present.

There were other physicians besides Dr. Jurin who possessed their particular *nostrums*; and when the nostrum was strongly recommended, and thought likely to cure any malady, it could not generally be separately purchased, but the inventor was called in to superintend and direct its use. Thus when Jurin and Hulse consulted about the employment of the lithontriptic, it had already been resolved that Lord Orford should take it; and though Sir Edward was of course told what the most important ingredients were, yet he probably was not acquainted with its actual composition. Dr. James used at first to be sent for, not because his skill was wanted, but because James's fever powders had been spoken of as the sure and only remedy. No doubt it became more lucrative when advertised and sold in packets, than when obtained by feeing the doctor. M.

BIBLIOGRAPHICAL RECORD

THE SPINE: ITS CURVATURES AND OTHER DISEASES, THEIR SYMPTOMS, TREATMENT, AND CURE: to which are added some Remarks on Paralysis. By CHARLES VERRAL, ESQ., Surgeon to the Hospital for the Cure of Distortions, etc. etc. London: 1851.

THIS work, which is extended to 234 pages, might with much advantage to the professional reader have been compressed into one-third of that space.

We are indebted to the author for the description of a lighter, more elegant, and, we believe, more effective apparatus than has hitherto been introduced for the treatment of lateral curvature of the spine. The instrument, moreover, possesses one great advantage, viz.; that all its moveable parts are simultaneous, regulated by one simple screw. Different forms of the apparatus are represented by wood-cuts in various parts of the work, and, as far as the mechanical contrivances are concerned, we conceive that much credit is due to MR. VERRAL. We sincerely wish that we could have expressed ourselves equally satisfied with the more strictly medical portions of the work.

The second and third chapters are devoted to the subject of the LATERAL CURVATURE OF THE SPINE, in which the author advocates a plan of treatment consisting of alternate exercise and repose; and points out that the recumbent position may have its advantages for such cases, as well as those means which are more directly calculated to remedy the debility in which the affection usually commences. The fact is clearly illustrated that in lateral curvature the vertebræ are not only inclined to one side, but are frequently rotated to a certain extent upon each other. The articulating surfaces by degrees become accustomed and adapted to the new position, and it is impossible to alter their directions, so long as the superincumbent weight of the head and shoulders tends to retain them in their abnormal situation. In the recumbent position, the articulating processes may be opposed by different corresponding surfaces, and by such portions of them as have not been altered in form by superincumbent pressure. For these reasons, we agree with Mr. Verral that the recumbent position, during certain periods of the day, may be of advantage in the treatment of lateral curvature of the spine.

We must, however, entirely dissent from the author when he says (p. 21), that marked benefit may be derived from putting the patient under such a course of medicine and regimen generally as should tend, in a slight degree, to produce temporary debility. "It must be pretty evident," he says, "that the more debilitated the system, and the more relaxed and flaccid the structures upon which our operations are to tell, the more readily will the deformity yield to the curative agency." We here approach the doctrine of the homœopathic school—want of power and its effects are to be cured by relaxation. If, indeed, the affair were one strictly of a mechanical nature, then, indeed, the softer and more pliable the parts, the more easily might we mould them to our will: but this is not so.

We are told (p. 8), that one of the causes of lateral curvature of the spine is, that "the ligaments become elongated, thin, and paler in colour"; and yet that it is advisable to commence the treatment of such cases "by inducing a certain amount of physical debility and consequent pliability of those structures upon which the mechanical contrivances are brought to bear"! (p. 21.)

The fourth chapter of the work is devoted to CARIES OF THE SPINE. Mr. Verral, in his preface, gives us a list of works that he has consulted to aid him in his investigations; and we cannot help feeling, that in addition to those he has named, it would have been more satisfactory had he included

the work of Sir B. Brodie on the joints, especially in reference to the treatment of the caries of the spine. Sir B. Brodie informs us, in his later editions, that he has long given up tormenting his patients suffering from scrofulous affections with blisters, issues, and setons. Mr. Verral, on the other hand, maintains that in caries of the spine, great benefit will attend the guarded employment of counter-irritation, and that he is somewhat prepossessed in favour of issues in severe cases. (pp. 146-7.)

In the fifth chapter, PARALYSIS, proceeding from disease of the spine, is treated of. Here, we have still to remark the exclusively mechanical view which the author takes of the diseases of which he treats, and of their supposed "cures". The first step to be taken in the treatment of paralysis, is to change the patient from the supine to the prone position, which shall at once "occasion any fluid agent that is making pressure upon the cord to change its situation, from the simple circumstance of gravitation". (p. 172.) In the chapter on angular projection, Mr. Verral says that he is in the daily habit of witnessing the disease in every varying stage of its distressing career, and "if the malady be not arrested in its incipiency, it goes on to the formation of abscess, extreme debility, hectic, and probably death". (p. 119). But in the chapter on paralysis resulting from angular curvatures, he says, that by steady perseverance in the treatment recommended, "restoration is, humanly speaking, certain". (p. 173.)

The chapter on RICKETS, furnishes us with another remarkable instance of the tendency displayed throughout the work to explain everything by reference to mechanical laws. "One phenomenon in connexion with the disease is the excessive precocity of intellect which characterizes its victims, a circumstance that would seem to result from the premature development of the brain, *owing clearly to the softened condition of the cranial bones offering less resistance to the rapid increase of the cerebral masses.*" (p. 231.) Had not nature, therefore, made the mistake of prematurely closing up our skulls, we should be a much more intelligent race than we now are!

The last chapter treats of SPINAL IRRITATION, or hysterical affections of the spine. Mr. Verral supposes, that in some cases this affection would appear to originate from a low, chronic, inflammatory state, either of the membranes of the spinal cord, or the coverings of the nerves as they pass out from the medullary canal—neither of which conditions involve any actual alteration of structure in the parts affected. (p. 222.) No attempt however is made, either by cases or otherwise, to prove the correctness of this opinion; and we must confess ourselves at a loss to understand what is meant by chronic inflammation, which produces no change of structure. "The recumbent position—particularly, or, I should say, exclusively, the prone—is of eminent service, and should be employed in the early treatment of the disease, with but little intermission"! (p. 223.)

In the first case of this supposed affection cited, a delicate, nervous girl, 17 years of age, who had for the most part led a sedentary life, was placed upon a prone couch, and a succession of blisters were applied over the fancied seat of the disease, whilst the slightest attempt at motion was forbidden. "At the expiration of two months or ten weeks, she was permitted to take gentle exercise in her ward." This is not, it must be admitted, a very encouraging result. In a second case, in less than *three months* the patient had so far recovered (?) as to be allowed to walk out daily for an hour with the aid of an instrument. (p. 233.)

Such cases really do not deserve a serious consideration, nor should we have noticed this part of the work, were it not to distinguish it from that in which some mechanical defect or contrivance is described. For this, which we should have much liked to have seen published in a separate form, we give the author every credit; but we would suggest to him, that in treating the subject as a whole, the laws of life must be studied and described, as well as those of mechanics.

On Bubo and Perinæal Abscess. By John L. Milton, Esq., M.R.C.S., pp. 32. London: 1851.

The pamphlet before us is printed for private distribution. Its principal object is to advocate the use of tartar emetic in cases of bubo threatening suppuration. The result of this treatment in the author's hands is stated to be,—"that in almost every case in which it was properly carried out, resolution was effected if the case came early enough under treatment; and that even in those in which suppuration had proceeded to a considerable extent, an immediate arrest of all the prominent symptoms was obtained" (p. 12).

The same plan of treatment is advocated for abscess in the perinæum.

In both cases the inflammation is treated of as if it were an abstract essence, while the *cause* of the symptoms is not once touched upon. If the author had considered *what* it was which in either case gave rise to the inflammation, we venture to believe that he would no longer entertain the idea that the evil could be removed by simply diminishing the vascular action of the part.

In syphilitic bubo, there is a poison in the part to be got rid of; and in perinæal abscess, there is usually an escape of urine from its usual channel. The inflammation and suppuration in both cases are attempts, either to limit the effects of, or to eliminate, the offending matter, and simply to "hint back" (p. 28) the actions which nature sets up, is nothing more or less than to attempt to frustrate the intentions for which those actions were instituted.

The reception of the author's practice in the particulars now referred to, he has candidly stated in his preface.

"I am not aware that I have made a single convert to my views, except among my patients. By my professional friends my opinions have been utterly neglected, or met with objections."

Prevention and Cure of many Chronic Diseases by Movements. An Exposition of the Principles and Practice of these Movements for the Correction of the Tendencies to Disease, in Infancy, Childhood, and Youth; and for the Cure of many Morbid Affections of Adults. By M. Roth, M.D. pp. 302. London: 1851.

Dr. Roth's name appears in the *Medical Directory's* list of homœopaths; but like other speculators of the same class, he tries to have two strings to his bow. It appears that Kinesipathy, like the other *pathies*, may be united with homœopathy; though each, when occasion requires, must be lustily proclaimed to be a complete system of therapeutics. Mr. Everest preaches that, Christianity was of little use till Hahnemann appeared; the Bishop is silent, and the *Homœopathic Times* endorses the blasphemy. Why then may not Dr. Roth inform as many of the quack-fanciers as he can gather round his standard, that homœopathy itself, (notwithstanding all that Hahnemann and Mr. Everest have said to the contrary), is often in need of a help, and that that help is the new *pathy*—Kinesipathy—practised to admiration in London by the author?

Kinesipathy is a term derived from two Greek words, Κινέω, I move, and πάθος, a disease. It is the name of a medical system invented in Stockholm, by a fencing-master of the name of Ling, who gradually transformed his gymnastic academy into an hospital. Ling, like many who trade on the gullibility of mankind, was a man of great shrewdness; and he appears likewise to have been a poet of some fame in his native town.

Dr. Roth has served up the science of Lingism very nicely for the London public; and we have no doubt that he may, in virtue of the attractive woodcuts, the elegant getting up of his volume, and the outrageous absurdity of

its contents, divide some of the spoils of Belgravian folly, with fashionable Mesmeric maidens, homœopathic, and hydro-homœopathic doctors.

Gymnastic exercises are undoubtedly most important in the cure and prevention of many diseases; and so have they ever been regarded by the medical profession. We have no more objection to the use of movements—riding, dancing, fencing, swimming, etc.—in the treatment of disease, than we have to the use of water as a therapeutic agent. Exercise and cold water are and ever have been remedies much and deservedly esteemed by physicians; but Kinesipathy and Hydropathy are merely vile trading systems of charlatanry, built upon the foundation of the virtues of these means when judiciously used.

The work of Dr. Roth consists of an introduction, and of chapters on the history, on the theory, and on the practice of the system. Mingled with much nonsense, there is some sense, but wonderfully little, considering the inherent excellence of the subject—medical and hygienic gymnastics. The general scope of the work may be sufficiently gathered from the following extracts: a formal analysis of the book would be out of place in a journal devoted to medicine.

Treatment of Gonorrhœa. "The prescription in gonorrhœa is generally (besides some movements depending upon particular circumstances) the following:—

"1. Percussion on the sacrum, in the stride-standing position.

"2. Transversal chopping on the neck, in a sitting position.

"3. Pressure above the os pubis, in the lying position, with elevated back, while the separated and bent legs are drawn towards the abdomen.

"4. Vibration of the perinæum in the same position.

"The treatment begins with percussing the sacrum in the stride-standing position, which in the first day or two not only allays and relieves the more violent inflammation and copious secretion, but also changes the whole state of the disease in such a manner, that the following treatment by movements, (different according to the state of the patient), produces an increased flow of arterial blood in the upper extremities, and the cure is very much accelerated. In the first stage, during which only a moderate stitching pain, tension, and little secretion appear, the percussion on the sacrum is alone sufficient, if repeated three or four times daily. If the symptoms become more violent, and accompanied by chordee and pains during urinating, etc., then other movements are necessary; they make use of the transversal chopping of the neck, which acts strongly against the chordee, and of the pressure above the os pubis in the above mentioned lying position, which increases the venous absorption of the bladder and sexual organs, by its effect on the excited nerves of these parts.

"In the second period, if the urinating is very difficult, the perinæum swollen and painful, the discharge mixed with blood, and fever is present, then a more general treatment is necessary. To increase the more local absorption in the urethra, vibrations along the whole tract of the perinæum, from before backwards, are employed." (pp. 231, 332).

It may be necessary to give our readers the author's explanation of

Chopping, as described in one of his preceding chapters. It is as follows:—"Chopping consists in alternative short blows produced by the external sides of both the operator's hands. Choppings are principally used on the posterior surface of the trunk, chest, and also on the limbs. If it is desirable that the succussion produced by this movement shall be less and softer, then the chopping is done with the external edges of the two little fingers, while the other fingers are spread apart, but not kept spasmodically fast, so that they act also by striking upon the little finger. Chopping may be confined to one part only, or may be exercised on a larger surface, by constantly moving the position of the hands. The chopping is called a *longitudinal* one, if the

hands are moved in the longitudinal direction of the trunk or of the limb, and a *transversal* one if the blows are executed across the limb." (p. 92.)

Suppressed Piles, it appears, are not amenable to the "harmonic medicine" of Hahnemann and Mr. Everest, *i. e.*, to real homœopathy, and therefore our author resorts to treatment which we doubt not the last named authority would consider quite as "frantic" as that of "the old school". This is the passage to which we refer:—"*Suppressed Piles, causing mental distress.* —After a sudden spontaneous or artificial stoppage of discharge of blood or slime, persons suffering from piles often become lunatics. These must be treated immediately, without any loss of time, by *movements acting very violently on the brain*, which must all be done in a horizontal position, and *the patient must be overturned, and as quickly as possible kept up and down by the assistants.* Many fear this overturning, because they wrongly believe that the blood acts only by its weight, and that it comes in too great a quantity to the brain. If the first were the case, the blood would never flow to the head in an upright position; with respect to the too great quantity, the blood is pressed on to the brain only, if the patient being nervous retains his breath, and actively resists while his trunk is moved up and down." (p. 227).

In all this the reader will observe that nux, lycopodium, and lachesis, etc., are never once mentioned by the homœopathic Dr. Roth. Well, truly, was it said at Brighton, that the dupes of homœopathy "have no conception of the vastness of its absurdity, and of the Protean wiles with which, setting honesty, consistency, and common sense at defiance, it bewitches the sick and the silly."

Report of the Speeches on Irregular Practice, delivered at the Nineteenth Anniversary Meeting of the Provincial Medical and Surgical Association, held at Brighton, August 13 and 14, 1851. pp. 32. London: 1851.

The various medical journals contain from time to time admirable exposures of the delusions and frauds practised by homœopaths and other irregular practitioners; but from the fact of professional periodicals not being suited for general perusal, we can hardly afford our patients, when they ask it, an opportunity of reading the opinions of medical men upon any prevailing or fashionable quackery. On the other hand, all the modern systems of charlatanry have journals in aid of their cause, which are obviously written solely for the public. Hygeism has its monthly *Hygeist;* homœopathy has its *Homœopathic Times*, and other prints; Mesmerism has its *Zoist*, et cetera; and Chronothermalism sends forth monthly *The Chronothermalist.* The extraordinary success of all the systems advocated in these periodicals is chiefly owing to their zealous, and often clever, advocacy by a stipendiary press, arrayed in the garb of pseudo-science. Quack medicines, in fact, are now being displaced by quack systems: and Professor Holloway will soon find that if he is to continue to work Lord Aldborough's leg successfully against Drs. Quin and Ransford's Mercurius, he must bring out, weekly, or monthly, *The Holloway Times.*

However much we may deplore the spread of quackery, we, as medical men, cannot do more, as regards the public, than point out our determination to keep aloof from it: and to this extent, as honest men, we are bound to go. The Brighton Speeches are particularly well suited to point out to the public, that the attitude of the Association, and we may add, of the whole profession, with regard to homœopathy, is not one of opposition, but one of defence; one which the Association was called on to assume, to preserve its respectability, and to entitle it to maintain its position as a society of honourable, truth-seeking, and scientific men. We, therefore, strongly recommend this pamphlet, as a publication admirably calculated to explain to intelligent laymen the real position which the profession has assumed towards homœopathic practitioners.

Orthodox Medicine: An Address delivered at the Annual Meeting of the Bath and Bristol Branch (June 26, 1851) of the Provincial Medical and Surgical Association. By John Addington Symonds, M.D., President for the Year. Worcester: 1851.

This is a very admirable address. Many of the topics are similar to those discussed in the Brighton speeches, and in other recent pamphlets; yet there are important subjects touched upon, which are not adverted to in them, or, indeed, in any authoritative publication. Dr. Symonds uses the plain and explicit language of an honest man; and yet, (notwithstanding the badness of the persons whom he has to characterize), he avoids all coarseness of expression.

It is fortunate for the profession when physicians and surgeons of deservedly high reputation, acquit themselves of a duty by coming forward to denounce loose professional moralty, and charlatanic practices. With the public, such questions may appear to involve merely rival medical systems; but with us they involve the momentous alternatives of honour or infamy. Shall we for fees, or for anything else, hold professional intercourse with men who deride and malign us, and yet, when it suits thoir mercenary ends, represent themselves to the same public as belonging to our body? Shall we hold mock consultations with such persons, who, if they are honest in their professions, believe that medicine and surgery, as practised by us, are not only useless, but that they are in very truth the scourge and the curse on the community?

Passing over what is, perhaps, the best part of the address, we will extract one short passsage, as it touches upon a point which we do not recollect to have seen so plainly handled before; but which, from frequent experience, we suspect must be one of great moment to many practitioners. Often, very often, have we been sent for in cases of real or supposed danger, hurriedly, or during the night, by parties who in all slight ailments are in the habit of tampering with homœopathy. The quacks have received the greater part of the fees, and we have had all the responsibility and harassment; and sometimes we have been called when it was too late.

"I strongly advise my brethren," says Dr. Symonds, "to take an uncompromising part, not only by refusing to co-operate, even in the most indirect manner, with homœopathic practitioners, but also to show the public in what light we regard these marauders. I need not tell you that the only really remunerative cases to the general practitioner (except in the feeling of satisfaction in the discharge of an arduous duty, in the achievement of success in a difficult art, and in the thought of having saved a life, or assuaged pain and distress), are those in which his duty consists mainly in standing by the bedside of the patient, ready to interpose, if in his judgment any emergency arises; though they are cases to the cure of which nature alone is usually adequate. Nothing can really compensate him for the anxiety incident to the life-and-death encounters in grave cases, to say nothing of fatiguing days and broken nights. If, therefore, his attendance is sought by a family in such cases only, (and the instinct of the patient or his friends will generally lead them away from homœopathists on such occasions), he is justified in requiring that his reward should be very different from what it is when he has all kinds of cases submitted to him.

"I have no fear that this view of the case can be considered mercenary. Everywhere it is allowed, that from no profession is more gratuitous aid received by the public, and I am proud to believe that it is held to be one of the highest privileges of the profession that it has the power, and is allowed to render help to mankind as a labour of love. But as our patients often quote to us, 'The labourer is worthy of his hire,' so we may urge that the

hire should bear relation to the kind and degree of the labour. To employ a soldier on no service but fighting in pitched battles, bivouacking on malarious plains, or leading the 'forlorn hope' of a storming party, and then to tender him for such service the same pay as a soldier who is engaged all the year round in ordinary garrison duty, or in the light routine of the parade ground, in an exchange for the hardships and perils of a campaign, would surely be considered to be very unreasonable and very unjust, yet it is a case precisely parallel with that to which I have just adverted." (pp. 17-18.)

MANUAL OF HUMAN PHYSIOLOGY FOR STUDENTS: being a Condensation of the Subject, a Conservation of the Matter, and a Record of Facts and Principles up to the present day. To each subject are appended, in notes, Summaries in Rhyme of the Composition of the Fluids and Solids, etc. By JOHN MORFORD COTTLE, Licentiate of the Royal College of Physicians, London. pp. 303. London: 1851.

This book is professedly written for students to get up enough of physiology to pass their examinations; and the author modestly announces that he does not desire to contest the wider field, already so well occupied by Carpenter and Kirkes. With such students as will not try to master larger and profounder works, the present is likely to prove a favourite; and we must say that, excepting the poetry, it is of a grade very superior to the majority of those designed for the use of the lazy and the idle.

The author gives a summary of each chapter in doggerel rhyme, which summaries, we suppose, are to be committed to memory by those who have only time or inclination to get up their knowledge by rote, to serve them as rallying ground, when before a board of examiners. As a specimen of this style—a style long in vogue with grinders—we give Dr. Cottle's poem on the

"MOTIONS OF THE STOMACH.

"The normal motions of the stomach need
No motive power from th' vagus; and indeed
The gastric juice alike preserves its course,
As free as are the movements of the horse.
Like as the horse is ruled by spur and bridle,
The vagus urges on, or makes them idle." (p. 72.)

Lest DR. COTTLE should contemplate doing for anatomy what he has done for physiology, we beg to subjoin for his use a couplet much revered by grinders, and men when being ground:—

"The larynx is just under the skin;
But the pharynx is much farther in."

MANUAL OF PHYSIOLOGY; INCLUDING PHYSIOLOGICAL ANATOMY. By WM. B. CARPENTER, M.D. *Second Edition.* With 190 illustrations. 12mo. pp. 616. London: 1851.

DR. CARPENTER has brought up his *Manual*, in this new and beautiful edition, to the present state of physiological science. Many alterations and additions have been made, as well as some omissions. This work is complete, without being too tedious for students: and to them we commend it as an admirable text-book. To those who may already possess one or both of Dr. Carpenter's larger treatises, the following passage from the preface is important:—"Although this Manual combines in some degree the scope of the author's *Principles of Physiology, General and Comparative*, and of his *Principles of Human Physiology*, yet it cannot be regarded as a mere abridgment of them, having been written, for the most part, with very little reference to them, and with every desire to make it complete in itself."

TRANSLATION OF THE PHARMACOPÆIA OF THE ROYAL COLLEGE OF PHYSICIANS OF LONDON, 1851: with Notes and Illustrations. By RICHARD PHILLIPS, F.R.S., L. and E., etc. (p. 567). London: 1851.

This well-known and standard work we are glad to find has not suffered in any degree by the melancholy event which has delayed its appearance. In a prefatory advertisement to this edition, Mr. J. Denham Smith gives the following explanation of the circumstances under which the duty of editor devolved upon him.[1]

"A portion of this work, on the completion of which the author had been laboriously engaged within a few days only of his decease, had been already consigned to the press, when his widow and executrix placed in my hands the copious manuscript and explanatory notes of my late highly valued friend and former teacher, in order that I might superintend its passage through the press. For the grateful task of editing this the author's last work, I possessed both the requisite leisure, and a long-standing acquaintance with his scientific views and methods of investigation; and most amply shall I be rewarded should I be deemed to have discharged this duty without detracting from the well-established reputation of the work."

In our opinion Mr. Smith has very ably and judiciously discharged his duty; and this, the last, is undoubtedly the best edition of Mr. Phillips' book.

The volume, like the *Pharmacopœia*, is divided into two parts: the first is devoted to the Materia Medica, and the second to the Pharmaceutical Preparations and Compounds.

The first part is little more than a translation of the original work. When required, however, clear and pertinent remarks are added on the tests; as in the case of acetic acid, iodide of potash, arsenious acid, etc. We have not space to critically examine this part of the work, but we may say that it seems to be well performed.

The second part is much more complete and useful than formerly. The diagrams and the notices of tests are improved; and the information regarding adulterations is greatly extended. Every article of the Materia Medica is separately treated of; and the manner in which the vegetable products are described, merits special praise.

We had intended to have taken this opportunity of entering at some length upon various topics connected with the *New London Pharmacopœia*, but we find that the demands upon the remaining pages of the current year render it necessary to postpone our remarks. In an early number of our volume for 1852, however, we hope to return to the subject of the *Pharmacopœia*, offering some criticisms upon its reviewers, as well as upon the work itself, its translators, and commentators. In the mean time, we have great confidence in commending Phillips' translation as a work admirably adapted to the wants of the prescriber, the dispenser, and the student. From its cheapness and elegance, as well as from its sterling value, we have no doubt of its having a large circulation, and a rapid sale.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

BELLADONNA IN SCARLET FEVER: THE ESSAY OF DR. PEYRE PORCHER.

Dr. Porcher has published a valuable essay in *The Charleston (U. S.) Medical Journal*, entitled "A Collection of, and an Examination into, the Evidences respecting the Employment of Atropa Belladonna, as a Preventive against Scarlet Fever." As the subject is an important one, we reprint nearly the whole of the paper.

Dr. Porcher's Essay. "In this paper, in which the task is for the first time attempted, since the appearance of Bayle's *Bibliothèque de Thérapeutique*, (which contains a pretty complete summary of the facts in his possession up to the time of its publication), we have been at the pains to collect and bring into one view all the information to be obtained touching the efficacy of Belladonna as a Prophylactic in Scarlatina. It contains the results of an examination of about four hundred volumes.[1]

"We insert the following list of works, to save future inquirers the trouble of going over the same ground.

London Lancet, 53 vols.

"From the *Dict. des Sc. Méd.*, under article 'Belladonna', we draw the following remarks: Administered in small doses, it acts on the nerves in a

[1] "In searching among some of those obtained from the Medical Society's Library, we have to express our obligations to the librarian, Dr. Lockwood, for his kind assistance."

way slightly analogous to that of the narcotics generally; but it possesses, in addition, a marked stimulating action on the general capillary system, and the exalant system more especially, from whence results abundant transudation, and the more copious suppuration from ulcers, a more free secretion of saliva, of urine, and sometimes even an increase in the menstrual flow, and of the alvine evacuations.

"Belladonna—*(Mérat and De Lens's Dictionnaire Univ. de Mat. Méd.*, 1849)—from whence we obtain the following, which are among the phenomena of poisoning by this plant, viz.: vertigo, weakness, a kind of delirious joy, hallucination of sight, faintness, nausea, dullness, conjunctival injection, dilated pupil, immobility, gesticulations, and inability to articulate sounds; small, weak pulse, sometimes accelerated, a kind of insensibility in the skin, terror, etc. After a condition characterised by stupor, accompanied with mobility of the tendons and paleness of the countenance, death closes the scene.

"We beg leave to quote from remarks by Mr. Ley, before the Royal Med. Botan. Society, in London *Lancet* for June 1844. From experiments upon his own person, he is of opinion, that belladonna is much less dangerous than many suppose. Instead of its 'diminishing sensation, irritability, and arterial action, in the first stage of its influence, he believes that it increases them all, and that the peculiar action of the remedy being exhausted, reaction takes place, and its effects, to wit—diminution of sensation, irritability and arterial action follow.' He observes that, 'soon after taking a grain of the extract, there is a peculiar taste in the mouth, and a diffused novel sensation over the whole body, which excites the attention forcibly and unpleasantly, saliva is secreted in diminished quantity. The nervous excitement becomes absolutely painful, with restlessness, and with the attempt to move, giddiness, with an affection of the cerebrum becoming evident. There is difficulty in swallowing, and the voice grows hoarse; it is as if the action of the parts were impeded by great loss of lubricating moisture of the mucous membranes.' The eyes and eye-lids also become dry; pain in the bowels may occur, and, perhaps, an evacuation, but neither purging nor diuresis is caused by it; 'sore throat and redness of the skin, resembling scarlatina, is sometimes produced, and inordinate menstrual discharge may occur suddenly in females. The attention is so entirely absorbed by the peculiar sensation, and the irritability of system, that no pursuit can be followed, the eye can see, but is indisposed to maintain attention to the object, and the ear has sensation and hears peculiar noises. The disposition to withdraw from all the excitements of passing influences becomes active, and the retirement, like weariness, brings repose.' In this stage of excitement, Dr. Ley observes, it is not difficult to trace an increased arterial action approaching to inflammation, and this being the first and immediate action of the remedy, we ought to reckon the subsidence or evanescence of these effects among the virtues of the medicine.

"We must present the concluding observations of this gentleman, as they have some bearing on the inquiry before us. 'Dr. Pereira,' he continues, 'is of the opinion that belladonna is not fitted for plethoric constitutions, nor for febrile and acute inflammatory cases, in which Mr. Ley coincides; but he thinks it may be rendered so by combination with other medicines, or by preceding its use by blood-letting. It has been his habit, he says, to produce the excitement, and to allow the reaction to go on undisturbed for a day or two. He expects more benefit on the second or third day of inaction, than from the immediate effect of the drug. In this way relief is experienced in scrofulous ophthalmia, in tooth-ache, etc., when the state of excitement has passed away. A decided astringent effect is produced by the exhibition of belladonna, in some chronic discharges from the mucous membranes, and the secretion in ulceration of the trachea is diminished, and the cough relieved hy it; various vesicular eruptions on the skin are also removed by

it, and when the contents of the vesicle have become semi-purulent, the true skin ulcerated, the ulcer being deep and devoid of healthy granulations, the edges being under the influence of the creeping vesicle, a single grain of the extract of belladonna will annihilate the eruption, and the ulcer will immediately assume a healthy appearance. This influence is well exemplified by that affection of the finger, where the cuticle is raised by a semi-purulent fluid around the nail. The cuticle being removed, the circle will still be enlarged by the separation of fresh cuticle, and the denuded surface pours out a copious discharge. 'The effect of one dose of belladonna is to dry the denuded surface, so that the disease no longer exists; and this is effected with so much rapidity, as almost to seem like magic.'

"Mr. Ley quotes cases from Mr. Liston's practice in University College Hospital, in one of which 'minute doses of belladonna cured an attack of erysipelas in two or three days'; and, in the other, a case of small ulceration on the legs, aggravated by a scald, and attended by much inflammation, 'after the fever was subdued, the belladonna speedily effected a cure.' Mr. L. finds a 'scaly, black, tobacco-smelling extract the best.'

"To repeat: Guersant, in *Dic. des Sc. Méd.*, states, that belladonna in small doses acts on the nerves in a way nearly analogous to that of the narcotics in general; but, besides, it has a marked stimulating action on the sanguineo-capillary system in general, and the exhalant system in particular, a consequence of which is the abundant transpiration its employment induces, as shown by its favourable influence on ulcers, an increased secretion of saliva, of urine, and even of the menstrual flow, and of the alvine evacuations.

"In the *Amer. Journ. of Med. Sciences*, O. S., vol. xix, 260, from *Journal de Chim.*, it is stated, that Dr. Chiorinth prescribed ʒiii of the oxide of zinc for a mare poisoned by ʒss of the extract of belladonna. The nervous system was greatly affected, the animal being attacked with palpitation and difficulty of respiration.

"In the 45th volume of the *Lancet*, there is a very complete paper by Dr. R. S. Hutchinson, on the action of belladonna, in which he contends that its action is on the spinal marrow and its nerves, and the very reverse of that of strichnine. The latter is stimulant upon this system of nerves, whilst the former is sedative. He gives it internally for neuralgias, in doses of a grain, three times a day. A number of cases are detailed by this gentleman. For its application in neuralgia, we may allude, in passing, to the papers in Bayle's *Bibliothèque de Thérap.* vol. ii; also, to the remarkable power claimed for it by a number of observers in curing cancer and scirrhus. Lambergen, Marteau de Granvilliers, and others, employed the infusion of the leaves with success in a number of cases of cancer of the breast. He supposes that, 'elle avait eu la vertu d'amenir une suppuration louable dans un cancer ouvert, et de résoudre le restant de la tumeur squirrheuse de la mamelle.' From the testimony of this gentleman, it acted very decidedly in changing the condition of the urinary secretions. 'By a peculiar and specific virtue, not only attacking and destroying the cancerous poison (le miasme cancéreux), which it diminishes in the blood, and as it exists in the mammary glands, but even carries it out through the urinary passages, in the same way as mercury and other specifics act in other disorders through the several secretions.' [Bayle.]

In a review of Chapman's *Lectures on the more important Eruptive Fevers*, etc., in the University of Pennsylvania, in the *British and Foreign Med. Review* for April 1846, we gather the following:

"'Dr. Elliottson mentions that, for nearly two years, all the children admitted into a particular ward under his care were seized with scarlatina, in consequence of a patient with the disease having been in the ward at that remote period, and this in despite of whitewashings and other cleansings.'

"Dr. C., who paid much attention to the duration of the incubative periods in contagion, observes:

" ' That of scarlatina is said to be from five to six days. My own conviction is that it is usually greater, though I speak diffidently on the point, having been unable to satisfy myself in regard to it. Equally subjected, apparently, to infection, I have seen individuals break out with the disease from the third to the eleventh day ; and we have had some cases recently reported, where, in a family of eight, the interval varied from the seventeenth to the twenty-sixth day, the average being seventeen days.' (p. 135.)

" The reviewer adds—' The professor is inclined to allow some weight to various powerful evidence in favour of belladonna as a prophylactic.'

" ' Yet, (he pithily adds,) by the assurance of Hahnemann, the author of the homœopathic doctrines, which originating in fraud and imposture, and continued by the most atrocious wickedness, that he was equally successful in the infinitesimal dose of a few drops, daily, of a solution which contained no more than the millionth part of a grain of the extract, distrust, and even ridicule, are cast over the whole affair, and our faith must be withdrawn and suspended till fresh and better evidence is afforded.' (p. 151 of his work.)

" ' To aconite, one day is the time which should be allowed for completing its action ; to belladonna, from three to six days should be given. In robust and active persons, who perspire much, the action of belladonna will be extinct in the course of about three days ; in persons in different conditions, its action may continue for six or seven days.'

" Belladonna as a Preservative against Scarlatina—experience of Dr. Schenck—(*Journal de Hufeland*, 1812.) From Bayle's *Biblioth. de Thérap.*, 391. Schenck, in inviting inquiries into the peculiar nature of the prophylactic property of belladonna, adds :

" ' Cet object est digne de la plus grande attention, et mérite qu'on le soumette à des expériences suivies ; car, se laisser prévenir contre ce moyen par l'extrême petitesse de la dose, se serait oublier qu'il est ici question d'un effet dynamique, c'est-à-dire, d'un effet sur le vivant, et qu'on ne peut apprécier ni par livres ni par grains. Quel est celui qui a pu déterminer pondérativement l'arome, ou bien la quantité d'un virus nécessaire pour produire un effet quelconque ? Etendre une substance, est-ce donc constamment l'affaiblir ? Et le liquide qui l'étend ne peut-il pas devenir un véhicule qui développe en elle une propriété nouvelle, un nouveau mode d'action plus subtil que celui qu'elle possédait auparavant.'

" In the *Lancet*, vol. xlv, for 1843, a reviewer contends that the eruptions produced by belladonna and that in scarlet fever are not identical, and that the former may be entirely accidental. He does not, however, furnish any numbers.

" Dr. Elliotson, in his *Practice of Medicine*, does not furnish us with any original information, but cautions the reader against the placing of too much credence in the preventive powers of belladonna.

" Tweedie, in his *Library*, states that he has no personal experience with the article. He mentions his having produced ' pain and redness of the fauces, with an efflorescence on the skin of the throat', by the administration of a sixth of a grain of belladonna three times a-day. He advises the making of experiments to test the question.

" Among the accounts unfavourable to the use of this preventive remedy, is one by Dr. Lehmann, published in the 22nd volume of *Rust's Magazine*, an abstract of which may be found in the *Amer. Journal*, vol. i, 1827, p. 207.

" In this memoir, he observes, that an epidemic appeared at Torgau, in 1825, of so violent a character, that one in eight of those affected with it died ; among these, thirty patients, all of tender age, fell victims. The belladonna was administered with confidence in many families in which the disease appeared, and there could be no doubt of the good quality of the extract ; nevertheless, it did not act either as a preservative, nor mitigate the severity of the disease. Dr. L. ' did not perceive any difference either in the violence of the disease, or its results, when it attacked those who had taken

the belladonna even for a long time, and in large doses, and those who had never taken the medicine.'

" Barth states (*Diss. Inaug. de Belladon. Scarlat. præsid.* Leipsic: 1827), that at Stratsund, in a frightful epidemic which prevailed, the belladonna did not act as a preservative. Dr. Mierendorf was said to have observed, that those children who took it were made more sick, and died in larger numbers than those who did not have recourse to it. Dr. Schmidt lost two children who had taken the belladonna.

" From a review of vol. ii of *Trans. of Prov. Med. and Surg. Association*, in *Brit. and For. Med. Rev.*, Jan. 1840, we find, in reference to a communication of Dr. Otto, on the diseases of Copenhagen, that 'belladonna is no longer regarded as a prophylactic against scarlatina.'

" Dr. Jos. Frank, (*Rust's Mag.* Bd. 22,) Teffel and Wagner oppose the administration of belladonna as a prophylactic; the first, however, on grounds purely theoretical.

" Review of articles by Kennedy, Belluomini, and others, on Scarlatina, in volume xvii of *Brit. and For. Med. Review*, 1844, p. 217.

" 'The results obtained', says the reviewer, 'were singularly conflicting.' M. Gondelle, in *Rev. Méd.*, Janvier, Mars, et Avril 1843, has published an exceedingly prolix essay on scarlatina, in which he labours to prove that belladonna is a prophylactic, 'but that its action, unlike that of vaccination, which destroys the liability to small-pox, is confined to removing the susceptibility to scarlatina during the time that it is employed, and ceases on its use being discontinued. Should this statement be substantiated, it may, perhaps, be the case, that the narcotic power of the belladonna, and of the kindred remedy aconite, blunts for the time the susceptibility of the constitution. On this supposition we might account for some who have been exposed to the contagion not contracting the disease. We confess that M. Guersant's favourable opinion of the prophylactic virtue of belladonna makes us hesitate, the writer adds, in the expression of our disbelief in its power. Still, it should be borne in mind, that the liability to scarlatina is much less than to small-pox and measles, and that many persons pass through life without being affected by it; and that the general result of the more recent experiments with the drug, were so much less favourable than those which were at first obtained, that Hahnemann was compelled to admit its frequent failure, and to resort to the supposition of a change in the fever in order to explain the fact.[1] For these cases he suggested the use of aconite, in which he is followed by Belluomini, and the rest of his disciples.' The following is extracted from the work of the author last cited:

" 'Belladonna is only a preservative against smooth scarlatina, and therefore it remains without effect when the prevailing epidemic is merely miliary scarlatina. Against this, the preservative is aconite. Now, as these two epidemics reign almost always at present promiscuously, whenever prudence suggests the use of a preservative, aconite and belladonna should be administered alternately. The doses of these medicines ought to be the same as those indicated for the dose, but taken at long intervals, beginning with aconite, when miliary scarlatina is dreaded, and with belladonna, if it be smooth scarlatina, and continuing the use of these medicines alternately.'

" Scarlatina, the best authorities assert, is an 'increasing malady', and its ravages progressively augment. In order to show that it is not apt to appear and suddenly disappear, we quote from Dr. Gregory's recent work on *Eruptive Fevers*, p. 182. The infecting distance of the miasm has not been investigated; but it is found that when it invades a school, no precautions avail anything towards preventing the spread of the infection. This has often been proved at the London Foundling Hospital. At Ackworth, in 1813, the

[1] " Those who wish to obtain a brief summary of the various experiments on the prophylactic powers of belladonna, are pointed to Meissner's *Forschungen*, vol. iii, S. 302, and vi, S. 441."

contagion lingered in the school four months, in spite of every effort. With regard to the susceptibility of this complaint, Dr. Binns tells us that out of 216 scholars at Ackworth school, 184 were affected. Dr. Adams remarks, that this is a larger proportion than is commonly found susceptible in districts or families. Like all other miasms, that of scarlet fever is capable of attachment to fomites, especially clothes.

" From *Archives Gén. de Médecine*, Juin 1824, which contains the original paper by Ernest Martini, which we also observe in Bayle's *Biblioth. de Thérap.*, ii, we find a pretty detailed account of the history of the remedy. We will translate and condense from this paper. In 1818, from a careful examination into the nature of scarlatina, Dr. Berndt came to the conclusion, that it was a disease affecting the nerves principally ; therefore, he thought, that whatever would excite the system might prove effectual as a prophylactic. Hence, the belladonna, recommended by Hahnemann in 1807, suggested itself to him, and he resolved to verify the opinions touching its efficacy. In order to obtain certain results, he employed the remedy upon individuals directly exposed to the contagion, and particularly on infants under five years of age, who are, it is well known, more apt to contract the disease. The doses used by Hahnemann seeming too minute, Dr. Berndt employed the following mixture :—℞ Extract belladon rec. parat. grs. ij, aquæ cinnamon. vinosæ unc. j, giving to children under one year three drops of this solution morning and evening ; three or four drops was given to those over two years of age, increasing the doses in the same proportion, according to the ages. Having used this treatment for a month or more, during the continuance of an epidemic, he had the satisfaction of observing that of 195 children exposed daily to the contagion, and to whom he administered the extract, there were but fourteen who, notwithstanding the use of the preventative, took the disease ; 181 continued exempt. The small proportion affected had the disease very mildly. Other experiments, made with three grains of the extract, given to a large number of persons exposed to the epidemic, were attended with the same happy results.

" In the London *Lancet*, p. 135, vol. xvi, we have, from *Hufeland's Journal*, some of the general deductions on the prophylactic powers of belladonna. Hufeland was led, both from his own experience, and that of a great many other practitioners, to form such a favourable opinion with respect to the powers of this medicine, that he is convinced that in epidemics of scarlet fever it ought universally to be resorted to, as the best means of preventing the disease altogether, or mitigating its violence. Among the conclusions are the following :—

" 1. The proper use of belladonna has, in most cases, prevented infection, even in those instances where, by the continual intercourse with patients labouring under scarlet fever, the predisposition towards it was greatly increased. 2. Numerous observations have shown that, by the general use of belladonna, epidemics of scarlet fever have actually been arrested. 3. In those few instances where the use of belladonna was insufficient to prevent infection, the disease has invariably been slight. 4. There are exceptions to above three points, but their number is extremely small.

" The Journal adds, that ' it seems that in some epidemics, belladonna has no protective powers at all ; the individual disposition, the method of using the remedy, and the quality of it, will, of course, have considerable influence on the result of the experiment.' The fresh extract is advised. *(Liter. Ann. der ges. Heilk.)* Effects of belladonna in preventing the contagion of scarlatina. From *Archives Gén. de Méd.*, Juin 1824, et *Journ. Comp. J.*, 1824, xviii, 369. See also *Edinburgh Journal*, January 1825.

" The discovery was made by Hahnemann[1] of Leipsic, in 1807, but he did not commence applying it till ten years afterwards.

[1] The parent of homœopathy ; and a mystic long before he became an insensate quack.

" Berndt, who, as we before observed, was the first to make a connected series of experiments, says, 'that in the epidemics of scarlet fever, which prevailed throughout the city in 1818-19, he used the belladonna as a preventive in children under sixteen years of age, freely and continuously exposed to the contagion. Of 119 cases, 14 only were affected'; and he adds, 'that afterwards, when he used a stronger preparation, every one escaped the disease.'

" Dr. Behr of Bernberg, states, that of forty-seven individuals who took the belladonna as a preventive, six only were attacked with the disease. Koreff, a professor at Berlin, affirms, from a very extensive and long-continued experience, that the most intimate intercourse may be kept up with patients affected with scarlet fever, provided the belladonna be taken in the proper dose for eight or nine days before exposure, and be continued till the period of desquamation.

" Other statements to the same effect have been accumulated in the memoirs alluded to, so that there is no want of authorities for the facts. The quantity given has generally been small. Even if the belladonna does not act as a preservative, 'it is supposed by this writer that the disease is never fatal in those taking it.'

" From *Rust's Magazine*, in *Edinburgh Journal*, 1826. Dr. Randhahn, of the Orphan Hospital of Langladorf, in Prussia, testifies, 'that in one of the apartments of the hospital, two children were attacked with scarlet fever in February 1825, and one hundred and sixty others were exposed to it. A solution of three grains of the extract in one ounce of vinous infusion of cinnamon, was given to each in small doses during the whole month of February. Up to the 21st of April, when the report was made, not a single case had occurred; and even two, who lived in the same chamber with those affected, did not suffer.'

" From *Hufeland's Journal*, in *Edinburgh Journal*, 1826, 242. Hufeland says:—'It gives him great joy to be able to confirm, by the results of fresh experience, the efficacy of belladonna, as a preventive against scarlatina. Five years have now elapsed since, in his Journal, the request was, for the first time, made to employ the belladonna with this view, and since that time, every year has brought fresh proofs of its power.'

" Dr. Kuntsmann of Berlin, employed the belladonna in every family in which he had an opportunity; in fact, in several instances, and with only one exception, always with success. In this case, as he afterwards found, the medicine had not been properly used. But as we see the scarlet fever only attacking certain members of a family, and sometimes leaving whole families unattacked, some doubts still remained in his mind about the efficacy of the medicine as a preventive of the disease. In January, however, of the year, a case occurred in his practice which, he said, tells very strongly for the alleged power of the belladonna. In an institution, of which he had direction, there were about seventy children of both sexes, from four to fourteen years of age. On the 25th of December, last year, the son of the director was attacked, and before Dr. R. was informed, two girls also, of four and seven years of age. He now separated the sick from the healthy as much as possible. Twelve drops of the mixture was the largest quantity administered. The disease afterwards made its appearance in no individual case until the 23rd of January, four weeks afterwards, when one boy was taken; the case was of a very mild nature. 'The second son of the director, who took no belladonna, was attacked with the scarlet fever in a very high degree.' 'The children took the medicine six weeks in succession, and he never saw any bad effects from its continuance.'

" Hufeland attributes the efficacy of belladonna to its power of diminishing nervous susceptibility, without which one cannot take the disease. (*Gaz. de Santé*, Mars 1826.) No one knows the nature, the cause, or the kind of perturbation which follows its administration; but to this perturbation Martini also

ascribes its preservative power. (*Rev. Méd.*, ii, 371.) M. Ibrélisle, physician at Metz, preserved twelve children from scarlatina with the belladonna, when the disease had attacked two hundred and six in the midst of whom they lived. (*Bull. de la Soc. d'Emulat.*, 1823, 201.) Dr. Velsen gave the plant to two hundred and forty-seven persons, of whom only thirteen took scarlatina. He gave two grains of the extract, dissolved in two ounces of water and two drachms of alcohol, of which fifteen to twenty drops were taken during the day. The inhabitants of entire villages in Germany, upon using belladonna, remained exempt, when the scarlet fever was in neighbouring ones. All the papers on the subject of the efficacy of the medicine as a preservative, were collected by Hufeland, in 1826, into one volume.[1] A few physicians, among whom we may mention Schwartze, did not coincide in the belief of this power in belladonna. (M. and De Lens, *cit. sup.*) Koreff, note communiquée à M. la Professeur Laennec, sur l'emploi de belladon. contre la contagion de la scarlatine. (*Bull. des Soc. Méd.*, i, 374.)

"Bayle, in 1830, published a notice favourable to the use of belladonna, by which it seemed that of 2027 individuals, in all, to whom it was administered, 1948 were preserved from scarlet fever, and 79 were attacked with it.

"Dusterborg, by means of belladonna administered for two weeks, preserved from scarlet fever all those who took the medicine. 'In order to ascertain the real value of the remedy, he purposely omitted to administer it to one child in every family; and this child alone, according to his report, was taken with the disease. He adds, however, that scarlet fever occasionally seized a child who had not been taking the remedy for three or four days, but it was, always, under these circumstances, mild, and often only manifested its presence by desquamation.'

"Zeuch, physician of the hospital for children in the Tyrol, after eighty-four children were attacked with scarlet fever, was induced to try the prophylactic effects of belladonna on the remaining sixty-seven. With a single exception, all were preserved from its attacks, though the disease was raging around.

"From Bayle, vol. ii, 508, we extract the RESULTS OF THE EXPERIENCE OF A NUMBER OF OBSERVERS.

"The *Edinburgh Journal*, vol. lx, p. 497, contains an abstract of an article from the *Bull. de l'Acad. Royale de Méd.*, 1843, by M. Stievenart.

[1] "La Vertu Préservative de la Belladonna contre la Scarlatine, pp. 226. Berlin: 1826."

"The circumstances rendered any trial of this kind of double value, as, on account of the fatality of the epidemic, 30 patients had already died out of 96 seized. In a small village of 250 individuals, 200 took the belladonna and were all preserved from the attacks of scarlet fever. Of the 50 others, 14 were seized, and 4 died. At the village of Curzies, the same gentleman, Dr. Stievenart, administered the belladonna to the children at the public school, and allowed them to continue at their lessons, and have communication with the other children of the village : 'all to whom the belladonna was administered escaped the scarlet fever, but a few who refused to take it were seized with the disease'. Dr. S. employed two grains of the recent alcoholic extract, dissolved in one ounce of aromatic infusion ; two drops being given daily to a child one year old, or he gave one-tenth of a grain of the powder of the root twice a day. He generally continued it some ten or fifteen days. The small doses never produced a toxicological effect. In five or six cases, he observed a rash like measles. 'He thinks fifteen days sufficient to put the system under the influence of the preservative power of the remedy, but he recommends a recurrence to it if the epidemic returns, or breaks out with renewed violence.'

"Observations by Massius, Professor of Medicine at Rostock. (*Biblioth. Mêd.*, xlvii, 260.) From Bayle's *Biblioth. de Thérap.*, ii, 394, we find that he relies from his own experience in the efficacy of belladonna as a prophylactic. In this he is sustained by Dr. Gumpert of Posen (see also *loc. cit.*), Maisier, of Magdebourg, and Velsen.

"From the supplementary volume, 1846, to Mérat and De Len's *Dict. de Mat. Méd.*, additional evidence is afforded us. Dr. Sazinot reports that of sixteen children to whom he administered belladonna as a preventive, twelve remained entirely exempt, although they were exposed to the contagion. Four of them had no eruption, but suffered from slight sore throat. (From *London Medical and Phys. Journal*, vi, 361, N.S.) Dr. Hillem-Kamp, during an epidemic of scarlet fever, prescribed the solution of the extract of belladonna to one hundred and five children, of from one to six years old; of this number, one half took the remedy regularly—twenty to thirty used it irregularly—from twenty to thirty did not take it at all. Of the first, five only had scarlatina; of the second, eight took the disease ; and of the last, eleven ; but of those who had taken the belladonna, none died. This gentleman used a solution of two grains of the extract in one ounce of water, giving morning and evening as many drops as the child had years. (*Journal de Hufeland*, Mars 1832.)

"From a review of Dr. Oppenheim's work on the *State of Medicine in Turkey*, in *British and Foreign Med. Rev.*, Oct. 1837, 393, we have the following statement of what is regarded as a 'marked instance of the prophylactic powers of belladonna in scarlatina', used on a large scale. 'The disease had also broken out among the troops in Monastir, where no separation of the healthy from the unhealthy was practicable; several soldiers had been carried off, and the disease had even snatched a victim from the Grand Visir's harem. The Visir, who loved his troops as his children, became alarmed, when I thought it my duty to make him acquainted with our preventive measures. He issued an order to his soldiers to take carefully a medicine that would be prepared for them; and as he set the example by taking it himself from the hands of his physician, they obeyed with less reluctance. As I had to fear that the counting of the drops would not be well attended to, I preferred the form of pills, in spite of the opposition of the apothecaries, who for a whole week were engaged in nothing else than in making pills, although only two battalions (1200 men) of regular troops were in the town. I directed one pound of extract of liquorice to be mixed with thirty-six grains of extract of belladonna, and the mass to be made into two-grain pills, of which each soldier was to take five, morning and evening. I entertained the hope that this dose, though smaller than usually prescribed,

would have the desired effect with men who had never taken any medicine, and who were all between the ages of fifteen and twenty-five; and the result answered my expectation; for, although the epidemic continued to rage in the city, and the soldiers were quartered on the Christian and Jewish part of the population, only twelve of all that had taken the belladonna fell sick, of which, however, one half died. In ten days previous to the administering of the medicine, more than forty cases of sickness had been entered on the sick list.'

"The London *Lancet*, vol. xxix, 1838, mentions, in a review of Professor Fleischman's *Practical Observations*, that the extract of belladonna (two grains to one ounce of distilled water) was given to fifty-two children, of from six to fourteen years of age. Each patient took, morning and evening, as many drops of the solution as he counted years, and this dose was in some instances increased. The remedy was thus administered during five weeks —the duration of the epidemic. Of the fifty-two individuals, forty-eight remained free from any attack, and four were affected with the disease. In two families, where the children commenced taking the remedy immediately on the disease attacking one of the family, all the children remained free from contagion, although they were in constant communication with the affected individual during the whole course of the disease. In twenty-three cases, Dr. F. remarked some of the ordinary symptoms of the action of the belladonna a few days after its use. Three were covered with miliary vesicles. Some of the conclusions drawn by this writer are, that it either counteracts the contagiousness of scarlatina, or that it diminishes the susceptibility to it—and that, when the disease does occur during its use, its character is much more mild.

"From Pereira, we learn that Bayle (*Bib. de Thérap.*, ii, 504), before alluded to, has collected from various publications 2027 cases of persons who took this medicine and were exposed to the contagion; of these 1948 escaped. Oppenheim (*Lond. Med. Gaz.*, xiii, 814) gave it to 1200 soldiers, and only twelve became affected. To these may be added Hufeland (*Lancet*, May 2, 1829) and Koreff (*Lond. Med. Gaz.*, iv, 297), who admit, from their own personal observations, the efficacy of the remedy, though they have not specified the number of cases in which they have tried it. But bearing in mind, Dr. P. adds, 'the well known capriciousness of scarlet fever in regard to the subjects of its attacks, and the large number of those who, though exposed to its influence, escape, the best evidence hitherto adduced in favour of the notion must be admitted to be inconclusive. While, therefore, the facts brought forward,' he continues, 'in favour of the existence of this prophylactic power are only negative, those which can be adduced against it are positive; for I conceive twenty cases of failure are more conclusive against the opinion here referred to, than one thousand of non-occurrence are in favour of it. Now Lehmann (see Bayle, *loc. cit. sup.*); Barth (*ibid.*); Wendt (Rust's and Casper's *Krit. Repert.*, xxii, 115); Muhrbeck (*Rust's Mag.*, xxiv, 485); Hoffmann (*ibid.*, xxv, s. 115); Bock (*ibid.*, s. 80); and many others that I could refer to, declare that it has failed in their hands to evince its prophylactic powers.' In this country, Dr. Pereira states, that we have no extended series of observations to quote; but the cases which he is acquainted with are decidedly against the efficacy of the remedy. A remarkable failure is mentioned by Dr. Sigmond (*Lancet*, 1836, '37, vol. ii, 78), of a family of eleven persons who took the supposed specific, yet every individual contracted the disease.

"Dr. Watson, in his *Practice of Physic.*, p. 1025, professes to have had no experience with belladonna as a prophylactic, though he advises the reader to give it a fair trial.

"The American editor of Watson, Dr. Condie, after noticing some of the arguments in its favour, says: 'We have ourselves given the belladonna to a number of children, on several occasions when the scarlet fever was prevailing epidemically, with a view of testing its prophylactic powers; but

although redness and dryness of the throat, and a diffuse scarlet efflorescence was produced by it, yet, in the majority of cases, we never found it in any instance to exhibit the slightest influence in shielding those who took it from an attack of the disease, or in mitigating in any degree its severity. In one case, the efflorescence produced by the belladonna was kept up for forty-eight hours; in a week afterwards, the child was attacked by the fever in the most virulent form, and died on the fourth day.' Dr. C. admits, however, that the testimony adduced by Steivenart is very strong in its favour, and that if the experiments, which were on an extended scale, were correctly stated and carefully made, 'they would go far to prove that belladonna *does* actually possess the property of shielding the constitution from an attack of scarlet fever.' We have already cited these experiments of Dr. S., which we obtained from another source.

"Dr. T. D. Mitchell, in his *Thérap.* and *Mat. Medica*, published in 1850, professes himself a believer in the prophylactic power of the article under consideration. The causes of failure he ascribes to using an inert article. He also cites Dr. Newbigging, 'who has recently tested the preventive powers of belladonna in a public institution', where seclusion had failed to arrest the spread of the disease; he gave the extract in doses of a sixth of a grain with marked success. (*Edinb. Monthly Journal*, Sept. 1849.)

"In Valenciennes, in 1846, four hundred children, we are told, were treated with belladonna to save them from scarlatina, then prevailing as an epidemic in the vicinity. All escaped, although only six had any efflorescence, and in one hundred and forty-five there was no apparent local manifestation of any kind.

"Dr. Mitchell, after alluding to the American testimony contained in Bell's *Bull. of the Med. Sciences* for February 1846, continues: 'And I add that I have employed the extract with such decidedly *preventive* efficacy, that it would be folly or madness to doubt. Again and again have I applied the aromatic solution, and have not only gained the desired result, so far as the *prevention* was concerned, but have allayed the perturbation of nervous mothers by exciting their confidence, and enlisting their fixed attention to its careful administration. This alone is worth all the trouble of the prescription.'

"Dr. Meigs, in his work on *Diseases of Children*, confesses to have had no experience, yet he admits the force of testimony adduced by others.

"Cazenave, p. 58 of his work on *Diseases of the Skin*, mentions that 'M. Biett saw the disease reign epidemically in one of the lofty valleys of Switzerland, and respect, almost without exception, children to whom the belladonna had been administered.'

"In the last volume (iii) of the *Trans. of the American Medical Association*, the Chairman of the Committee on Practical Medicine and Epidemics, Dr. J. K. Mitchell, observes as follows. As it is so pertinent, we will extract it entire. 'Too little attention has been paid to the subject of the prophylaxis of belladonna against the inroads of scarlatina. A careful examination of the recorded evidence, shows that no professional point rests upon higher proof than this. One of the committee having been impressed by the force of the evidence, endeavoured to put it to the test of a prolonged and varied experiment, with results of the most variable character. It is true that either scarlatina, or some disease very like to it, is often far from being readily propagated by contagion, whilst at other times it is rapidly disseminated from person to person. This fact renders very difficult a satisfactory solution of this question; but it may not be amiss to say, that with one failure out of thirteen experiments made in several different years, scarlatina has been apparently divested of its contagious power when treated by belladonna. In the last experiment, recently made, one of eight children in a single family was attacked with severe, well marked scarlatina. The other children, being immediately placed under the use of belladonna, were per-

mitted to have constant access to the apartment of the one attacked. All of them escaped the disease. Without segregation, so far as the subject has been examined, with but one exception, the unprotected have been thus preserved from the disease. The greatest difficulty lies in the scarcity of good extract of belladonna. But this may be obviated so soon as the demand will justify experiments for its better preservation. The best formulary is that which holds the alcoholic extract in solution in camphor water, and of this a quarter of a grain a day may be administered to a child of three years of age. These suggestions are made chiefly with a view to attract the attention of rural physicians to an experiment, which may be best examined in the very limited localities in which they reside.'

"From the report on Practical Medicine, by Dr. Austin Flint, in the forthcoming volume of the *Trans. of the American Medical Association*, the reporter states: 'Of the value of *belladonna* as a prophylactic agent in this disease (scarlatina), a member of the committee, Dr. R. Haymond, of Brookville, Indiana, expresses, in a letter to the chairman of the committee, strong testimony, based on a large opportunity for observation. He states that, for the last ten or twelve years, his attention has been directed to this subject; and that, during this period, he must have administered this remedy, for that end, in between two and three hundred cases. Of the whole number, but *two* have ever contracted the disease, and in both these cases, the disease was mild and easily managed. In both instances, the eruption varied from the usual appearance, the red points being larger and more distinct, resembling somewhat the eruption of measles.'

"In an article in the *Southern Jour. Medicine and Pharmacy*, vol. i, No. 1, we find an article by John S. Erwin, M.D., entitled 'A Short Sketch of Scarlatina', from observations made during the epidemic of 1843, in Buncome Co., N. C. From the way in which it made its appearance, Dr. E. was led to the opinion that it spread independently of communication. He says that the statement of Dr. Green, that those who 'have taken the medicine generally escape the disease altogether, or, if they do become affected, have it in the mildest possible form', agrees precisely with what he knew to be facts. 'During the prevalence of the epidemic, Dr. Hardy gave notice that he would prepare the belladonna for all who wished to try the experiment. Anxiety, of course, led many parents to avail themselves of this their only hope; he followed the original mode of prescription, dissolving three grains of the extract in one ounce of cinnamon water, and directing two or three drops, morning and evening, to a child under one year old, and one drop for every year above that age. He and myself kept an account of two hundred and fifty children, who took it thus; and of that number, less than half a dozen had the disease, and they had it very mildly. After eight or ten days' use of the medicine, there was an eruption over most of the surface, in some cases profuse and troublesome from itching. Those families which did not take the preparation, had the disease with scarce an exception. I recollect a remarkable incident that occurred in a particular neighbourhood. A poor woman, with a family of sixteen children, used it carefully according to directions, and it is notorious that her family alone escaped, when hundreds were attacked. Many other striking cases might be enumerated to prove its efficacy, both there and elsewhere; but, to avoid prolixity, they must be omitted. Dr. McKee, in the extension of the same epidemic, exhibited the belladonna with the same astonishing powers of prevention. These facts coming under my own observation, I cannot but believe it to be almost an infallible prophylactic when properly used.'

"The result of our inquiries among some of the medical gentlemen in this city, is as follows. We may add, that few had the opportunity of making accurate observations. Dr. S. H. Dickson has not found it effectual in preventing the appearance of scarlet fever, though he has not given it an extensive trial. Dr. E. Geddings, also, is not disposed to put much faith in it.

Drs. Moultrie and Prioleau have seen no particular effects. Dr. H. R. Frost informs us that he has recently been administering it to forty or more persons, and he is impressed with its beneficial influences. Drs. Lebby and Robertson, from a comparatively limited experience with its use, are inclined to rely upon it. Dr. Cain has used it in a number of cases, and he thinks very favourably of it; he saw but one instance when a child with the eruption of belladonna took the disease, and that in a modified form, and it recovered. His own child had a very thick rash on the face from taking the belladonna. Dr. Ogier, though he cannot furnish the numbers, has experienced such benefit from its use that he confides in its prophylactic powers. Dr. De Saussure has tried it on a few occasions, and thinks favourably of it. We have ourselves administered the belladonna to several persons; none of these, though exposed to the disease, suffered from it. We did not notice the scarlet efflorescence.

"From the *Minute Book* of the Charlestown Orphan House, we find, from the physician's annual report for the year 1838, that a 'frightful epidemic of scarlet fever' prevailed. There were 136 inmates, including 114 children, 12 officers, and 10 servants; of the first, 67 had the disease. Through the kindness of Dr. George Logan, the attending physician, and of Mr. Campbell, the superintendent of the house, we are enabled to make the following abstracts. We gather from the symptoms related, that the disease showed itself in by no means a mild form; yet of the 67 who suffered from it, only one died. 'The progress of the disease was here arrested, and more than two months have elapsed since its entire disappearance. That almost fifty inmates of the house, generally alike predisposed in constitution, and alike exposed to contagion in its active stages, should have escaped, is indeed a pathological fact worthy of record, which neither the admission of accident nor idiosyncracy can explain. Was it attributable to a returning salubrity of the locality? or shall we venture to ascribe it to the persevering exhibition of belladonna, which was carefully administered for three weeks, morning and evening, in accordance with the views of Dr. Hahnemann, of Leipsic, and also of Dr. Koreff, of Berlin, who employed it with extraordinary success as a prophylactic.' Dr. L. remarks upon the similarity between the effects produced by belladonna, and those by the administration of arsenic.

"In reviewing the testimony afforded by the preceding facts, our opinions, if we are allowed to express them, are decidedly in favour of the prophylactic power of belladonna. However some may consider the evidence of a negative character, and therefore unworthy of confidence, yet, from its cumulation, from the careful way in which some observers conducted their inquiries, and from the possibility of failures[1] being owing to the use of an inferior or badly prepared drug, we cannot but conceive that to discard it as utterly indecisive, would be indulging a spirit of irrational incredulity, leading to the rejection of any amount of merely presumptive proof. But assuredly under circumstances like these, granting that the efficacy of the means is only problematical, none should hesitate to employ measures so simple in their application, and so safe in their consequences. The failure to avail ourselves of the prophylactic influences of belladonna, we cannot now but regard as a violation of those sacred obligations, which force us to leave nothing untried which *may* contribute so largely to the mitigation, or eradication, of one of the severest inflictions of the hand of God.

"After carefully considering the nature of the action of belladonna, and the nature and course of, and the pathological phenomena accompanying scarlatina, in order to endeavour to ascertain what relations there may be between the administration of the one, and the existence, or non-existence of the other, we draw the following conclusions:

"Belladonna, in the comparatively small doses used, may not, it is true,

[1] Frequently, we suspect, to inadequacy of the dose. Ed. Lond. J. of Med.

have the same toxicological effects that larger quantities produce, yet, either in large, or in continued small doses, we find that it acts, first, on the external cutaneous surface, stimulating the sanguineous capillaries in general and the exhalants in particular, as shown by the scarlet efflorescence, and by the more copious discharge from ulcers; 2nd, on the internal mucous membranes, producing dryness, heat, and swelling of the throat and fauces; and, 3rd, on the nerves, affecting the entire cerebro-spinal system with its ramifications, inducing delirium, dilatation of pupil, relaxation of muscular fibres generally, a kind of narcotism, and, finally, death.

"All of these it may, and probably does, reach, by being received into the blood.

"Now in scarlatina, whatever be its true nature, we find the onus of the disease resting upon these very organs, and influencing these very functions, which we observe most liable to be affected by the belladonna. We need not cite the usual and well-known train of symptoms so characteristic of the disease.

"May not, then, the prophylactic power of the drug, gradually introduced, depend upon an antagonism going on. The influences induced by it gradually modifying the condition of the organisms and their functions, may weaken or destroy the noxious agent—or, the general nervous erythism in which the system is thrown, may render it insusceptible to the incursion of the epidemic, which seeks for its seat, as we remarked, precisely those localities pre-occupied by the drug, supposing it to have been previously administered.

"Moreover, in scarlatina, from the disturbance to the healthy play of affinities throughout the entire system, renal derangements are of frequent occurrence, and our therapeutic resources are consequently directed to this important secretion. Belladonna, from the observation of those who employed it for cancerous affection, as well as for the prevention of scarlatina, is shown to produce a very decided determination towards, or free secretion from, this great emunctory. May not this also be one of the channels through which it exerts so beneficial an influence? So powerful was the effect produced upon the kidneys and bladder, that to this some of the early writers attributed its ability to cleanse and purify the blood, and hence to eradicate the cancerous diathesis.

"In a word, belladonna, by its obvious action on the several parts of the body, or on its functions, may so impregnate, or produce such a condition or *status* of them, as materially to modify, neutralize, or destroy, the noxious influences of a virus or miasm (scarlatina), which is about to seize upon, multiply itself, or be absorbed, in the same parts, or act upon the same functions of the system."

TRICHIASIS OF THE URINARY PASSAGES; PILIMICTION.

M. Rayer has published an elaborate article on the above subject, in the *Gazette Médicale* for August 2, 9, and 16, 1851. He had never seen a case in which hairs were passed in the urine, until a child, in whom this occurred, was sent to him by Dr. Paulin.

Hippocrates is supposed by some to refer to urinary trichiasis in the following words. "When thick urine contains small pieces of fleshy substance, or hair-like matters, it is from the kidneys that these are furnished."[1] This is Galen's reading, in his commentary; and M. Rayer thinks it likely that he had seen both flesh-like substances (clots) and hair-like filaments, excreted with the urine; but that Hippocrates speaks of but one thing—*small hair-like fleshy substances.* Celsus, in speaking of *carunculæ quædam*

[1] Ὁκοσοισιν ἐν τῳ ὑρῳ παχει ἐοντι σαρκία μικρὰ, ἢ ὥσπερ τρίχες ξυνεξέρχονται, τουτέοισιν ἀπὸ τῶν νεφρῶν ἐκκρίνεται.

exiguæ quasi capilli in the urine (*Lib.* ii, *Lect.* 7), very probably refers to filaments of fibrin : and the same remark may be made with regard to the Arabian writers. Altogether, the old authors speak often enough of substances *like hair* passed with the urine ; but there is no distinct reference to true hairs.

M. Rayer examines the subject under the following heads.

I. Hairs in the kidneys, or rather in the pelvis :—in the ureters ?

II. Hairs found in the bladder, and developed in the urinary passages.

III. Hairs found in the bladder or passed with the urine, proceeding from tumours which have opened into the bladder.

IV. Hairs in the prostate, or the urethral canal.

V. Hairs in urine, containing also mucus, blood, pus, or other foreign matters.

VI. Hairs in the urine of persons who have uric acid, gravel, or calculi.

VII. Hairs encrusted with phosphate of lime and phosphate of magnesia, and sometimes with a certain proportion of uric acid (*gravelle pileuse* of Magendie) : also hairs serving as the nuclei of phosphatic and other calculi.

VIII. Hairs in the urine ; gravelly matter of uncertain nature : purulent urine.

XI. Hair-like filaments, and hairs of animals found in the urine, sediments, gravel, or calculi, and mistaken for human hairs.

I. Hairs in the Pelvis of the Kidney, or in the Uterus. M. Rayer has, with others, sometimes found fibrinous filaments in the ureters, formed of blood from the kidneys ; and he thinks that the remarks of Hippocrates and Galen may apply to these. Bichat alone enunciates the fact, that hairs sometimes grow from mucous surfaces, as the stomach, intestines, or bladder : but he does not bring forward sufficient proof, although it is rather difficult to believe that so accurate an observer should have been deceived. There is no case to prove the formation of true hairs in the ureters.

II. Hairs developed in the Urinary Passages, and found in the Bladder. J. F. Meckel says that the bladder is sometimes bristled with hairs (*herissée de poils*) ; but this is rather a presumption deduced from pilimiction than an anatomical fact. Hoffmann, in the *Ephem. Natur. Curios.*, centaine v and vi, observ. 45, relates the case of a child, aged 6 years, who had strangury and tenesmus, with dysuria, and emission of hairs. It died ; and two calculi were found in the bladder, as well as fine hairs, straight or rolled up, scattered here and there. M. Maillet, as well as M. Rayer, have seen hairs in the stomach of the horse ; but have not been able to find them in the human stomach, nor in the urinary organs. The latter point, however, requires further investigation.

III. Hairs found in the Bladder or passed with the Urine, and furnished by Tumours opening into the Bladder. Hairs have sometimes been found, either free or attached to portions of membrane, in the bladders of women who have, during life, presented a tumour of greater or less size in the neighbourhood of one of the ovaries. After death, it has been ascertained that the cyst has opened into the bladder, with the walls of which it had become intimately adherent. It will hence be readily understood, that the pilimiction which some of these patients have presented during life is altogether distinct from true trichiasis, or growth of hairs in the urinary passages.

Several cases of this kind have been collected by M. Rayer, from various sources.

Dr. Amos Hamelin, of Durham, New York, related the case of a woman, aged 24 years, who was delivered at full term of a dead infant. Six days after, she was attacked with puerperal fever, and died on the twenty-second day. On *post-mortem* examination, a tumour, as large as a hen's egg, was found near the right ovary. It was adherent to the bladder, into which

there projected from the tumour a large bunch of hairs, which were from four to twelve inches long. The tumour contained osseous matter, and a small quantity of cerebriform substance.[1]

M. Delpech relates the case of a pregnant woman, who passed hairs with her urine ; and this state continued after she was delivered. Suspecting that there was a calculus in the bladder, M. Delpech incised the urethra, and removed a small calculus with several bunches of hairs. Two months after, the patient was again seized with pain, and again passed hairs. The bladder was again examined, and from it was removed a substance as large as an egg, having at one end a piece of membrane in which were implanted hairs, and enclosing a piece of bone like a zygomatic apophysis. The piece of bone contained a molar tooth, like that of a child five or six years old.[2]

Dr. Edward Philips, of Andover, relates the case of a woman, 30 years old, who had had dysuria from her youth. At 28 years of age, she had inflammation of the bladder, which was treated by antiphlogistics. A tumour was felt, extending from the lower surface of the liver towards the umbilicus. The patient died after having had symptoms of peritonitis. An encysted tumour was found in the right ovary, containing a creamy matter, and a tuft of hairs ; and the same substances were found in the bladder. At the inferior and posterior part of the latter organ, there was a cyst filled with creamy matter and hair, and also containing an incisor tooth, implanted in a piece of bone resembling an alveolus. The specimen is preserved in the Museum of the Royal College of Surgeons of England.[3]

M. De la Rivière, junior, gives an account of a woman, aged 58, who complained of pain in the hypogastric region, with dysuria. Catheterism was followed by an abundant evacuation of pus, which gave some relief. The symptoms returned ; she had purulent urine, vomiting, and diarrhœa ; and died. The bladder was adherent to the uterus : it contained some pieces of bone, and a roll of interlaced hairs, with purulent matter.[4]

M. Hippolyte Larrey gives the case of a woman, 33 years old, who, after three pregnancies, presented symptoms of which the following is a summary : a tumour as large as an egg in the left iliac region ; abscess in the hypogastrium, followed by fistula, from which proceeded pus, hairs, and urine ; emission of hairs with the urine ; a calculus, with hairs as its nucleus. A hairy tumour and a calculus were removed, and she recovered.[5]

A case evidently analogous to the preceding is recorded by Schenck, in his *Obs. Med.*, lib. iii, *De Urinis*, ob. 24, p. 486, as having occurred in an Apulian woman in the year 1573.

In several cases also, where the *débris* of a fœtus have been passed through the rectum and bladder, it is very probable that there were hairs.

IV. Hairs in the Urethra, and in the Prostatic and Seminal Ducts. No true case of this kind has probably been observed ; but fibrinous or purulent filaments have doubtless been mistaken for hairs.

V. Hairs in the Urine, which at the same time contains Mucus, Blood, Pus, or other Foreign Animal Matters. Cases of this nature have been recorded by Tulpius, Fabricius Hildanus, Spielenberger, and Zacutus Lusitanicus ; but M. Rayer suspects that the hairs were introduced from without. In two of the cases, they much resembled hog's bristles ; and, in Spielenberger's case, they were of the same colours and size as those

of the lap-dog belonging to the lady who passed them. The *Gazette Médicale* for 1851, p. 192, contains a case of cystic trichiasis, by M. Kræmer, occurring in a man 42 years of age. The hairs were finer than those of the head ; and were not those of the pubic region.

VI. HAIRS IN THE URINE OF THE SUBJECTS OF URIC ACID GRAVEL OR CALCULI. M. Rayer remarks, with regard to Dr. Golding Bird's observation that crystals of uric acid are often formed round a hair, that it is more likely that the hairs have been accidentally mixed with the urine, than that they have been passed with it.

M. Rayer relates the case of a boy ten years old, who was sent to him by M. Paulin. The child had been accustomed to a tonic and highly nitrogenised diet from infancy. Small hairs, and fragments of hair, which could not be easily accounted for, were passed in the urine ; and the sediment contained groups of microscopic uric acid crystals.

Dr. William Henry has recorded the case of an old gentleman who passed hairs, with uric acid gravel. No details are given of the treatment or the termination of the case.[1]

M. Rayer also refers to the case communicated by Mr. Paget, of Leicester, to the Medico-Chirurgical Society[2] last year, in which the urachus remained open, and a ring-shaped calculus, formed on a hair in the bladder, was extracted through the umbilicus.

VII. HAIRS ENCRUSTED WITH PHOSPHATE OF LIME OR OF MAGNESIA, AND SOMETIMES WITH URIC ACID : ALSO HAIRS SERVING AS THE NUCLEI OF CALCULI, PHOSPHATIC, OR OF UNKNOWN COMPOSITION. M. Magendie describes, in his *Recherches Physiologiques et Médicales sur les causes, etc., de la Gravelle*, an affection which he terms *gravelle pileuse*, in which small hairs, from a line to an inch or more in length, are passed with the gravel. M. Civiale, in his *Traité de l'Affection Calculeuse*, says, that he has often found dry mucous filaments among the gravel ; and still oftener, hairs introduced from the dust floating in the atmosphere. M. Rayer believes that he here alludes to pieces of cotton, wool, etc., which may easily escape from the clothing, etc. ; and these can readily be distinguished from real hairs. He quotes the details of two cases, in which gravel and small calculi were mixed with hairs in the urine : one is related by Mr. James Mitchell, in the *Edinburgh Medical and Surgical Journal* for July 1828 ; the other by Mr. Edward Parker, in vol. xxvii of the *Medico-Chirurgical Transactions*.

Some of the observations of Sir B. Brodie, M. Civiale, etc., on the formation of calculi round hairs as a nucleus are referred to. M. Rayer doubts the vesical origin of these hairs.

VIII. HAIRS IN THE URINE; GRAVEL OF AN INDETERMINATE NATURE ; PURULENT URINE. Under this head is given the account of an interesting case, which formed the subject of a scientific correspondence between Sir Hans Sloane, Dr. Yonge, of Plymouth, and Mr. J. Powell, at the early part of the last century. The correspondence is given in the *Philosophical Transactions* of that period. The subject was a plethoric woman, 50 years old. She had frequent nephritic pains, with purulent and gravelly urine. In the progress of the case, during an attack of pain, she passed a large quantity of matter containing a tuft of small hairs. Leeuwenhoek examined some of them, and believed them to be filaments of wool.

IX. HAIR-LIKE FILAMENTS IN THE URINE, IN THE SEDIMENTS, IN GRAVEL, OR IN CALCULI, CAPABLE OF BEING CONFOUNDED WITH HUMAN HAIRS. Under this head M. Rayer includes,—

1. Fibrinous filaments, more or less decolorised.
2. Mucous filaments, concrete or dried.

---

[1] Medico-Chirurgical Transactions, vol. x, 1819.

[2] Medico-Chirurgical Transactions, vol. xxxiii, 1850.

3. Filaments of coagulated albumen ?—described by Dr. G. Bird, but thought by M. Rayer to be more probably casts of tubes.
4. Confervæ, etc., developed in the urine or on its surface some time after emission.
5. Filaments of linen, cotton, or wool, coloured or not.
6. Hairs of other animals, added accidentally or intentionally to the urine after it has been passed.

Conclusions. The hairs which are sometimes observed in the urinary passages, in the urine, in gravel, or in calculi, may arise in one of three ways:—1. By being formed in the urinary passages (trichiasis); 2. By being evacuated from cysts; 3. By being introduced from without.

1. *Trichiasis of the urinary passages* is a very rare affection. The number of cases in which it is alleged to have taken place is much reduced, when we remove from them those in which the urine was not examined as soon as it was voided, and those where the true nature of the hairs has not been established. Trichiasis is characterised by the emission of hairs in urine, either not sensibly altered in its appearance and composition, or containing more or less mucus, blood, or pus. The hairs may be intermingled with uric acid or phosphatic gravel; they may also be deposited on the surface, or disseminated in the interior, of calculi.

The emission of hairs sometimes takes place without pain (simple trichiasis); but it is more frequently accompanied by such complications, as dysuria, and sanguinolent, or purulent urine, etc.

The causes of this singular affection are quite unknown. From the cases observed, it appears most frequently to coexist with inflammation of the mucous membrane of the urinary passages, with gravel, or with calculi. Trichiasis has been observed in children, adults, and old persons, both male and female.

Nothing is yet known of the arrangement of the hairs, or of the anatomical state of the mucous membrane in trichiasis of the urinary passages; Maurice Hoffmann and Bichat having unfortunately omitted to examine the mucous membrane in those cases in which they allege that they found hairs in the urinary organs after death.

When trichiasis coexists with uric acid gravel, the employment of alkalies is indicated, as in simple gravel; acids are preferable when it is phosphatic gravel that the hairs are mixed with. For inflammation accompanying trichiasis, the ordinary antiphlogistic remedies are to be employed.

2. *The evacuation of hairs from cysts* constitutes a distinct pathological condition. These cases of pilimiction have only been observed in women; but the facts are generally well authenticated. This form is distinguished from ordinary pilimiction by the existence of a tumour, generally in the vicinity of one of the ovaries, and which can be recognised by a careful examination *per rectum* and *per vaginam*. The knowledge of any accidental circumstances which may have preceded the pilimiction will render the diagnosis more easy; while the emission or extraction from the urethra of pieces of membrane covered with hair, fragments of bone, teeth, etc., will confirm it. The surgeon may sometimes render very efficacious aid to nature by promoting the expulsion of hairs, teeth, calculi, etc., or by extracting them.

3. *The introduction of hairs into the bladder from without* is rare, but has occurred. A bunch of hairs, introduced into the bladder, has been known to become the nucleus of a calculus. Some surgeons believe that hairs may be introduced with the catheter; and M. Rayer has found hairs, filaments of wool, linen, and cotton, with fragments of calculi, often enough to lead him to suppose that they were introduced during lithotrity.

DR. JENNER ON THE USE OF THE NEUTRAL SULPHITES IN THE TREATMENT OF DISEASES ATTENDED BY THE DEVELOPMENT OF PARISITIC PLANTS, ESPECIALLY THE SARCINA VENTRICULI.

In the *Medical Times* of the 23rd August, there is an interesting Clinical Lecture, of which we give the following abstract. Dr. Jenner has certainly added to the therapeutic resources of the physician, and thrown new light on the nature of a rare disease.

I seize this occasion of illustrating the advantages that the science of medicine has derived from the progress of the collateral sciences, and of proving to you that the microscope is not a mere toy for the non-practical man, but, "one aid the more" in enabling us to determine the disease under which the patient labours, and *so* of treating him the more successfully, and that a knowledge of chemistry may serve, in some cases, to direct us in our choice of remedies. * * * * *

Case. James Martin, now aged sixty-six, the son of healthy parents, who died at the ages of eighty-two and eighty respectively, enlisted into the Artillery when eighteen years of age. He was discharged in 1824, and was working in the Thames Tunnel when the water broke in. In 1829, he entered the police force, in which he continued for seven years. After leaving it, he entered the Queen of Spain's service, and returned with the Legion in 1837. Though formerly of intemperate habits, he avers that for many years he had been very sober. With the exception of an attack of ague while in America, his health, up to the time of the accident in the Thames Tunnel, was excellent. From that event, he dates the commencement of his present ailment. While in the police, he suffered from intense pain in the epigastrium, and used often to retire into back streets, and there lean with his abdomen firmly fixed against an iron post. At first, the vomiting occurred once or twice a week; afterwards, every day. It was at this time, he says, that he first vomited blood. From the time of the accident he has been subject to constipation, for which he long tried all sorts of quack medicines; and, to relieve the pain in the abdomen, he took a teaspoonful of carbonate of soda twice a day.

In the early part of 1838, he entered University College Hospital, and, by his own account, has been unable to work since. He has been, at different times, both an in and an out-patient at this and other hospitals, and, on one occasion, was an inmate of the parish infirmary. He was an out-patient when I was appointed to this hospital, but too ill to attend himself. His wife came for his medicines. It was in consequence of the description she gave of the vomited matters (viz., that they frothed over the vessel in which they were received, like yeast), that I examined them microscopically. I then found the bodies described by Mr. Goodsir, in 1842, as sarcina ventriculi.

[Dr. Jenner visited the patient a year ago; and his state then was much as on admission into the hospital.]

While an out-patient, I tried for his relief nitrate of silver, hydrocyanic acid, creasote, morphia, henbane, large doses of carbonate of soda, etc. I thought the morphia lessened the frequency of the vomiting, but, although it produced drowsiness, it seemed to increase the pain. With difficulty I persuaded him to come into the hospital; and, so satisfied was his wife that death would speedily terminate his sufferings, that, after he had been in a few days, she earnestly entreated me to discharge him, lest he should die here.

He was admitted as an in-patient March 15th, 1851, and on the 16th the following notes of the case were taken:—Mind and special senses normal; *arcus senilis* strongly marked; can walk with facility, but feels weak; expression worn; is extremely thin; skin cool; mucous membranes pale; no sallowness of complexion, no anasarca, legs drawn up towards his abdomen, and his arms around his knees, shoulders bent forwards, his head resting on

the elevated inferior extremities ; tongue large, flabby, indented at the edges, and thinly furred ; no dysphagia ; appetite generally good ; had for his dinner yesterday two potatoes and some broth ; dined between twelve and one o'clock ; at five o'clock, P.M., vomited, ejecting the whole of the matters now in the basin in about five minutes ; the quantity of ejected matter reserved is two quarts.

Characters of the Vomited Matter. Floating on the surface is a layer, from a quarter to half an inch thick, of a brownish colour, closely resembling yeast in general characters, entangling in its substance quantities of air-bubbles. *Microscopical Elements.* Striated muscular fibres : sarcinæ ventriculi in great numbers, of a dark yellowish colour ; torulæ very numerous, undistinguishable from the yeast-plant in size and shape ; fat globules and starch.

After eating his dinner, felt comfortable and satisfied for two hours, then experienced considerable thirst ; about four o'clock, P.M., took a cupful of cold fluid. He thinks that cold fluids excite vomiting, hot prevent it ; that cold fluids cause pain, hot fluids relieve it ; from the time of drinking the fluid he felt severe burning twisting pain over nearly the whole abdomen ; the burning pain was most severe about the epigastric region, the twisting pain about the umbilicus ; to use his own expression, "he felt in a burning flame"; much flatus was discharged before vomiting, chiefly by belching ; each eructation of flatus was attended with severe sense of burning up the centre of the sternum, called by the patient "a flashing pain"; after vomiting, the pain and burning were considerably relieved ; still the pain continued during the whole night, increasing in severity at intervals. Five grains of extract of colocynth, with two drops of croton oil, were taken last night ; these operated about eight o'clock A.M., producing three stools ; the action of the bowels relieved a sensation of tightness. He had this morning for his breakfast, about eight o'clock A.M., a cup of tea and a little bread and butter. At twelve o'clock, complained of a nipping pain between the umbilicus and pubes, a burning pain from the epigastric region upwards over the right mammary and sternal region ; no vomiting to-day ; complains of tightness and fulness of abdomen. Abdomen convex ; convexity less marked at epigastric and hypochondriac regions, than below the umbilicus ; interval between recti-muscles distinct ; tenderness in epigastric and umbilical regions ; slight tenderness also in hypogastric, more in hypochondriac and umbilical regions. Some sense of resistance on pressure over recti-muscles ; resonance generally normal ; no tumour to be detected in any part of abdomen : there is, however, greater fulness in the vicinity of the pylorus than elsewhere (from tenderness and distension, the manipulation was less deep than subsequently) ; passes his urine freely ; pulse 60, regular ; lungs[1] and heart generally healthy, only the second sound at the base is murmurish. The stool contains a large amount of yellow amorphous matter, sarcinæ, and triple phosphates ; its reaction alkaline.

The daily reports from this time tell of his continued suffering ; of the frequency with which he was observed in (what is termed, in some of the reports) his old position.

On May the 29th, the report states him to have been much freer from pain. All sense of "flashing burning" gone ; lies ordinarily with legs extended, as if free from pain. His present state offers a striking contrast to his condition on admission. Bowels acted to-day. No stool the preceding three days.

As the hardness of the abdomen disappeared, and the distension diminished, it was pretty clearly made out that the stomach was dilated, the stomach-note being audible to the umbilicus ; and an ill-defined solid body was imperfectly felt about two inches to the right of the middle line, midway between the umbilicus and cartilages of the ribs.

---

[1] The case has been much abridged as regards the organs not bearing directly on the disease.

His present state you have all witnessed ; he suffers little pain ; is freed from the eructation of flatus ; his position is unconstrained ; his abdomen is much less full than on admission ; he is gaining flesh ; the worn expression is comparatively trifling, and he sleeps well. The alteration in his general carriage and position strikes his wife and friends most forcibly. It is, he affirms, many years since he enjoyed the same state of comfort. I must briefly advert to the condition of his urine. It is acid when first passed, but becomes alkaline rather more quickly than healthy urine should. One of my excellent clinical clerks, Mr. Simpson, has been kind enough to examine it daily for some time, and he notices no difference in the degree of acidity, as manifested by litmus paper, whether Martin is vomiting or not. An analysis of the matter vomited before the man's admission to the hospital, was kindly made by Professor Graham. It contained a large excess of free hydrochloric acid, a little acetic acid, alcohol, and sugar ; the gas disengaged was carbonic acid. It was identical, in all essential particulars, Mr. Graham says, with the matter vomited by a man suffering from sarcina ventriculi, under the care of Dr. Bence Jones, in St. George's Hospital.

Now, did the primary disease in the case of Martin, consist in the presence of the sarcina in the stomach, or was the sarcina (as Schlossberger from his cases concludes it invariably is) merely an epiphenomenon ?

Let us see what lesions of the stomach experience has shown to be coincident with the occurrence of the sarcinæ. It appears from cases on record, and especially from the observations of Dr. Todd, recorded in the *Medical Gazette* of May 2, that if the food is retarded in its passage through the stomach, sarcinæ are developed there, and that thickening of the pylorus, narrowing of the pyloric orifice, and dilatation of the stomach, are the lesions most frequently found after death in such cases. Now, the pylorus is, in its healthy state, closed by muscular action. The muscular fibres by which this closure is effected, are, I need not say, of the kind termed plain, *i. e.*, they belong to the class of involuntary muscles.

Constriction of the pylorus may be organic or spasmodic. The pylorus is the seat of ulceration ; the ulcer heals ; contraction of the cicatrix follows ; and hence stricture of the pyloric opening. The submucous tissue is the seat of the exudation of lymph, simple fibrillating or contractile lymph, or of fibro-plastic blastema ; permanent stricture of the pylorus is the result ; or the same tissue is the seat of cancerous infiltration, and coarctation of the same part follows. An error in diet is committed ; digestion is imperfectly performed ; and the pylorus, healthy in structure, refuses to allow the offending substance to pass into the duodenum. It is a well-known law of the animal economy, that increased demand leads to increased supply ; that when a part is called on to perform extra duty, not only is the nutritive material carried to that part in quantity sufficient to compensate for waste, but in still larger quantities ; and hence hypertrophy of the over-exercised structure ensues. This is especially true of the muscular system, and peculiarly so of the involuntary portion of that system.

Again, experience proves that when, from any cause, coarctation of the orifice leading from the hollow viscus takes place, the viscus itself frequently undergoes dilatation ; whatever, therefore, interferes with the free exit of food through the pylorus, may lead to dilatation of the stomach.

Taking all these facts into consideration, it seems to me that the very presence of the sarcinæ, and of the fermenting intensely acid fluid may possibly, nay probably, (by keeping the muscular fibres that close the pylorus in constant action), be, in some cases, the cause of the organic coarctation of the pylorus and the consequent dilatation of the stomach, which are, as I tell you, so frequently the lesions found after death, where these vegetables have been detected in the vomited matter during life. But supposing that organic disease exists anterior to the development of the torulæ, and the sarcinæ, and to the secretion of the acid fermenting fluid, yet must we allow that the

irritation produced by their presence would be likely to excite spasmodic closure of the pylorus, and so add, at least, to the difficulty with which the contents of the stomach would find their way through the organically coarctated orifice; while the rapid disengagement of gas could not fail to increase the dilatation of the stomach, already over-distended by the ingesta.

Thus, then, whether the primary disease be (as, in some cases, I am disposed to regard it to be) the secretion of a fluid favourable to the development of the germs of sarcinæ, or whether the development of these bodies be the result of the retardation of the food in a dilated stomach, the consequence of a mechanical impediment to its transit through the pylorus (as in many cases I have no doubt *it is*); whether the vegetable organisms, and the fermentation which accompanies their development, be the cause or the consequence of the pyloric stricture, still must it be desirable to check their development and prevent their growth, as a means, if not of curing, at least of retarding, the progress of the organic disease.

But, allowing for a moment that our expectations could not reach thus far, yet, would it still be a gain to prevent the distension caused by the disengagement of the carbonic acid, the product of fermentation, to check the formation of that flatus, the very eructation of which is a constant source of distress to the patient. "The three symptoms"—says Dr. Walshe, speaking of cancer of the stomach—"which most torture patients, and for which they most earnestly implore relief, are flatus, vomiting, and constipation." But to return to Martin, and to the bearing of his case on the question here stated. Some years since, he suffered from mechanical violence; subsequently he had hæmatemesis, suffered from pain in the abdomen, and vomited his food often many hours after eating it; and presumptive evidence is afforded, by percussion and palpation, of dilatation of the stomach, and thickening of the pylorus. When he first came under our observation, the symptoms, according to his own and his wife's account, had continued almost unabated in intensity for many years, and certainly they were as severe three years since as they were on his admission.

The long continuance of the stomach disease (more than twenty years) without marked alteration of the symptoms, without the implication of other organs, and without any indication of the existence of constitutionally malignant disease, as well as the fact that vomiting of blood was among the earliest of the symptoms, renders the existence of schirrhus of the pylorus improbable, while it renders the existence of ulceration in the vicinity of the pylorus, cicatrisation of the ulcer, and subsequent thickening of the submucous tissue, extremely probable; but still remember, only probable. Taking, however, this view of the primary stomach disease, I cannot but think that this organic coarctation of the pyloric orifice and dilatation of the stomach, have both been increased by the presence of the sarcinæ, the torulæ, the acid fluid that, under the stimulus of their presence, is poured into the stomach in such large quantities, and the gas which accompanies their formation. I have read to you some notes, which illustrate the improvement that has taken place in our patient's condition since his admission into the hospital. Let us now see by what means that improvement has been effected.

It appears from the notes, that, from his first admission till the 5th of April, he vomited almost daily an enormous amount of thick fluid in a state of fermentation, loaded with sarcinæ and torulæ. To give you an idea of the quantity, I may mention, that, on March 16, he vomited two quarts; on the 17th, one quart; on the 19th, a pint and a half; on the 20th, one quart; on the 22nd, five pints; on the 24th, two pints and a half; the drugs given during the same three weeks were hydrocyanic acid, acetate of morphia, and sulphate of zinc. You will remember he had previously taken creosote, nitrate of silver, etc.

He now commenced to take sulphite of potash. The power exercised by the remedy has been most remarkable and most unequivocal.

Before taking it, he was vomiting daily from forty to one hundred ounces of the fluid, loaded with sarcinæ and torulæ; thus, on the first of April, he vomited one hundred ounces; on the evening of the 2nd, between seventy and eighty ounces, although he had the same morning, from the action of sulphate of zinc, vomited fifty ounces. No vomiting on the 3rd. On the 4th, in consequence of the extreme pain and sense of distension, sulphate of zinc was again administered.

On the 5th, he took ʒss. of the sulphite of potash early in the morning; in the evening he vomited. On the 6th the dose was increased to one drachm. On the 7th, he vomited twelve ounces only of acid fluid, on the surface of which there was but a small amount of scum; it contained perfect sarcinæ, but no torulæ.

From the 8th, he took three drachms of the sulphite daily, each dose being given in ʒiss. of water. At 6 A.M. on the 9th, he ejected from the stomach four ounces; the sarcinæ were now decidedly less numerous, and there were no torulæ. In the evening of the 6th he again vomited, but the vomited matters were now free from sarcinæ and torulæ, and there was no appearance of fermentation. Between the 9th and the 18th he vomited three times, but on neither occasion did the vomited matter contain sarcinæ or torulæ.

From the 16th of May to the 19th of June, the vomited matter contained no trace of sarcinæ or torulæ, and had lost its yeasty odour and appearance. *During these thirty-three days he ejected about two hundred and thirty ounces of acid fluid; during the first eight days of his residence here he ejected three hundred and eighty ounces.*

Now, gentlemen, I wish particularly to impress upon you the marked improvement that followed in this case from the cessation of the production of the sarcinæ. Coetaneous with their disappearance, the sense of distension and the terrific eructation of flatus ceased; the burning pain at the epigastrium abated considerably, and the pains which our patient described as "flashing, darting upward", vanished. By preventing the formation of the sarcinæ and stopping the fermentation, we have, then, greatly relieved his sufferings; and, allowing the existence of organic stricture of the pylorus, we have placed the patient in a much more favourable position than before, for we have removed a cause of constant spasmodic constriction of the pylorus, and have placed the stomach in a much more favourable position to resume its normal dimensions, by preventing the formation of the gas, one cause of its constant distension; and it is obvious, that if a dilated, hollow muscular viscus is to resume its normal size, it must never be allowed to become distended.

But perhaps it may be supposed that diet has assisted in removing the sarcinæ. Not at all, for Martin has had a pretty liberal supply of arrowroot, beef-tea, mutton, milk, bread, and potatoes, with two ounces of rum daily. It is true the sarcinæ return directly the sulphite of soda is omitted; but then, even though it were necessary for this man to continue its use for life, it would be no great trouble. Sulphite of soda is not more disagreeable to the palate than carbonate of soda, and is less injurious, and many take the latter daily. But I hope, by steadily pursuing its use, by the employment of unfermented bread, as to-day suggested by Mr. Graham, and by some other alterations in his diet and drugs, that ultimately he may be able to omit the sulphite entirely.

I cannot conclude without observing, that considerable benefit may be anticipated from the employment of sulphurous acid in all diseases attended with the developement of parasitic plants. I would mention porrigo especially. That it would prevent the growth of the epiphyte there is little doubt; and, should it do so, and yet not cure the disease, the question of the

relation between the two would be settled. In some forms of dyspepsia, attended with the discharge of large quantities of flatus, I think I have seen considerable benefit from its use. On the whole, I am satisfied that in the sulphite of soda we have a valuable addition to our materia medica.

Let me advise such of you as may be tempted to employ the neutral sulphites, to test them before administering them. An omission of this precaution may lead to disappointment.

Without the microscope, the vegetable bodies could not have been detected, and without the aid of the chemist the remedy for them would have been unknown. Let me add, that I have shown that more than temporary benefit sometimes accrues to the patient from the treatment of individual symptoms.

WAYS IN WHICH DEATH OCCURS.

In a series of able papers, *On the Different Ways in which Death Occurs*, Mr. B. W. Richardson comes to the following conclusions respecting *syncope*.

Syncope may arise from two kinds of derangements in the circulating machinery,—firstly, from blood being *diverted* from the heart; and, secondly, from the heart being *overcharged* with blood.

The heart does not depend for its power to act on any nervous agency, but simply on the stimulus of blood. The value of the recumbent posture in restoring animation during syncope, does not rest on the cause (so commonly believed), that during recumbency the brain is re-supplied with blood, and so the heart with nervous power, but on the fact, that when a person faints whilst sitting or standing, the heart fails to do more than to throw its blood over the arch of the aorta; and as this even is not done with sufficient force to ensure a returning venous current in opposition to gravity, the whole of the blood is allowed to accumulate in the vessels below the heart. But the patient at this point falls, or is laid down, with the upper part of the body lowest, the position of the ascending venous currents is thus entirely changed, the returning blood gravitates into the heart, and the organ re-supplied with stimulus, starts again into play, and animation returns.

This explanation affords also a key to many pathological phenomena; thus hæmorrhages from the lower half of the body are always much more dangerous than those from the upper, because in such cases the lower half of the body is a running cistern—not a reservoir of blood.

Syncope, following purgation, or the abstraction of fluids from cavities, is induced by the sudden rush of blood that takes place into the unloaded parts, the heart being thus as effectually robbed as in hæmorrhage.

Ruptures or wounds of the heart may not be followed by instant death, and this especially holds good if the wound or rupture occurs at the upper part of the organ; because in such cases, as soon as the organ gets so full as to pour out its blood through the artificial opening, contraction of the walls of the heart begins to take place, which contraction, as it expels the blood through the natural channels, closes also the rupture or wound.

Rupture of the sound heart scarcely ever occurs, except from a severe fall, in which the body alights on the feet or breech. Such falls lead to rupture of the heart or aorta, by the concussion of falling bringing down the blood that is passing through the ascending aorta, in the same way as the concussion produced by bringing the bottom of a bottle, containing a fluid or powdered substance, sharply on a hard body causes the powder or fluid to sink lower. In this way also, aneurism at the root of the aorta is accounted for, as produced by leaping, riding, and the like; here, the concussion, though not sufficient to cause a rupture, leads to a state next to rupture—viz., dilatation.

A beautiful provision against these accidents is found in inferior animals, where running, leaping, etc., are required, inasmuch as in them the circu-

lating currents from the limbs do not enter the heart perpendicularly, but through the medium of horizontal vessels, so that no amount of concussion in falling upon the feet can overwhelm the heart with an increased flow of blood upon it.

In syncope during advanced pregnancy, the danger is very great, because the recumbent position is of no avail; for the gravid uterus falling backwards on the vessels running to the heart, acts like a ligature around them.

Syncope in labour never, or at all events rarely, occurs during a pain: this, in consequence of the mechanical necessity, that by each uterine contraction a large quantity of blood previously contained in the uterus is poured back into the general circulation, by which the heart is continually supplied with stimulus.

Heat, applied to the general surface, will sometimes give rise to syncope when the heart is hypertrophied. The syncopal attack is brought on in this case from an increased temperature dilating the capillaries, into which the over-acting heart forces its blood and empties itself.

Syncope may occur from the heart being overpowered with blood, and becoming paralysed by its own efforts, in the same manner as ordinary muscles are sometimes temporarily paralysed by sudden extreme exertion. Death probably arose from syncope so induced, in those experiments on rabbits, where Sir Astley Cooper suddenly arrested the flow of blood passing through the carotid and vertebral arteries; and cases are narrated in which a tendency to syncope has followed the compression of large arteries in the human subject.

The heart may also be overwhelmed from causes acting on the venous system. Thus from the days of Harvey it has been known, that in abstracting blood from the arm, the patient often faints on the removal of the fillet. This ensues from the flood of nervous blood suddenly released, returning upon the enfeebled heart and overpowering it in a greater or lesser degree, just as in transfusion of blood after hæmorrhage the heart is liable to be overpowered, if the injected blood is thrown into the circulation with too much force. A case is also supplied to illustrate that a temporary mechanical arrest of the venous circulation in the neck, may be followed by the same effects on the obstacle being suddenly removed.

Under the head of syncope from derangements at the heart, the effects of barriers (as indurated valves, etc.) in the cavities of the heart, and the effects of shocks to the heart, are considered. Reasons are adduced to prove that barriers on the left side of the heart are most dangerous, and it is suggested that all barriers act detrimentally in two ways—firstly, by opposing the currents of the blood, and secondly, by preventing the walls of the heart from approximating closely during their contraction, thus rendering the organ unfit to adapt itself to various quantities of blood.

Among the causes which act on an *obstructed* heart to produce syncope, *exertion* is placed first by Mr. Richardson; and the doctrines of Dr. Latham concerning shocks to the heart are dwelt upon. It is shown that the cause why the heart never gets over a severe shock, as described by Dr. Latham, rests in the fact, that the heart can never rest after the shock, and so never regains full power. It may play on, but its nice equilibrium is lost.

Exhaustion of the body, and sudden changes of position, are also dwelt upon as common causes of syncope during the existence of obstructions at the heart. And lastly, an opinion is expressed, that in some states the blood during life, in the course of agitation against the valves of the heart, may deposit its fibrine. And that in the event of an indurated valve being present, a fibrinous coagulum may be suddenly deposited upon it, of sufficient size to arrest the play of the heart, and to bring on fatal syncope. A case illustrative is also supplied.—[Abstracted from *London Medical Gazette*, February 28th, March 21st, April 11th, August 8th, 1851.]

COLCHICUM IN THE COMA AND DELIRIUM OF SCARLATINA.

The paramount importance of restoring the action of the kidneys in scarlatina is fully recognised by all practitioners; but the best method of accomplishing this object is not always easily determined. We have used colchicum for the cerebral symptoms as well as for the rheumatism of scarlet fever, and we have seen both good and evil results from its action. It must be borne in mind, that in scarlatina the kidneys are in a state of excessive hyperæmia, and that to relieve this condition is a primary indication. The appropriate means will vary according to the nature of the case; but we confess that we would rather trust to large hot bran poultices to the loins, and the due exhibition of carbonate of ammonia internally, in such cases as those referred to by Dr. Hughes Bennett, than to the method he advises. The use of colchicum, however, is a proper subject of investigation and experiment. In this way, its legitimate sphere may be determined. Its conjunction with carbonate of ammonia we look on as judicious. For the sake of drawing attention to the subject, we quote the following notice by Dr. Hughes Bennett from the *Edinburgh Monthly Journal* for August 1851:—

"A boy, æt. 14, entered the clinical ward on the third day after experiencing distinct rigors. There was restless delirium, and constant moving of the head from side to side on the pillow. He was apparently conscious when spoken to, but could not answer questions; the tongue was protruded with difficulty, dry, and of bright red colour, studded with florid elevations; deglutition was much impeded—bowels open—pulse 130, weak—urine voided with difficulty, and diminished in quantity—sp. gr. 1025—not acted on by heat and nitric acid—skin hot and dry, covered with the bright red scarlatinal eruption—ordered salines and slight diuretics. He continued in the same condition, the angina, coma and alternating delirium, however, being more pronounced until the sixth day. During this period all the urine passed was carefully examined. The amount was diminished (seventeen ounces per day), but it was free from deposit, and unaffected by heat or nitric acid. ℞ Sp. æther. nit. ʒiij; pot. acet. ʒiij; tr. colchici ℥ss. aquæ, ℥iij. Ft. mist. A teaspoonful to be taken every four hours. On the following day all coma and delirium had disappeared. He answers questions when put to him—skin cool—eruption faded—pulse 96, weak—passed thirty ounces of urine, which is turbid, with small flakes of a membranous character floating in it. On the eighth day the quantity of urine excreted was fifty ounces, and it was still more loaded with sediments. On examining the urine with a microscope, it was seen to contain—1st, membranous flakes, composed of aggregated rounded particles, apparently agglutinated together, and strongly resembling some forms of vegetable tissue—2d, rounded and irregular masses with spicula—3d, amorphous molecular masses. The whole of these elements, on being analysed by Mr. Drummond, were found to consist of urate of ammonia. Next day the urine was only slightly turbid, and on the following one, was perfectly clear. From this time the boy gradually recovered.

"Commentary.—This was a very severe case of scarlatina. The angina was intense, occasionally rendering deglutition impossible. There was delirium on the third day, alternating at night with coma, which was often profound. The worst result was apprehended. It recurred to me that the head symptoms in this as in several cases of typhus, might probably depend not so much upon inflammation of the brain, as is generally supposed, as upon absorption of, and poisoning by, urea; an idea that appeared to me supported by the diminished quantity of the renal excretion, as well as its freedom from all deposit. Remembering the alleged virtues of colchicum in increasing the elimination of this excretion, I ordered it, in combination with diuretics, and the result was remarkable. For on the next day, not only had the fever diminished, but the urine was increased in amount and loaded with urates to an extent and in a form I had never previously seen. It may be argued that the fever had terminated by a natural crisis on the

seventh day; but I cannot help thinking that in this case nature was assisted by the colchicum and diuretics. At all events, this medicine seems to me worthy of more extensive trial in scarlatina accompanied by diminution of urine and head symptoms."

DR. CATHCART LEES ON VOMITING, AS SYMPTOMATIC OF DISEASE OF THE KIDNEYS.

Dr. Cathcart Lees has published, in the *Dublin Quarterly Journal of Medical Science* for August 1851, some remarks on the sympathetic vomiting which occurs in connexion with disease of the kidneys. He says that, if the vomiting be symptomatic of a calculus in the kidneys or ureter, the diagnosis is seldom very difficult, as the situation, the suddenness, and the violence of the pain, coincident with severe vomiting, generally guide to the seat of the disease. If there be disease of the kidneys without a calculus, or if the calculus cause no pain or tumour, the diagnosis is more difficult. In a case published in the *Dublin Quarterly Journal*, new series, vol. viii, p. 357, Dr. Lees states that vomiting led him to suspect the presence of a renal calculus —a diagnosis which afterwards proved correct. He believes that the vomiting in this case arose from mechanical irritation by the phosphatic crystals, the stomach participating through the influence of the splanchnic nerves.

In another case, an old woman had suffered from constant vomiting: after death, the left kidney was replaced by a large cyst, from the mouth of the ureter having been blocked up by a calculus, so as to prevent the excretion of urine. In another case of a man aged 43, admitted into the Meath Hospital under Dr. Lees, there was frequent vomiting, without sufficient evidence of gastric disease. From an examination of the urine, Dr. Lees diagnosed disease of the kidneys, most probably fatty degeneration; andt his opinion was confirmed some time after by *post-mortem* examination.

Nausea and vomiting are very frequent towards the latter periods of chronic degeneration of the kidneys; but they furnish no positive diagnosis, being met with in various renal affections. There is nothing in the nature of the matters evacuated, or in the times of vomiting, which seem likely to serve as a correct guide to the *seat* of the disease. We must therefore take into consideration the history, age, and sex of the patient, and particularly the situation to which the pain is referred; and, even with the most careful examination, we shall often be puzzled, particularly in obscure cases of vomiting connected with cerebral disease.

In the treatment of these cases of chronic vomiting, if it occurs early in the morning, when the patient is fasting, Dr. Lees finds the most successful plan to be that of making him take some light kind of food before getting up, remaining quiet for a short time afterwards. If it occurs at an early period of the disease, and particularly if pain or weight in the loins is complained of, cupping in that region to three or four ounces, affords great relief. In some cases, most satisfactory results have followed the use of equal parts of boiled milk and lime-water, given frequently during the day, especially when diarrhœa was present. In other cases, one, two, or three drops of hydrocyanic acid, with three grains of bicarbonate of soda, repeated every three hours, and given immediately before food or drink, is taken, proves useful. Creasote, in doses of one or two drops, frequently repeated, is also often of service. In one case—a young girl labouring under general anasarca, with constant vomiting and severe diarrhœa—much benefit was derived from the liquor ferri pernitratis, in five-drop doses, four times a day.

Occasionally a blister over the stomach, a little brandy, or from twenty to thirty drops of Hoffmann's anodyne liquor, will check the vomiting. Opium is objectionable, on account of the tendency to head symptoms which exist when the structure of the kidneys is deranged, and because, in many cases, it is difficult to determine whether the symptoms are caused by mere mechanical irritation or obstruction, or whether they depend on the general poisoning of the system with urea and other excrementitious substances.

SURGERY.

DIAGNOSIS OF GRANULAR AND GONORRHŒAL OPHTHALMIA.

M. Henrotay, in the *Annales d'Oculistique*, points out the distinctive marks between granular and gonorrhœal ophthalmia. He observes that it is only by local inspection, and by the progress of the case, that the nature of the affection can be decided on ; for the antecedents are often deceptive. A man who has gonorrhœa may have common granular ophthalmia ; and a man free from gonorrhœal symptoms, may accidentally get blennorrhagic ophthalmia.

The starting point in the diagnosis, is the *marked difference in the mode of development of the two affections.* The invasion and progress of gonorrhœal ophthalmia is very rapid ; and hence it produces œdema rather than firm granulations. This character is found both in the lesions of the conjunctiva and of the upper eyelid. The swelling of this eyelid is, in fact, œdematous ; its external surface presents a slightly bluish aspect. The impression made by the fingers remains for some time. It is very difficult to erect the eyelid : and, when this is effected, the mucous membrane is found to be smooth, and the ecchemosis to be serous.

In granular ophthalmia, on the other hand, the evolution of the disease is less rapid ;[1] hence firmer granulations are formed. The enlargement of the upper eyelid is not altogether œdematous, but depends in a great measure on the great development of palpebral granulations. The external face of the eyelids preserves its natural colour, or is a little red. The fingers leave no mark ; the eyelid is easily turned back ; its internal surface is rough. The muco-pus is more creamy, and the chemosis is sanguineous.

Granular ophthalmia may last long, and become chronic ; in which state, an acute attack may be occasionally brought on. Gonorrhœal ophthalmia either disorganises the eye, or gets well in a few days.

M. Henrotay says, that epistaxis is of very common occurrence in sub-acute purulent ophthalmia, but that he has never met with it in gonorrhœal ophthalmia. He does not attach much importance to the pre-auricular bubo, mentioned by M. Hairion. [Abridged from *Gazette Médicale*, 16th Aug., 1851.]

PHAGEDENIC ULCERATION OF THE VULVA.

M. Huguier presented to the Surgical Society of Paris, Oct. 1, 1851, a specimen of this form of disease, which, in his published researches, he has distinguished from other forms of ulceration with which it has been confounded.

A woman suffering under lupus of the external generative organs, had been several months under the care of M. Vernois. The usual modes of treatment had all failed ; the ulceration, continuing its ravages, had destroyed all the vestibule, a part of the nymphæ, half of the urethra, and had extended to the soft parts on the pubis. Five months since, this patient came under the care of M. Huguier, who, seeing the inutility of previous treatment, and the tendency of the disease to spread, determined upon an operation. By means of a bistoury, all the disease was removed ; the entire urethra was sacrificed, the incisions having been carried to the sub-pubic ligament ; a part of the recto-vaginal septum was also removed. Hæmorrhage was but trifling. The cure was perfect. The loss of the urethra did not impair the functions of the bladder. Cicatrisation was complete in twenty days. Two months afterwards she had died from an iliac abscess, with caries of the bone.

M. Huguier presented the genitals of this patient ; no trace of lupus

[1] This does not agree with the statement of M. Fallot, that military ophthalmia is sometimes very rapid in its course.

could be discovered; the cicatrices were perfectly healthy. M. Huguier stated that he had frequently performed the same operation with equal success. [*Medical Gazette.*]

NECROSIS OF THE CRANIAL BONES AFTER ERYSIPELAS.

M. Larrey relates the following singular case:—In a patient, 52 years of age, the scalp having become detached by suppuration, inflammation of the bone followed, and was productive of necrosis and separation of the entire bones of the arch of the skull. The patient had not presented any signs of disorder of the cerebral system, although the membranes of the brain were covered only by integument, so that the movements of elevation and depression of the brain were perceptible.

*** A parallel to this case was seen in that of a patient in Bethlehem Hospital, who, having been too vigilantly watched, to permit his executing his suicidal intentions in any other way, laid the back of his head on the fire, and completely charred the scalp, destroying the vitality of a large portion of the skull. The arch of the cranium became detached, and was deposited by Mr. Lawrence in the museum of St. Bartholomew's Hospital, while the patient was living in Bethlehem for several years with only membranous and tegumentary covering to his brain. [*Medical Gazette.*]

OBSTETRICS.

INDIAN HEMP: ITS POWER OF INCREASING UTERINE CONTRACTION DURING LABOUR.

Dr. Alexander Christison, in a series of papers upon the *Natural History, Action, and Uses of Indian Hemp*, has made a most important addition to our knowledge of therapeutic agents. He establishes its remarkable power of increasing the force of uterine contraction during labour. After subject seven cases, he makes the following remarks:—

"There can be no doubt that the *intensity* of the pains was greatly augmented by the hemp, except in the last case, where, after the effects of the first dose passed off, no action followed the repetition of it. This case was an exception to all the others.

"It is worthy of remark, that in none of these cases were the ordinary physiological effects produced; there was no excitement or intoxicating action, and there did not seem to be the least tendency to sleep in any of them.

"In conclusion, I may state what appears to be the most obvious difference between the action of ergot of rye, and that of Indian hemp. First,—While the effect of ergot does not come on for some considerable time, that of hemp, if it is to appear, is observed within two or three minutes. Secondly,—The action of ergot is of a lasting character, that of hemp is confined to a few pains shortly after its administration. Thirdly,—The action of hemp is more energetic, and perhaps more certainly induced, that that of ergot.

"There appears little doubt, then, that Indian hemp may often prove of essential service in promoting uterine contraction in tedious labours.

"More extended experience will show how far these effects may be depended on, and to what cases hemp is most applicable.

"Mode of Administration. Indian hemp may be administered in several ways. The extract, in the form of pill, produces the most gradual effect, and the disagreeable taste of the solution is avoided; but its action in this form is very uncertain. The following emulsion has been recommended:—A scruple of the extract rubbed in a warm mortar with a drachm of olive oil, to which are added half an ounce of mucilage, and seven ounces and a half

of distilled water (Bromfield). But the simplest method is to use the tincture, which should be dropped into a little water, and immediately swallowed. The water may be sweetened with sugar, or an aromatic, such as compound tincture of cardamoms, may be added. The usual strength of the tincture is three grains of the extract to a drachm of rectified spirit.

"The extract may be given in doses of one to six grains; the tincture in doses of ten to thirty drops, for ordinary purposes. Less than thirty drops is of little service in promoting uterine contractions; and greatly larger doses, as much as one or two drachms repeatedly, must be used in the treatment of tetanus, in which disease there is very great tolerance of the remedy.

STEINLEIN ON THE CONTENTS OF FATTY OVARIAN CYSTS.

Dr. Steinlein, of Zurich, has investigated the occasional formation of hairs, teeth, and pieces of bone, in ovarian cysts. They cannot be considered as the products of extra-uterine gestation, for they are met with in individuals who have not reached puberty.

The cyst is composed of several layers; an external one, formed of fibres of loose areolar tissues, irregularly disposed; another layer, in which the fibres are more regular; then a layer of elastic tissues, and finally an epithelial coat. This epithelium covers the whole internal surface, and it exhibits a great number of small isolated dull spots, contrasting with the brilliancy of the rest of the surface. On the bright portions, the epithelial cells are round and regularly disposed, while the cells in the other parts form lamellæ, laid one on the other. If the lamellæ be removed, round and regularly arranged epithelium cells are found beneath them. Most commonly, there is a small wart-like projection on these dull spots. If the epithelium be removed, an appearance is presented of highly-developed papillæ, regularly disposed. Microscopic examination confirms the resemblance to the dermis. These are the parts where the hairs are found, in a hair-follicle; sebaceous glands also open into the follicle, and there are also sudoriparous glands. This analogy in structure between the ovarian cysts and the external skin, explains the presence of fat: it is the secretion of the sebaceous follicles.

These cysts commence as small fleshy bodies, as large as a hemp-seed, occupying the situation of a Graafian follicle. At a later period, the body becomes isolated from the follicle, and is connected to it only by a pedicle, conveying blood-vessels. The sebaceous glands are soon developed; fat fills the cyst, and epithelial scales are mixed with it, as also, in time, the secretion of the sweat-glands.

In very young cysts, there are no hairs; these are first formed in the wart-like projections. They have the same structure and development as ordinary hairs; they may attain the length of four inches, and then fall off, being succeeded by new ones. This explains the number of hairs occasionally found. The presence of teeth is not at all inexplicable, when we remember that they are naturally formed from a folding-in of the external integument. The pieces of bone are not so easily explained; they may bear some relation to the osseous formations occasionally met with in the skin. [*Zeitschrift für Ratunelle Medicin*, quoted in *Gazette Médicale*, June 7, 1851.]

CONGENITAL SMALLPOX IN TWINS.

Dr. Ayer was called, in haste, to Mrs. P., and found her in great pain. On examination, the head of a small fœtus was found born. The uterine contractions were active, and its full delivery effected in a moment, attended by a feeble cry. The pains continued, a bag of fluid was felt protruding, and soon a second fœtus was expelled dead. Two separate placentæ were afterwards removed. The infants were of the size and development of six months. The living one had a dozen or more of pustules, on the face, head,

and breast; one or two were noticed on the abdomen, but none on the limbs. Three or four were good-sized, plump, and well-defined pustules of smallpox. The remainder were not so full, but evidently of the same character. This one survived its birth two hours. The dead child had no offensive odour: the abdomen was dark purple, and the cuticle quite loose. Its whole body, especially the abdomen, was marked with depressions, similar to those of variola in infants, after death. No elevations or pustules were noticed; these marks only remained.

Three weeks before the abortion, the mother, I was informed, had broken out with variola, after the usual premonitory symptoms, and had just recovered when I saw her. The disease was so mild that a physician was not called. She could not trace her miscarriage to any over-exertion, or any cause, except the attack of varioloid. Whether the mother infected the two at the same period, and the death of one caused the expulsion of both; or one had the disease first, and the second received it from him, are questions of some interest, but difficult, from the evidence, to decide. [Boston *Medical and Surgical Journal*, 18th June, 1851.]

SMALLPOX DURING THE SEVENTH MONTH OF PREGNANCY: PLUMP CHILD BORN AT THE FULL TERM.

Dr. S. F. Parcher, of E. Boston, writes as follows to the Boston *Medical and Surgical Journal*, for July 2, 1851:—

"I was called, recently, to attend a young married lady, who, I was informed, had been suffering *intense* pain for the twenty-four hours previous. I found the patient with hot skin, dry red tongue, high arterial excitement; pulse 110 per minute, full; severe pain in the head and back, and in the *seventh* month of pregnancy. Prescribed leeches to the temples, and hyd. and jalap, āā gr. x, followed with saline draught, and diaphoretics. In about thirty hours pustules made their appearance, and continued until the case assumed the appearance of genuine smallpox. She passed through the various stages favourably, and convalesced as rapidly as usual, save a slight ophthalmia, which retarded somewhat the cure, went her full time, and gave birth to a fine, plump, healthy girl, without the least appearance of its having had the disease. Vaccination had no effect upon it.

"*Query.* Can the mother, during the last months of pregnancy, go through with smallpox and not affect the child in utero? If so infected, will there not be unmistakeable evidence upon the skin? or does exclusion of light and air prevent scarring, and thereby leave a smooth surface?"

EXTRA-UTERINE PREGNANCY OF TWENTY YEARS' DURATION.

A woman, forty years of age, was suddenly seized with symptoms of internal strangulation, under which she sank. Dr. Christian, under whose care she was, discovered in the abdomen a large tumour, situate in the right iliac fossa and lumbar region. This tumour had first appeared some months after her marriage, twenty years before, at which time labour had come on at the sixth or seventh month, without any result; the movements of the fœtus had suddenly ceased, and the labour itself was arrested. After this period she had borne eight children. The autopsy showed a tumour of the size of a large ostrich's egg, enveloped in a cyst with ossified walls, except at its superior part, and enclosing a fœtus of six or seven months, as well preserved as if it had been artificially enclosed after the labour,—still having its umbilical cord fixed to the interior wall of the envelope which represented the placenta, and which was completely ossified. [*Pilad. Med. Examiner*, in *L'Union Médicale*, 15th July 1851.]

REPORTS OF SOCIETIES.

MEDICAL SOCIETY OF LONDON.

Friday, October 10, 1851.

Edward W. Murphy, M.D., President, in the Chair.

Homœopathy. This was a Special General Meeting of the Society, held for the purpose of considering the subject of medical men practising the homœopathic system of quackery. Fifty-seven fellows were present.

The following Resolutions recommended by the Council were unanimously adopted :—

i. That in the opinion of this Society, the practice of homœopathy, or the prescribing medicines in what are called "infinitesimal doses", under a pretence that they are useful in the cure of disease, is founded in palpable error, is a delusion on the part of the practitioner, a deception on the public, and manifestly dangerous to its welfare.

ii. That the Fellows of the Medical Society of London cannot honourably hold any professional communion with homœopathists.

iii. That consequently, any Fellow of this Society who shall hereafter practise homœopathy, or who shall knowingly meet in consultation any professed homœopathist, will thereby render himself unworthy of the Fellowship of this Society.

Saturday, October 11, 1851.

Edward W. Murphy, M.D., President, in the Chair.

This was the first ordinary meeting of the society. Fifty-eight fellows were present ; and also a number of visitors.

Duration of Pregnancy. By Dr. Murphy. Dr. Murphy stated, that he proposed, upon some future occasion, to bring forward the subject more fully : he, therefore, on this occasion limited himself to a mere outline of the method he had pursued, and its results. He hoped that other practitioners might aid him in the solution of the problem by adopting a similar plan. The two questions he proposed for consideration are,—Is the duration of pregnancy a fixed or a variable period ? and, if it be decided that it is variable, What are the limits of its variation ? The usual mode of calculating the term of pregnancy is by dating from the last period of the menses to the time of delivery, the gross results being corrected by deducting as many days as is supposed necessary to avoid error. Some, believing that conception may take place at any time, deduct one-half the menstrual interval ; while those who consider that conception can only take place at a menstrual period, date either from the last catamenia, or from that which should have happened, but for conception. This estimate being compared with the period of quickening, a result is obtained sufficiently accurate for ordinary practical purposes, but not precise enough for legal evidence. Other indications have, therefore, been sought for. Peculiar sensations are experienced by some women at the time of conception : some cases of this kind, described by Dr. Montgomery, would tend to fix the duration of the pregnancy at two hundred and eighty days. In other cases it has been ascertained by the date of a solitary intercourse, which, of course, fixes the date of conception ; the same period of two hundred and eighty days is, from such cases, given by Sir C. Clarke and others, and from these facts many are inclined to regard that period as the correct duration of pregnancy. To this opinion, however, Dr. Murphy does not subscribe, as these cases are comparatively few in number, and, if the rule were different, might easily form an exception to it without invalidating it. He would, therefore, call in the aid of statistics for

the solution of the problem; this he commenced some years since, at the University College Hospital, when forming a register of obstetric cases. The following method was adopted:—When a letter for attendance was applied for, an inquiry was made as to the catamenia, the age of the applicant at its commencement, its period, and its last appearance. With regard to the last question, some could only give the month, others were precise as to the date, and some were too irregular to date from. The last were excluded from the inquiry, as, for instance, some who were nursing either had no change, or a very irregular one; others had been always irregular before pregnancy, and therefore could not be depended on; and again, with others, the catamenia had evidently continued after conception: all these were excluded as the others were noted, and when delivery occurred, that also was noted, the interval between the two giving the gross duration of pregnancy, which was afterwards corrected, so as to make as near an approach to accuracy as possible. Of these cases, some time back, a table of 186 was formed. The corrections were made as follows:—If the period exceeded 280 days, and the woman had given the exact date when she was last unwell, the whole menstrual interval was deducted; so, if the whole period were 328 days, and 28 days were the menstrual interval, 300 days would be regarded as the true duration. It was considered that the woman might be in error, and it was thought safer to suppose that conception occurred just before the catamenia which had been arrested. Subsequently 280 days were regarded as the true period, and in any cases that exceed, the menstrual period is deducted, the result being presumed to be accurate. From his records of 965 cases, Dr. Murphy has formed four tables: 1st, those in which the duration of pregnancy exceeded 280 days, including 303 cases; 2nd, those that are exactly that period, including 378 cases; 3rd, those between 260 and 280 days, including 201 cases; and 4th, those below 260, including 83 cases. The 4th, or last table, he (Dr. Murphy) looks upon as instances of premature labour. From these tables he gathers that the duration of pregnancy is not a fixed but a variable period, as in the lower animals, varying, however, only within certain limits. Those limits are not yet ascertained. He regards 260 days, or 37 weeks, as the shortest period; he has attended mature infants born at that date. The longest period is yet *sub judice*, the cases in the first table being yet under examination, and requiring correction.

Saturday, October 18, 1851.

Edward E. Murphy, President, M.D., in the Chair.

Therapeutic Uses of Creasote. By B. W. Richardson, Esq. Mr. Richardson had never used creasote in true Asiatic cholera, but he had fully tested its value as an astringent, and in some cases of diarrhœa, he had never before seen half so good a remedy. The cases in which it is most useful are of three kinds: 1st. Cases of diarrhœa during ordinary epidemics, where the disorder cannot be traced to the presence of foreign matter in the intestines. 2nd. Cases where profuse diarrhœa follows the employment of purgatives, given to remove foreign matters during intestinal disorders. 3rd. Cases in which, after an acute diarrhœa, the patient continues to be troubled with frequent and sudden liquid evacuations, not attended with pain or great constitutional disorder. Creasote often succeeds when all other astringents fail; it is speedy in its action; lastly, it does not leave the bowels constipated, unless carried too far in its administration. Occasionally, during its use, it produces a dry, white, filmy state of tongue, and other symptoms of feverishness. When this occurs the remedy must not be continued longer; indeed, it is rarely required after such symptoms, the purging being usually arrested before they appear. With children the dose given must be very small, or such good results will not follow; the one-eighth, one-sixth, and one-fourth part of a drop, is sufficient for babes from one to two years of age. With adults the dose, as an astringent, is from one

and a half to two minims. Mr. Kesteven mentions the value of creasote as an astringent, and supposes that this value depends on the power which creasote has of coagulating albuminous fluids. To this it may be objected, that the quantities of the creasote employed medicinally are not sufficient to produce such coagulation in the intestines. Mr. Richardson assigned to creasote powerful diaphoretic and antispasmodic qualities, and said, that on the vascular system it rather acted as a stimulant than as a sedative. Its power in stopping vomiting depended upon the dose, which should be small. Given in its full dose, as an astringent, it sometimes *excites* vomiting, in which case hydrocyanic acid is usefully combined with it. To lessen its nauseous qualities, it is best to unite it with syrup of tolu and tincture of cardamoms, and camphor julep or water. It may also be prescribed advantageously with the preparations of either when they are indicated.

Gelatinous Polypus from the Ear—New Polypus Forceps. Mr. Harvey exhibited a gelatinous polypus which he had extracted from the ear by means of a new kind of forceps which he had invented for the purpose. He observed that in these cases it was most desirable that the morbid growth should be extracted entire; for if it was broken or otherwise injured in attempts at its removal, it gave rise to much inconvenience, and required tedious and troublesome after-treatment. The forceps which he had constructed, and which he had been in the habit of using for a long time with satisfactory results, were not dissimilar to those of Assalini, but had a somewhat longer blade, were flattened on either side, and terminated with theee rows of teeth. The foreign body was firmly grasped by these teeth, and removed by a rotary motion, the instrument admitting of that. This Mr. Harvey regarded as of great importance to the operator on the ear. It was also sufficiently small to admit of being used with a bivalve speculum in the auditory canal, the operator being thus afforded an opportunity of investigating the origin of polypi. The instrument was shown to the Society.

The Affinities and Prophylaxis of Variola. Mr. Dendy read an elaborate communication on this subject.

MISCELLANEOUS INTELLIGENCE.

Homœopathy:—London and Provincial Medical Protection and Benevolent Society. The following resolutions have been unanimously adopted:—

That in the opinion of the Committee of the London and Provincial Medical Protection and Benevolent Society, the practising of homœopathy by legally qualified medical men is calculated to excite ridicule, and thus to lower the profession in public estimation.

As one of the principal objects of this Society is to raise the tone of public feeling towards the profession, the committee feel, that by including among their members professors of homœopathy they would be directly opposing the objects of the Society.

The committee therefore decide, that any member of the profession who professes to practise, or does practise homœopathy, is ineligible to be a member of this Society. The committee are further of opinion, that they could not conscientiously employ the power of this Society in collecting monies from the public for homœopathic attendance, believing, as they do, homœopathic practice to be an entire imposture.

Homœopathy and the St. Andrew's Graduates. On Friday, October 17, the Senatus Academicus of the University of St. Andrew's met for the purpose of conferring degrees on the candidates who have passed through their examinations successfully. There were present seventeen candidates, who signed the subsequent address, which was presented to the rector. The

memorialists were courteously informed that the senate had no power to comply with their request. We are not aware whether the describer of the anatomy of Lucifer and Michael,[1] who is Mesmerist and homœopath to boot, signed the diplomas or not. But this would matter little after the admirable protest of the candidates for the degree.

"*To the Rector and Senatus Academicus, University of St. Andrew's.*

"We, the undersigned Candidates for the degree of Doctor of Medicine in this University, having understood that our diplomas will probably be signed by the Professor of Civil History, who is an avowed homœopathist, and holding as we do the opinion that the doctrines of Hahnemann are utterly irreconcilable with common sense, and with those medical tenets in which we have been educated, and which we trust will ever guide our professional career, respectfully request of the Senatus Academicus that they will adopt such measures as they may deem expedient for the purpose of preventing that desecration of our diplomas which we consider would be inflicted on them if a homœopathic signature were affixed thereto.

"University of St. Andrew's, October 1851." [*Lancet*, 25th October.]

Homœopathy. The Faculty of Physicians and Surgeons of Glasgow, at a meeting held on the 1st September, unanimously passed the following Resolution:—

The Faculty having had their attention called to certain resolutions by the Royal Colleges of Edinburgh in reference to homœopathy, and heard the opinion of their council, to whom the matter was referred at last meeting, do now in conformity with that opinion, express their concurrence in, and approbation of, the view taken by the Royal Colleges as specially detailed in the resolutions of the Royal College of Physicians; but as none of the Fellows or Licentiates of the Faculty, so far as known to them, have hitherto professed or countenanced this system, they consider any further notice of the subject on their part in the mean time unnecessary.

Dr. Henderson of Edinburgh University. In spite of the broad hints which have been given to this Professor, he still clings to his chair. Never did a man hold a more extraordinary position. The Medical Faculty, it seems, have not the power to get rid of him: but the College of Physicians are anxious to expel him from their body, and on the fourth instant they meet to receive the opinion of council as to their possessing the power of elimination. The Medico-Chirurgical Society of Edinburgh proposes, we have heard, at its first meeting to erase his name, and the names of all homœopathic practitioners, from the roll of members.

Office Bearers of the Harveian Society for the Session 1851-52. —Presidents: Dr. J. Bird and Mr. H. Obré.—Treasurer: Dr. J. Ridge.—Honorary Secretary: Dr. R. H. Powell.—Members of Council: Dr. Chowne, Dr. R. Quain, and Mr. H. B. Norman; *ex officio* members inclusive.

New City Lunatic Asylum. The City authorities are about to erect a Lunatic Asylum expressly for the poor of the city of London.

New Infirmary, Torbay. The building—a very handsome one—is so far completed as to afford accommodation for the meetings of the Managing Committee.

---

[1] Dr. Macdonald has described the Anatomy of Angels.

General Hospital at Birmingham. On Friday, October 3, an investigation was commenced into certain charges brought by Mr. Gutteridge, one of the Life Governors of the Birmingham General Hospital, against Mr. Alfred Baker, one of the surgeons to the institution. The Earl of Dartmouth was in the chair. The charges were, that Mr. Baker had operated on a patient for ovarian dropsy, without informing her of her risk, and contrary to the opinion of his colleagues; that he had rashly and cruelly tied the carotid artery, and thereby killed the patient, in a case of supposed aneurism of the arteria innominata in an old man: that he had amputated a boy's leg at the hip-joint, instead of at a safe part below. The investigation lasted during seven days, much evidence being called on both sides; and terminated in the drawing up of a report by the Weekly Board, in which they perfectly exonerated Mr. Baker from all the charges brought against him by Mr. Gutteridge. In closing the report, they expressed their "strongest condemnation" of Mr. Gutteridge's conduct, in publishing his attack on Mr. Baker in the form of a pamphlet, before consulting the Weekly Board on the subject of the alleged professional misconduct of that gentleman. They concluded by recording their unanimous opinion, that "Mr. Baker is entitled to retain the full confidence of the governors and subscribers." The whole of the investigation is reported in the *Birmingham Mercury*, for Oct. 18th.

Queen's College, Birmingham: Fellowships. The Queen's College, at Birmingham, has recently obtained powers, under a supplemental charter, to elect as fellows of the college such of its members as may distinguish themselves during their studies, and who subsequently obtain a diploma in medicine or surgery, or become graduates in medicine, law, or arts. The authorities of the college intend to confer this honour, in the first instance, upon such of the earlier members of the institution (the Royal School of Medicine), as the Principal and Council may determine to be eligible; and in accordance with the provisions of the charter, Dr. Roden, of Kidderminster, and Dr. Barker, of Bedford, have been elected fellows of the college. These, with Mr. G. B. Masfen, a Warneford medallist, and resident medical officer of the Stafford Infirmary, are the first three members of the profession selected for this distinction under the new charter. Amongst other privileges the fellows are entitled to vote at all meetings of the governors, to free admission to the medical and general libraries, to the museums, dissecting room, to the lectures of the professors, and to dine in the college hall.

APPOINTMENTS.

Hancock, Henry, Esq., Lettsomian Lecturer on Surgery to the Medical Society of London, in room of Mr. Guthrie, whose term of office had expired.

Ogle, Dr., has been appointed Regius Professor of Medicine at Oxford, in room of Dr. Kidd, deceased.

Pereira, Dr., elected Physician to the London Hospital, in room of Dr. Frampton, resigned.

Winslow, Forbes, M.D., Lettsomian Lecturer on Medicine to the Medical Society of London, in room of Dr. G. O. Rees, whose term of office had expired.

OBITUARY.

Baron, John, M.D., F.R.S., at an advanced age, at St. Margaret's Terrace, Cheltenham, on 2nd October. Dr. Baron was the friend and able biographer of Jenner.

Roe, G. C., M.D., Inspector General of Hospitals, at Madras, on 4th September.

TO CORRESPONDENTS.

To the Editor of the London Journal of Medicine.

Sir,—I felt so highly gratified on a perusal of your generous notice of my forthcoming *Lexicon* in the Journal for this month, that I trust you will bear with me in thus expressing my hearty thanks for your liberality. The immediate effect has been an addition of names to my subscription list.

My power to escape from professional duties is at present very limited. Hence the favour conferred by your kind recommendation, and the saving of time and toil effected by the ready cooperation of those who have acted upon it, are greater than can well be supposed.

Again offering grateful acknowledgement to you, and to those you have influenced, I am, Sir, your obliged,

Leeds, 16th October, 1851. R. G. Mayne.

Dr. Dundas' Paper on Quinine in Continued Fever appeared in a recent number of the *Medical Times.*

Dr. Grigor's note has been received; and his request shall be complied with.

Mr. Everest's Sermon: Free Kirk Preachers. A Scottish correspondent wishes us to publish facts regarding certain mystical preachers in the Free Kirk, who espouse homœopathy from house to house, and teach other kindred follies of German origin. We do not feel that it is within the province of this Journal to enter upon such matters; but if the rumours regarding the homœopatic dealings of the Rev. J. Wright of Nenthorn, be so current as stated to us, there is an ecclesiastical tribunal not likely to flinch from an inquiry into their truth or falsehood. We beg to inform our correspondent that Mr. Everest's Sermon is published (price one shilling) by Aylott and Jones, 8, Paternoster Row. Ample specimens of this production have already been laid before our readers. [*Vide* p. 872-874.] His Letter to Dr. Cormack is nearly as striking an example as the Sermon, of the impious and raving character of homœopathy. At p. 11 of the *Letter* we read as follows:—"What is the law of cure? What is the formula for it? What is the general expression for it? Is there no such thing? From the highest point to which balloon ever reached, fling forth a stone into space, and I will give you an expression by which you may find its place to a foot at any moment of its fall. $S = m\,T^2$. So the Almighty does His work. Now, Dr. Rose Cormack, how do you do yours? Produce your rule!"—No better idea can be formed, by a disciplined mind, of the impiety and absurdity of homœopathy than by a perusal, (without note or comment), of the *Organon* of Hahnemann and the writings of Mr. Everest, his friend and chief apostle; especially, when it is borne in mind, that the last production of Mr. Everest has been much lauded, and heartily adopted by the *Homœopathic Times*, the weekly organ of the Quins, the Hendersons, the Calvert Hollands, and the Ransfords. Mr. Everest wishes to know where such "naughty words" as *lie* and *blasphemy* can be found: he cannot fancy where a "clergyman's son" learnt them: but he ought to have known that these terms are often used in a very plain-dealing book called the Bible, *where a lie is called a lie, and where blasphemy is called blasphemy.* Surely a clergyman ought to be as well acquainted with this book as a clergyman's son. We had intended to review Mr. Everest's Sermon and Letter, but from the abundance of scientific matter now before us it is impossible for us to do more than call attention to them, as exhibiting the worst phase of homœopathy,—as showing that it is now preached as a doctrine of the Bible by clergymen of the English Church, without any episcopal interference. Our colleges may be shamefully remiss in repudiating error; but they are fully equalled in laxity of doctrine and want of discipline by the Bishops. The heretical *isms* in the Church, are at least as numerous as our charlatanic *pathies;* and the proverb—"*doctors differ*"—is quite as applicable to clergymen as to physicians.

LONDON JOURNAL OF MEDICINE,

A MONTHLY

Record of the Medical Sciences.

DECEMBER 1851.—No. XXXVI.

ORIGINAL COMMUNICATIONS.

ON THE HEALTH OF LONDON DURING THE SIX MONTHS TERMINATING SEPTEMBER 27, 1581.

By JOHN WEBSTER, M.D., F.R.S., Fellow of the Royal College of Physicians, Consulting Physician to St. George and St. James's Dispensary, etc.

CONSIDERING the recent enormous and constantly changing population collected in London during the period to which this report refers, from all parts of the empire, and from foreign countries, it is particularly interesting to ascertain, how far the sanitary condition of the capital manifested any difference from that of the corresponding period of previous or ordinary years? The inquiry is highly important, alike to the political economist and to the physician. With the view of supplying evidence whereon to found deductions respecting several vital questions, I now proceed, in accordance with the method I have hitherto adopted; first, to enumerate the gross amount of deaths recorded throughout the metropolitan districts during the half year ending the 27th of last September; and afterwards, to give a few details illustrating the varied mortality produced by particular maladies, in order thereby to point out wherein recent results differed from, or resembled, those met with during the parallel six months of the previous year.

The health of the metropolis during the past summer and autumn, although in some respects not so satisfactory as throughout the same months of the year 1850, has not been remarkable either for the severity of prevalent diseases, or on account of its aggregate mortality. During the six months terminating on the 27th of last September, the total deaths amounted to 25,980, contradistinguished to 22,816 during the parallel period of 1850, thus making an increase of 3,164. However, it should be remembered, the majority of deaths took place during the first three months of the recent half year, when 1,845 more deaths were recorded than the number which occurred during the same quarter of 1850; but the excess was only 148 beyond the number

reported throughout the parallel season of 1848, whilst it was not more than 85, if compared with the second quarter of 1849, notwithstanding that the latter was the great cholera year. When reflecting upon these varied statements, it should be always recollected, that during the months of April, May, and June, of the current year, the metropolitan population became enormously augmented, whilst many of the assembled strangers were placed, unavoidably, under unfavourable mental, and physical influences. The principal augmentation in the rate of mortality occurred during May, when upwards of half the additional 1,854 deaths took place, the excess being 959 fatal cases beyond the amount reported during the parallel month of the former year; hence, indicating that May was the most sickly portion of the entire half year referred to in the present report.

Throughout July, August, and September, the number of deaths, from all causes, was likewise somewhat greater than in the same quarter of 1850, the increase amounting to 1,309 cases; whereas, if the same quarter be compared with the same three months of 1848, the returns give 616 fewer deaths during the recent season. During the second and third quarters of 1848, the deaths amounted to 26,448, which makes 468 more than in the same months of 1851; and as the excess was 14,137 in the great cholera year, or 1849, the public may well rest satisfied with the recent healthy state of the metropolitan population, although its aggregate mortality exceeded that reported in 1850. Instead of experiencing famine, plague, pestilence, riot, rebellion, and crimes sufficient to shake society to its centre, as many predicted, nothing of the kind has occurred; for which we assuredly have much reason to be grateful to Providence.

Diseases which have lately Exhibited a Diminished Rate of Mortality. Several diseases have proved rather less fatal than in the parallel six months of 1850. From scarlatina, 460 persons died, in place of 550 deaths during the parallel six months of the previous year, thereby making a decrease of 90 fatal cases; from erysipelas, the deaths were 150, instead of 168; by apoplexy, 606 against 618; from dropsy, 362, in place of 382; from influenza, 115, instead of 123; from enteritis, 187, in place of 193; from hepatitis, 95, against 107; from peritonitis, 95, instead of 112; from nephria, 57, against 67; from ovarian dropsy, 24, in place of 35; from aneurism, 35, instead of 44; from hæmorrhage, 97, in lieu of 106; and from rheumatism, 102 fatal cases were recorded during the recent six months, against 110 met with in the similar two quarters of the former season.

To the different maladies now enumerated as prevailing less fatally, it is gratifying to add two affections, not only on account of the diminished mortality they produced, but also as leading to important conclusions respecting the improved habits of the general metropolitan population. The causes of death now alluded to, are intemperance and delirium tremens. From the first, 29 persons are reported to have died instead of 39 during the parallel six months of 1850; and delirium tremens cut off 67 individuals, contradistinguished to 96 during the previous period. Statements like the above are exceedingly gratifying, and may be justly brought forward as good evidence that sobriety characterised the immense masses of people frequenting London during

the past season. Taken in conjunction with other facts not now alluded to, as it would be out of place to bring them under discussion, although sufficiently obvious, it will at once be acknowledged, that, so few persons having died, comparatively speaking, from excess in ardent spirits, is an indication of considerable social improvement.

Diseases which have Exhibited an Increased Rate of Mortality. Several maladies have been both more prevalent and more fatal than during the summer and early autumn of last year. This remark applies especially to infantile complaints, and to several affections of the organs of respiration.

Small-pox occupies a most prominent position in this mortuary scale, seeing that the deaths by that truly pestilential malady were last season more than double those in the previous period, 452 persons having recently died from variola, in place of 212 fatal cases of the same complaint during the parallel two quarters of the preceding year. In reference, also, to the greatly augmented mortality from small-pox, it ought to be specially mentioned, that nearly the whole deaths occurred in patients under 15 years of age; 392 out of the whole 452 reported being within that limit, and of these, it should be stated, a large proportion were very young children. An immense majority of those so affected were unprotected by vaccination; and numerous parents had even obstinately refused to avail themselves of the protective influence of cow-pock, notwithstanding they were urgently solicited by friends and medical men to have their children vaccinated. It is most lamentable to find so much prejudice and ignorance still prevailing amongst the lower ranks in regard to the invaluable benefits which Jenner has conferred upon the community.

Occasionally, individuals are attacked by secondary small-pox; and death has thereby supervened in after life, although the party had been vaccinated during infancy. Similar results sometimes follow natural and inoculated variola; but all cases of secondary small-pox being exceptional, they cannot outweigh the many millions of instances in which vaccination has proved protective.

However untenable several of the objections which some individuals continue to entertain against the efficacy of vaccination may appear, such prejudices become excusable, to a certain extent, when the limited opportunities are remembered, which these parties have enjoyed of obtaining correct information respecting cow-pock; as also their defective general education. Uneducated persons belonging to the labouring classes, especially in the rural districts, deserve pity rather than censure, when obstinately objecting to allow their children to be vaccinated, and are certainly much less blamable than those benighted members of the middle and upper ranks of society, who patronise prevailing quackeries, whether homœopathy, Mesmerism, hydropathy, or the use of secret remedies. To find educated men and women, arrived at the years of discretion, who have had ample opportunities of acquiring knowledge, and of exercising their intellectual faculties, believing in the wonderful stories palmed upon credulous imaginations by peripatetic lecturers and pseudo-philosophers, is far more strange than to meet with uneducated people doubting the prophylactic powers

of vaccination. The latter should be commiserated, whilst the former deserve only condemnation.

From measles, a considerable increase in the rate of mortality has been also observed, 755 deaths from that complaint having recently occurred, against 410 fatal cases during the parallel six months of 1850. From convulsions, 955 individuals died, in place of 839 during the previous period. Hydrocephalus also proved fatal to 812 persons, instead of 677; whilst bronchitis, always a serious disease in very young, as in persons of advanced age, caused death to 1,330, contradistinguished to 1,076 during the similar two quarters of the former year. Hooping-cough likewise proved more destructive than previously; 1,094 deaths having taken place from this disease, instead of 706 recorded in the two previous parallel quarters.

Phthisis has proved more deadly than in the former summer and autumn; 3,498 deaths occurred from that malady during the six months embraced by the present report, instead of 3,056 in the two similar quarters of the previous year, giving an excess of 442 deaths, or an increase of nearly 15 per cent.: from pneumonia 1,387 died, instead of 1,151, being an excess of 236 deaths. Typhus has likewise proved more fatal, 1,055 deaths having been reported, instead of 900 during the second and third quarters of 1850. Diseases affecting the abdominal viscera have exhibited a larger mortality during the present than in the corresponding six months of the previous year. For instance, diarrhœa carried off 1,647 persons, in place of 1,361 in the former season; from cholera, 191 patients died, instead of 96; from liver disease, 283, in lieu of 253; whilst 86 deaths were reported from jaundice, in place of 75 in the previous period; from inflammation of the brain, 286 persons lost their lives, instead of 268; epilepsy recently carried off 168 patients, instead of 132; and lastly, from scrofula, 210 deaths were recorded, against 157 met with in the former half year.

Notwithstanding repeated allusions in former reports to the number of infants who annually lose their lives from being deprived of their mothers' milk, and in spite of frequent remarks respecting a practice which produces most disastrous consequences, the evil continues to prevail quite as much, if not more extensively than before. This truth is clearly demonstrated by the fact, that 119 deaths occurred from the want of breast-milk during the last six months; whereas, the total number of infants who sank under that privation was 89 in the parallel two quarters of the preceding year; giving an increase of 30 deaths during the more recent period. Statements like the above are by no means creditable to the parties concerned, seeing that they indicate the continuance of a custom producing most serious results, which the laws both of nature and common sense strongly condemn. However agreeable the practice may prove to certain fashionable mothers, anxious to avoid the trouble of suckling their own offspring, or profitable to hireling parents, induced by lucre and additional physical comforts, it is not less true that their respective infants frequently become victims of neglect and privation. This picture is not overdrawn, but forms a true representation of the evils occasioned by employing wet-nurses; therefore the system ought to be discountenanced—not patronised by wealthy and aristocratic members of society.

Diseases Exhibiting a nearly Uniform Rate of Mortality. Notwithstanding the immense metropolitan population, and the various causes inimical to health, which are frequently, but also irregularly, in operation, it is both curious and instructive to notice the singular uniformity often observed to prevail, in regard to the number of deaths produced by certain diseases during consecutive years, and even under apparently adverse or opposite circumstances. The facts about to be detailed in illustration of similar peculiarities are interesting; and however impossible it must appear for any person to foretell the number of individuals who might be carried off by particular diseases, it nevertheless can be safely asserted, that the mortality produced by several complaints is often remarkably uniform. On this point, the experience obtained during last summer and autumn is instructive, especially as the results noticed coincide, in some respects, with previous observations. For instance, during the six months terminating on the 27th of last September, from paralysis, 506 deaths occurred, instead of 507 in the parallel quarters of the preceding year; from cancer, 451 fatal cases were reported, against 457; from asthma, 217, in lieu of 210; from disease of the kidneys, 143, against 142; during child-birth, 107 women died, instead of 116; whilst from hernia, 69 fatal cases were recently reported, contradistinguished from 62 in the six parallel months of the previous season.

Besides the preceding illustrations of uniformity in the number of deaths produced by certain diseases throughout consecutive years, it also deserves mention, that 53 individuals died insane during the last six months, in place of 51 in the former season. Further, 15 deaths were recorded from stone, against 13; and of diabetes, the fatal cases amounted to 20, instead of 18 met with in the previous period. Similar remarks equally apply to diseases affecting joints, from which causes 87 persons recently died, in place of 91. Again, from affections of the uterus, 89 deaths occurred, instead of 82 in the former half year. From heart complaints, which proved fatal to 830 persons during last season, 801 were reported in the parallel six months of 1850. Regarding diseases of the heart, it deserves being mentioned as an interesting fact, that a large proportion of the 830 fatal cases took place in patients at the prime of life, whilst very few deaths by the same class of affections were met with previous to puberty. This opinion is shown to be well founded by the fact, that only 34 individuals died from heart-disease under the age of 15, whereas 494 deaths were reported in persons from 15 to 60, whilst the remaining 302 fatal cases occurred in patients who had passed the latter term of life. According to these data, medical practitioners may therefore very justly assert, that diseases of the heart are more common during manhood than at any other period, whilst they prove fatal in greater number to parties about the prime of life, than to youths or children.

Age of Individuals who have Died. In connexion with repeated statements contained in previous reports, I have again to request special attention to a circumstance, which, although by no means novel, still appears astounding; namely, the fact, that almost one half of the whole deaths recorded throughout London during the last six months,

occurred in young persons, many being even children or infants. This conclusion is based upon the return of ages stated in the mortuary reports, from which it appears, that not less than 12,651 cases out of 25,980 deaths recently registered, took place in patients under their fifteenth year; 8,263 from that age to 60, or in the prime of life; and 4,914 in parties who had passed their grand climacteric; thus leaving only 152 persons whose exact ages were not ascertained. That so large a proportion as nearly fifty per cent. of the entire mortality recently met with in the metropolis, should have taken place solely amongst the juvenile, deserves most serious attention on the part of physicians and philanthropists, in order to ascertain how premature mortality may be stayed or corrected. That physical defects, and constitutional tendency to disease in certain individuals, greatly contribute towards augmenting the number of deaths amongst the younger portion of mankind, cannot be questioned, knowing that these powerful influences are too often in operation. Independent, however, of such potent causes of disease and consequent death, no medical observer can deny, that improper feeding, defective clothing, and a total disregard of many hygienic rules essential to the preservation of health, besides the frequent neglect of ordinary prophylactic measures, whereby some of the existing evils might be mitigated, have all very materially contributed to produce the lamentable concatenation of cause and effect now briefly delineated. Without attempting to discuss on the present occasion these important questions in the manner they deserve, I will only now remark, that prejudice, and long-established usages fostered by ignorance, not only exercise great influence in perpetuating existing evils, but they often act as repulsive antagonists to progress and improvement, besides being frequently arrayed in opposition to all change, even when recommended by reason or experience. Notwithstanding these obstacles, knowing how essential it is in the cure of disease, or in the abatement of any social mischief, first to learn its cause and nature, prior to settling treatment proper to pursue, I have been induced again to notice the excessive mortality among London children, in order that professional men may further investigate the subject, and so suggest effectual means to remove, or alleviate, similar calamities.

Mortality among the Pauper Population. Somewhat analogous to the observations previously made, the total number of deaths recorded throughout all the charitable institutions of London during the last half year, again constitutes a considerable proportion. Amongst the 25,980 fatal cases reported in the six months terminating on the 27th of last September, nearly one-sixth, or 3,959 deaths took place in the workhouses, asylums, prisons, and hospitals, thereby giving 15·23 per cent. of the aggregate mortality, of whom many, it may be added, were medically treated and otherwise supported, during their last illness, at the expense of others, or by the general community. Another important matter regarding the eleemosynary part of the population, who recently died within the walls of public institutions, also deserves particular notice,—namely, the disparity existing betwixt the number of male and female inmates. The deaths amongst the former class predominated considerably; seeing that 2,319 out of the 3,959 re-

corded in all these establishments belonged to the male sex, thereby leaving 1,640, or about two-fifths, to the other, which gives an excess of 679 deaths, or 41·40 per cent. amongst the male residents.

Having very fully discussed in my former reports the mortality met with at various charitable institutions of the metropolis, it seems wholly superfluous again to enter upon such subjects at any length, more especially as there is ground for believing that detailed statements of the most interesting agenda, recorded at several public charities, will be eventually published by delegated official authorities. In the confident hope that such expectations may be speedily realised, and believing farther, that authentic statements of this kind will prove both instructive to the medical profession, and through them, to the public at large, I shall confine all present remarks respecting these institutions, to a few cursory observations, illustrative of the recent mortality recorded in the workhouses, prisons, and general hospitals of London; from which inquirers, taking an interest in similar questions, may be able to deduce their own inferences, and also to compare them with previous statistical observations.

Workhouses. Upwards of half the aggregate deaths recorded in the public medical institutions of London during the last six months, took place amongst the residents of workhouses, the number being 2,216 out of the total 3,959 deaths reported. Amongst these, it should be likewise stated, that the majority were male patients, the relative proportion being 1,125 males, to 1,091 females. If the 2,216 deaths now mentioned to have taken place in workhouses might be adopted as a criterion of the recent state of public health, it may be inferred, with some show of reason, that as one-eleventh of the total mortality recently recorded in London, supervened amongst paupers belonging to the different parishes, perhaps the same proportion of sickness occurred elsewhere as in these establishments. At the same time, if the above mortality be compared with the amount reported from London workhouses during the six months immediately preceding the two quarters terminating on the 27th of last September, less serious disease has of late generally prevailed, seeing the deaths have been actually fewer than in the former half year, when 2,564 persons died in parish workhouses and infirmaries, being an increase of 348 fatal cases. This result was doubtless owing, in great part, to the milder temperature of summer, compared with the cold weather of winter, which always proves inimical to the health of old persons, as also to children; and as many of the former class become inmates of these eleemosynary institutions, the proportion of deaths therein is usually considerable.

Metropolitan Prisons. The health of prisoners confined in London gaols has been recently exceedingly satisfactory, and quite as much so as on any previous occasion; only 32 persons having died throughout all the public establishments of that description in the metropolis during the last six months, of whom 27 were male, and only five female inmates. During the parallel two quarters of 1850, the total deaths in the same prisons were, however, 44, thus making a diminution of 12 cases in the last half year; and as the mortality

during the six months ending on the 29th of last March, was only 27, or five fatal cases less than in the recent period, no doubt can be entertained that London gaols are generally salubrious, the single exception being the Penitentiary. This conclusion is proved to be correct, seeing that eight of the 32 deaths recently reported from all the London prisons, occurred in that establishment; and as 10 of the 27 fatal cases also met with in the various gaols during the half year immediately preceding, took place in this prison, nearly one-third of the whole deaths, or 18 cases out of 59 recorded throughout the entire twelve months, were inmates of the Penitentiary, such statements corroborate the inferences now enunciated. The salubrity of most is very well known; and individuals whose health was bad on committal, have often become improved in condition after a short residence in prison. Indeed, a facetious physician is reported to have said, in reference to similar beneficial results, that idle and luxurious invalids having their constitutions affected from irregular habits, would frequently find it ameliorated by adopting prison rules, whilst they also had the same "change of air". The observation coincides with experience, and indicates the observer's shrewdness, as well as his knowledge of human nature.

General Hospitals. Having adverted at considerable length in my last report on the health of London, to the movement of patients recorded in these public charitable establishments, I do not at present propose again to discuss this important subject, beyond making a few cursory remarks in reference to the mortality met with amongst the patients. Compared with the parallel two quarters of the preceding year, the number of deaths reported from all the general hospitals of London, is rather greater in the recent, than in the previous parallel season; seeing the aggregate fatal cases amounted to 1,051 at the above institutions during the half year ending on the 28th of September 1850; whereas, from the same charities, 1,073 deaths were recently reported. However, in the six months terminating on the 29th of last March, the total mortality was greater, as 1,111 patients then died in the different hospitals. This result was somewhat analogous to the statements already reported from workhouses, and most likely depended upon similar influences, viz., the low temperature and severe weather of winter compared with summer, whereby the latter season proved more salubrious to inmates of the various charities, whether general hospitals or parochial infirmaries.

Another peculiarity in reference to the recent mortality reported from hospitals also deserves notice, namely, the large proportion of male patients who died in the above institutions, compared with females, nearly two-thirds of the whole deaths recorded having been of the former, and only about one-third of the latter sex, the exact numbers being 664 male, and 409 female patients. These facts therefore prove, that more disease, and certainly a greater number of severe accidents usually occur among the male population of London, resorting to general hospitals for relief, during sickness and physical injuries, than among its female inhabitants, although the latter are most numerous. But this point having been investigated in a former report, and conclusions having been deduced from the official returns of six

general hospitals, it seems unnecessary again to bring forward additional evidence upon that subject.

Besides the characteristic feature now pourtrayed respecting the preponderance of male patients in metropolitan hospitals, it also deserves remark, that the first three months embraced by the present report seem to have proved more unhealthy to inmates of these institutions than the latter quarter, comprising July, August, and September. During the former period, or throughout April, May, and June, the aggregate deaths in all the general hospitals amounted to 577, consisting of 366 male, and 211 female patients; whereas in the latter three months, the total number of fatal cases reported from the same charities, fell to 496, of whom 298 were male, and 198 female inmates; thus giving a diminution of 81 deaths, or one-seventh in favour of the more recent quarter. Such statements become more significant, when readers recollect that London contained a larger population last autumn than at any previous epoch; and as hospitals would be the most likely refuge of strangers, besides other persons meeting with accidents in over-crowded streets or elsewhere, the fact of fewer deaths having taken place at these institutions during the last three months, than in the preceding quarter, appears presumptive proof that casualties of all kinds were then less numerous. Taken cumulatively, but especially if viewed in reference to the existing population, the diminished rate of mortality in general hospitals must be held as highly satisfactory; and although the total deaths, from all causes, exceeded by 1,359 cases the amount recorded during the parallel three months of 1850, nevertheless the metropolis was certainly not insalubrious; on the contrary, considering the actual number of inhabitants, it was healthy.

Before taking leave of the eleemosynary institutions, as the subject may be interesting to many readers, I would again revert to the small number of deaths reported from the various charities, in order to contrast the results with those observed in Parisian establishments of the same description. In the French capital, although the total population ranges less than half that of London, the number who annually die in the workhouses *(hospices)*, and civil and military hospitals of the former city, is nearly treble the ratio of the latter, if viewed in reference to the number of inhabitants. Take, for illustration, 1849 and '50; seeing those years supply the most recent official returns now published upon similar subjects. During 1849, exclusive of the 19,188 fatal cases of cholera, which then prevailed in Paris, 9,871 persons, out of a gross mortality of 29,985, from all other causes excepting cholera, died in public institutions, thereby showing, that nearly one-third, or 32·94 per cent. of the total mortality in the above city, took place amongst the poorer classes. Again, throughout 1850, notwithstanding the aggregate deaths in Paris were under the previous year, being only 27,856 from all causes, still so many as 10,079 patients actually died in the public medical establishments of the French capital, thus making upwards of one-third, or 36·14 per cent. of the entire mortality who were inmates of such establishments at the period of death, the remaining 17,777 having died in their own domiciles. These instructive data indicate a very different state of matters from the ordinary occurrences recorded in London, where,

instead of only 64 persons in every hundred dying at home, as in Paris last year, the proportion was about 84 per hundred. Other points possessing much interest, in reference to the different rate of mortality recorded in the two capitals now compared, might be discussed; but I refrain, lest I exhaust the reader's patience.

Concluding Remarks. On reviewing the various facts contained in previous paragraphs, and considering that the 25,980 fatal cases reported, during the six months terminating on the 27th of last September, ought not to be regarded as exclusively representing the ordinary mortality incident to the 2,400,000 inhabitants usually living in London, but, in reality, appertaining to a much larger number of human beings liable to attacks of disease, at the time congregated within the British metropolis, the public have much reason to feel grateful that the number of deaths recently recorded was not more considerable. Another instructive point should be likewise borne in remembrance, namely, that the causes whereby the late increased mortality in great part arose, were infantile complaints, the victims being chiefly infants and young children:—not adults resident in London, or strangers attracted thither by the Great Exhibition, of whom the great majority were men and women. This reasonable inference becomes more significant, seeing that several determined objectors to the recent gathering of nations had gravely asserted, that the large assemblage of persons who would thus be brought in contact, must produce every imaginable kind of disease and misfortune.

In support of the view now promulgated, respecting the partially increased number of deaths recently recorded, compared with the amount met with during the parallel two quarters of last year, it will suffice to state, that the excess of fatal cases from hooping-cough having been 388, from measles 345, from diarrhœa 286, from hydrocephalus 235, from small-pox 240, and from convulsions 116, during the last six months; it thus appears that more than half the total excess, or 1,510 cases were produced by the half-dozen complaints above mentioned. Besides this peculiar feature in infantile diseases, it may be added, that although diarrhœa cannot be classed under that division, nevertheless, amongst the 1,649 deaths produced by it, 1,354 of the cases occurred in patients previous to puberty, many being infants.

Statisticians, fully competent to form an opinion upon the subject, having estimated that 3,000,000 individuals, at least, beyond the usual resident population, actually visited London during the six months embraced in this report, the recent amount of mortality must have been thereby materially influenced; although the actual increase was not at all commensurate with the augmented number of residents, nay, speaking comparatively, respecting the actual population at the time, the ratio of deaths was rather below that of many ordinary seasons. Applying this mode of reasoning to the subject under discussion, let us suppose that an army of 50,000 men having lost, during six months, a certain number by ordinary complaints, were augmented to 100,000 rank and file, of course double the number of deaths would still give the same rate of mortality; but if the increase in mortality was only one-half the previous amount, then the actual ratio of deaths had diminished. Again, take a fleet having a certain number of sailors on board; if so

many died within a limited period, the mortality would be relatively the same, should double the number of deaths be registered after the crews had become, by new arrivals, twice as numerous. Were either of these contingent results to arise, there would be nothing extraordinary in such occurrences to excite astonishment. Instead, therefore, of assuming the late augmentation of deaths throughout the metropolis as any evidence of its recent insalubrity, the facts seem clearly to warrant an opposite conclusion. Irrespective of the great accession of inhabitants, if the total fatal cases recorded in London during the last six months, be compared with the amount reported in the two parallel periods of 1847 or 1848—the year 1849 being exceptional, as the cholera then prevailed epidemically—the average rate of mortality will appear nearly alike; seeing that the total deaths during the second and third quarters of 1847 were 25,548, or only 432 fewer than last season; whereas, in the six similar months of 1848, when the gross mortality amounted to 26,453, there occurred an increase of 473 fatal cases, notwithstanding the ordinary population was much less considerable than recently.

Unquestionably, the residents of the metropolis never became doubled in amount at exactly the same period, the additional visitors being distributed over the whole six months, especially during the last quarter; nevertheless, as all were under nearly the same influences, and equally liable, or exposed to attacks of disease, the aggregate number of persons present must be taken into calculation, when estimating the average rate of mortality. It has also been shown, in a previous paragraph, that the recent actual augmentation in the number of deaths was almost exclusively confined to children, and did not materially affect the adult population; so far from the vast crowding together of human beings in London, from all districts and climates, having produced deleterious effects upon their health, the very reverse supervened. Consequently, when we cast a retrospective glance over many remarkable features characterising the events of the last six months, amongst various subjects worthy of special notice, none seems more peculiarly instructive and impressive than the remarkable salubrity of the season, the absence of any severe epidemic, and the small amount of severe accidents. These reflections ought to make men grateful; and as doubtless some of the results now described were greatly promoted through the precautions taken by public authorities, the sanitary measures previously adopted, and the admirable spirit which animated all parties frequenting the metropolis, every recollection of the Great Exhibition and the recent concourse of nations cannot but prove agreeable, and ought to excite within us deep gratitude to the Almighty Ruler of the universe.

24, Brook Street, November 1851.

A CASE OF CHOLERA TERMINATING WITH PERICARDITIS.

By EDWARD BALLARD, M.D.Lond., late Physician to the St. Pancras Royal General Dispensary, etc.

Case. Mr. C—, aged 30, residing at Retford, by occupation a cabinet-maker, requested me to visit him at seven P.M., September 5, 1849, in consultation with Mr. W. Gylby, his ordinary medical adviser. That gentleman informed me that the patient, although well capable of following his employment, did not enjoy habitually robust health, but that there had at no time been any indication that he suffered at all from renal disease. It appeared that, on September 4th, he was occupied for four hours in a house where some persons had died of cholera, (located there by several intolerable nuisances around it), in measuring one of these persons for a coffin, etc. He was of a timid disposition, and had an impression on his mind, that he should be attacked by the disease. In the course of the morning of the 5th, he was seized with diarrhœa; and at 2 P.M., after having eaten his dinner, vomiting and epigastric pain supervened. At the time I saw him, he was discharging frequently the regular choleraic evacuations, and shortly began to suffer from cramps in the legs and abdomen. He was ordered acetate of lead in pills, with acetate of morphia; flannel bandages were placed upon the legs, and he was "packed" in blankets. The pills having been vomited, calomel was substituted for the lead, and effervescing draughts, with hydrocyanic acid, were given.

September 6th. We found that the vomiting and purging had been but trifling during the night, his skin was sweating abundantly, and the cramps had been less frequent. His hands, however, were purple, shrivelled, and cold; voice feeble; pulse small, and intermitting at each third beat; breath cool, but not so cold as is often observed; he was complaining much of dyspnœa; urine quite suppressed; cold water, if drank, caused a return of the vomiting and cramps. Six ounces of blood were taken from the arm, with immediate relief to the dyspnœa, and return of regularity with increased fulness of the pulse. In the evening, he expressed himself much relieved; his voice was stronger, and breath less cold. The blood drawn in the morning presented a large coagulum of deficient firmness.

September 7th. He said he felt better. There had been no vomiting and no cramps, but I noticed that he was very restless, his eyes had an unnatural appearance, and when a question was put to him, he appeared to hesitate, as if in meditation upon it before giving his answer. Mr. Gylby informed me, that there had been a *bilious evacuation* from the bowels. In the afternoon of this day, some return of dyspnœa had induced Mr. G. to apply a blister to the epigastrium, which relieved it greatly.

September 8th. Mr. G. informed me that the patient had "vomited a quantity of pure bile", and that he had had some interrupted sleep during the night, and had passed another "bilious stool". The blueness had disappeared from the hands, and they were warmer; but there had been delirium during the night and this morning. The restlessness had remarkably increased; he was tossing about in all directions upon the bed, and there was the same expression of the eyes as on the day before. From time to time he drew a deep sigh. The pos-

sibility of pericarditis suggested itself to my mind, as explanatory of the observed phenomena, which I had noticed under similar conditions before. On examination of the cardiac region, which I consequently made, I found the first sound of the heart defective, but not quite lost; and accompanying the second, and extending partly into the interval, there was a *very obvious friction sound*, audible over the situation of the base of the heart only. The heart's dulness on percussion was not increased. Six leeches were applied over the situation of the friction sound and followed by warm poultices; and his calomel and morphia were continued. Some carbonate of ammonia had also been added to his draughts. When I visited him in the after part of the day he was asleep, and had passed another bilious stool. The evacuations were all thrown away prior to my visits, probably from dread of infection.

September 9th. I was informed he had slept soundly during the night, and had passed no urine, although I had directed that any he passed should be preserved for examination. I found him in the morning in a state of stupor, from which he could only be partially roused; but there was, notwithstanding, the same tossing about the bed from one side to the other, and throwing about of the arms, as noticed before. The pulse was imperceptible at the wrist, *and the friction sound was double, and extended over the whole cardiac region.* At noon, he died. An examination of the body was not allowed.

Remarks. The principal interest which attaches itself to this case is pathological. A patient, in progress of recovery from the collapse of cholera, dies with the physical signs of pericarditis strongly pronounced, and with symptoms referable to the cerebral faculties, such as occur sometimes in that disease, and in connexion with uræmia. There are two matters to be regretted: one is, that the evacuations of urine (if they ever occurred) were allowed to be mixed with the stools, and so systematically thrown away; and the other, that there was no opportunity afforded of discovering, after death, the condition of the kidneys. Thus, therefore, we cannot, on the one hand, positively affirm that urine never was secreted, or being secreted, that the amount of urea discharged was defective; or, on the other, be certain that degeneration of the kidney had not been present prior to the choleraic seizure. These are points to which it is fair and proper we should not close our eyes. Still, it is to be recollected, that chemical analysis has shown that an inordinate quantity of urea in the blood is a condition which is remarked in the reactive stage of this disease, as well as in renal degeneration; that there was no history of renal symptoms prior to the occurrence of cholera; and that the pericarditis occurred just at that period when it was to be expected that uræmia, as the result of the cholera, would be most intense, and consequently most likely to produce its poisonous effects. Hence, even if renal disease had been proved to be present prior to the attack of cholera, it would still have remained in the highest degree probable that the latter, by augmenting the uræmia, had aided the former in poisoning the patient's blood. This at least may, I think, be fairly concluded from the case under consideration. Taking this view of the matter, I need scarcely say, that the pathological interest of the case lies in its connexion with the results of the valuable researches of Dr. John Taylor on the causes of pericarditis.

42, Myddelton Square, October 8, 1851.

DEPRESSION OF THE UPPER AND ANTERIOR ASPECT OF THE THORAX,

CONSEQUENT UPON POSTURE IN OCCUPATION, SIMULATING THE DEPRESSION OF PHTHISIS.

By S. SCOTT ALISON, M.D., Licentiate of the Royal College of Physicians of London.

Some years ago, a man, about 40 years of age, requested my advice for severe pectoral symptoms, prostration of strength, and extreme emaciation. He believed himself to be suffering from consumption. His breathing was laboured; he spoke with evident difficulty, and coughed almost incessantly. He expectorated a great deal, and perspired much: in short, he ran over the usual symptoms of a man in the last stage of phthisis.

On his drawing off his shirt, in order to my making a closer examination, I perceived that the forepart of the three upper left ribs was much depressed, and that, during inspiration, they failed to rise as in the healthy chest. So far, this corresponded with, and corroborated the idea of the patient himself, that his disease was consumption. But going further, I found that the cardiac and vocal resonance was not increased; that percussion elicited no materially dull sound; and that vesicular respiration was going forward, though mixed up with large mucous râle. The other side of the chest was healthy in form, and likewise in sound, except that rhonchus in the larger air tubes was extensive. With these encouraging facts, I ventured to disregard the flattening of the left side, and assured the patient that his disease was not consumption. The treatment adopted was what is usual in such cases of bronchitis, and included counter-irritation. The more acute symptoms passed off, and in some months the patient was restored to his usual health.

I had the curiosity to ascertain the subsequent history of this man, and I therefore visited him within the last few days. I found that he had some two years back discontinued his occupation, that of a cabinet-maker, in consequence of his health being delicate, and had since employed himself at a lighter business, requiring less exertion and stooping. He still coughed a good deal, and felt weakly, but he had as much flesh as when I discontinued seeing him some four years ago. I requested to be allowed to see his chest; and though there was evidently some flattening on the left side, it was materially less than formerly,—a change which I attribute to the discontinuance of his former occupation. He had formerly been employed the greater part of the day at a low bench, sawing and planeing, with the chest inclined forward, and to the left, and with the right shoulder more elevated than the left. This had been his daily occupation from boyhood; and it had affected him doubtless the more readily, from his constitution being delicate, from his osseous frame being unusually slight, and from his habits being somewhat irregular. Throughout the chest vesicular respiration was established, and any little mucous râle to be heard was confined to the right mammary region, and was not to be made out in the region of the flattened ribs.

Since my attention was drawn by this case to the depression of the

upper and forepart of the chest by posture in occupation, regarding it with some interest in relation to the flattening caused by phthisis, I have observed the same alteration in form, produced by posture in other patients; but guided by the case related, I have avoided confounding it with the same alteration dependent upon pulmonary disease. In some cases, the flattening is found on the right side; in some on both sides, including the upper portion of the sternum. When the entire upper portion of the chest is greatly depressed, which is the case particularly in those workmen who are employed in drilling wood on a very low bench, and who increase the force of the left hand holding the drill, by pressing it with the under surface of the lower jaw, and the upper portion of the front of the chest, the thorax at its back aspect becomes gibbous, the dorsal vertebræ forming a segment of a circle, while the cervical and lumbar vertebræ remain in a comparatively straight line. When the depression takes place on one side, for the most part the spine is somewhat distorted, the dorsal vertebræ forming a curve whose convexity is directed to the opposite side. For the most part, in proportion to the flattening or depression of one side, there is observed a greater fulness of the opposite side of the thorax.

Such alterations in the form of the chest, consequent upon posture, are in themselves significant of little or no internal injury. In such cases, the internal organs present no signs of alteration in their structure, very little of disturbed function, and for the most part, evidence only of slight displacement. The bodies of men whose chests have been very considerably altered in form have been opened, and the thoracic viscera have displayed no signs of morbid alteration. I have carefully examined during life the lungs and heart of many suffering from flattening of the chest thus induced, and have in most cases failed to detect any material internal lesion.

I have been informed, both by workmen themselves and by their employers, that posture, even when it succeeds in causing flattening of the breast, gibbosity of the back, and inequality of the shoulders, is operative, if to any, to only a very slight extent, to the injury of health. The workmen have invariably said, that their diseases, and even their chest ailments, are more due to close and heated workshops and to dust, than to any other cause; while the masters have, with obvious justice, referred not a little of the illness of their men to the irregularity of their habits, and their excesses.

Neither induced by internal disease, nor inducing any such, of what import, it may be asked, can such alterations be? What they possess not themselves, they may acquire, if taken for the signs of internal disease. That importance which depression of the chest, the result merely of posture, does not possess, it acquires, if taken, or liable to be taken, for depression the result of phthisis. It is with this view that the subject is here considered. The mistake may be made, and has been made; but it need not be made, for each kind of depression has its respective concurring signs.

The depression of the chest, simply the result of posture, is to be known from the same alteration induced by phthisis, by the absence of the other signs of that disease, such as the prolonged expiration, the decided dulness on percussion, the reduced vesicular breathing, the increased resonance in the early stages, the cavernous respiration,

pectoriloquy, and the other sounds emanating from cavities in the structure of the lungs in the third stage.

When the depression is the result of posture, for the most part the loss of room in the cavity of the chest in one side is compensated by a corresponding amplification of the other; and when the whole upper part of the chest is depressed, an increase of room is secured for the lungs and heart, by the gibbous back already referred to. On the other hand, depression of the ribs consequent upon tubercular deposit, has no compensation, for this reason, that the depression is the result of the reduced contents of the chest, and follows, *pari passu*, upon the internal reduction. In this case, nothing internal is displaced, so there is no occasion for an increase of space elsewhere.

With the help of these physical signs, the two forms of depression may be diagnosticated, even when the depression from posture is associated with bronchitis, with emaciation and hectic fever, as in the case I have related.

It is to be observed, that though depression of the chest may have originated in posture in occupation, yet it may after a time become associated with phthisis, and owe its further development to that disease. In such a case, depression formerly unaccompanied by decided dulness, reduced vesicular murmur, etc., will now be attended by them. It may be, that the depression will be abnormally great, and that the amplification of the chest in some other quarter, which compensated the loss of space, may yet exist.

It perhaps has tended, on the part of young practitioners, to cause the depression of the chest from posture in working men to be mistaken for a sign of phthisis, that the depression referred to is more common amongst the weak and sickly than amongst the robust. The delicate of frame, the irregular in habit, and the ill-fed, sooner yield to the deforming influence of posture than the opposite. It is an interesting fact, that on visiting a certain cabinet manufactory on a late occasion, I did not see one man who appeared distorted or unhealthy. I was informed that the men were well paid, and that the master could afford to employ only regular men. The same day I was taken to a workshop devoted to the same description of trade: I was told that the master was poor, did a lower kind of business, and paid his workpeople indifferently. I found the men thin, sickly, and the shoulders unsymmetrical. The most perfect specimen of the flat breast and the gibbous back which I have seen, met me there.

It appears that on the discontinuance of the posture which has induced the depression, the deformity becomes disposed to remove. A material elevation has certainly taken place in the left side of the patient whose case is related at the commencement of this communication. No such correction takes place in phthisis; doubtless, here, as in cases of ricketty curvature of the limbs, there is an ever-watchful principle at work in the body, ready to restore, under favourable circumstances, the natural conformation. It only awaits the removal of untoward circumstances, too strong to be overcome, which have neutralised it for a time, in order that it may recal the formative organs from their erring course to their normal action. How beautiful is such a reparation; how it tells of God in every living thing; how encouraging to the physician, as well as soul-improving to the man!

Although it has been mentioned as one of the diagnostic signs of depression of the ribs consequent upon posture, that percussion affords no decided dulness as in phthisis, there is little doubt that I have made out in numerous cases of flat breasts, the result of posture, as well as a natural characteristic, a certain amount of dulness. I am convinced that the resounding clearness, which we obtain from a prominent or barrel-like breast containing healthy viscera, is seldom or never elicited from the flat chest. On the other hand, the amplified part, such as the gibbous back, is more resonant than the natural back. The flat and contracted thorax I have often found to give out sounds on percussion somewhat dull, although the contained lung was in no degree solidified; and again, I have frequently evoked sounds from the rounded, and prominent, and barrel-like thorax, much clearer and ringing, although there was no reason to believe that the lungs were more filled with air than in cases of flattened chest.

These facts have led me to believe, that the resonance of the chest is due, less than is usually credited, to the quantity of air in the lung, and that it is materially affected by the form of the bony frame. But perhaps this is matter for consideration at another time; and it will suffice to have referred to the point, which is one which should be taken into account, when the student gauges the acoustic properties of the thorax in disease. Yet I may allude for a moment to the analogous formation of musical instruments. The sounding board of some pianos is somewhat arched in order to increase the sound; and when by any accident this form is reduced, the sound is proportionably lost. The arched form of other musical instruments favours this resonance. It is not otherwise with the human thorax. Such being the case, the student, in order that he may the more accurately appreciate the sounds of the thorax, as signs of the condition of the contained viscera, would do well to make himself acquainted with the respective sounds of the different kinds of thorax in health, as a preliminary to the study of those of the same part in disease.

Park-street, Grosvenor-square, October 1851.

ON THE RELATIONS OF UTERINE TO CONSTITUTIONAL DISORDER.

By F. W. MACKENZIE, M.D., Physician to the Paddington Free Dispensary for the Diseases of Women and Children, Fellow of University College, etc.

(Continued from p. 1006 of last Number.)

In the preceding observations, I have treated more particularly of the influence of derangement of the cerebro-spinal portion of the nervous system upon the uterine organs, as exemplifying one form of the relations which subsist between uterine and constitutional disorder. I referred more especially to spinal irritation, as a consequence of certain mental affections on the one hand, and the cause of uterine diseases on the other; and I adduced several facts and cases in support of the opinions which I ventured to express. I shall now proceed to treat of morbid conditions of the sympathetic or ganglionic portion of the nervous system, as connected with the question under consideration; and, in doing so, will select the subject of Chylopoietic Disorder, as being best calculated to illustrate the nature, the extent, and the importance of their relations to uterine pathology.

But, in speaking of chylopoietic disorder, it may be necessary to premise, that the term admits of a more extended and somewhat different signification to that which is ordinarily attached to it. We speak, for instance, of indigestion, dyspepsia, bilious disorders, disorder of the digestive organs, etc., as implying some derangement of the stomach, liver, or other portion of the alimentary canal, whilst in reality it is often the case that these affections are but the manifestations of a more deep-seated disorder, one involving either the nervous system at large, or the ganglionic portion in particular. For, just as it is true, that various local disorders of parts, which are supplied with nerves from the cerebro-spinal axis, depend upon irritation or disease of the cerebral or spinal ganglia, so is it true that many functional affections of the stomach, liver, and intestines, and of other organs, whose nerves are derived from the sympathetic, depend primarily upon irritation, or disease of the ganglia of this portion of the nervous system. It is probable, indeed, that it is from impressions made upon these ganglia that the digestive organs participate so largely in morbid states of the constitution, and have hence been regarded as the centre of sympathy; that it is upon these ganglia that all mental and emotional stimuli immediately operate; and that it is these which are primarily influenced by abnormal conditions of the blood. The impressions so made are doubtless soon followed by various functional disorders of the chylopoietic viscera; but these are, in many cases, rather symptomatic of disease of the ganglia, than diseases of the viscera themselves.

But however regarded, there is no system of organs which is so liable to disorder as the digestive, whether from the operation of causes which are directly applied to them—constitutional derangement, mental affections, or sympathy; and there is none, the disorders of which react so injuriously upon the constitution at large, or the uterine organs in particular. There are few instances of uterine disease which are not

attended with some form of chylopoietic disorder, either as a cause, a consequence, or an accidental complication; and upon this association of morbid actions, or rather upon the reciprocal influence which the disorders of one organ exercise upon those of the other, may be said to depend much of the difficulty which attends the treatment of uterine diseases. On looking to the table published in the preceding part of this inquiry, it will be found, that digestive disorder was an almost invariable concomitant in the cases referred to; that in by far the larger number it had existed as an antecedent; whilst the history and results of treatment, which will hereafter be alluded to, tend to show that this antecedence was not merely casual, but that the chylopoietic disorder was generally the cause of the uterine. On these grounds, then, alone, the disorders in question demand a careful consideration, in connexion with the present inquiry, inasmuch as they must have important relations to the pathology of uterine diseases.

And if, in the first place, it be asked, what are the circumstances in which such disorders arise? It may be replied, that they are referrible to two principal sources; the one comprehending all such causes as, applied to the *surface of the gastro-intestinal mucous membrane*, are calculated to produce irritation or disorder, such as those connected with errors and irregularities of diet, and the presence of crude, unhealthy, or undigested matters in the primæ viæ; the other, various constitutional causes, referrible to the blood, the nervous system generally, or particular organs or parts, or such states of mind as are calculated to act unfavourably upon the *ganglia of the sympathetic*, which more immediately preside over the functions of these viscera.

Thus, whenever the constitutional powers are greatly depressed, or the body is enfeebled, either from disease, want, privation, mental, or any other causes, it will follow, that the stomach and digestive organs, participating in this general weakness or depression, will become morbidly susceptible, and thus readily disordered, either spontaneously, or through the operation of some trivial disturbing cause.

But in other cases, and when no such general weakness or depression exists, the digestive organs may become deranged, from various local irritations or diseases in remote parts of the body, and this in conformity with a principle which will hereafter be referred to. Thus we observe in all the affections of important organs, such as the brain, lungs, heart, kidneys, uterus, etc, that the stomach becomes sympathetically disordered, and such disorder the cause of various secondary diseases; but such consequences are not confined to the more important organs of the body alone, for irritation wherever existing, however trivial in degree, or however apparently unimportant the part, may, under certain circumstances, also affect the stomach and digestive organs; and here, as in the former case, the affection thus secondarily produced will again react upon the constitution, as well as on particular parts, variously disturbing the former, and leading to divers local diseases in regard to the latter.

Thus it happens that in persons who inherit a feeble constitution, or in whom it has been acquired, whose nervous system is naturally irritable, or has been rendered so by any causes whatsoever, who have been the subjects of severe disease, who have been addicted to irregularities of diet, whose health has suffered from a residence in tropical

climates, from sedentary pursuits, intense study, privation, or anxiety, and in those in whom the blood is impoverished or deteriorated, the digestive organs become morbidly susceptible, and are thus readily disordered.

Now, in this general enumeration of the circumstances in which chylopoietic disorders arise, it will be found that nearly all of them apply with particular force to the habits and constitution of the female, as distinguished from the male. In her, the brain and the nervous system are more sensitive, and consequently more liable to be disordered by mental and other causes. In her, the constitutional powers are less vigorous, and these are often still further reduced by sedentary habits, and a disregard of proper hygienic measures. Education, in many instances, and particular pursuits in others, impair still more the tone of the nervous system, and proportionately injure the constitution; whilst from the concurrence of these several causes an impoverished condition of the blood, sooner or later, is induced, which cooperates with them in originating and maintaining an irritable and disordered state of the stomach and digestive organs: and the disorder thus secondarily induced, seldom fails to react again upon the constitution, and thus to produce a state of general irritation, which is favourable to the production of various local diseases.

But in this general reaction it will be found, that some organs are more liable to be disordered than others, according as the sympathy between the stomach and particular organs is more or less intimate. The stomach has been truly said to be the centre of sympathy, but the nature of this sympathy varies very considerably in regard to different organs. With none is it so intimate as with the uterus, and we may hence, in conformity with the acknowledged laws which regulate this principle of action, as deduced from a careful consideration of various facts and circumstances, legitimately account for the frequent, and, indeed, almost constant occurrence of uterine disease, as a consequence of chylopoietic disorder.

The sympathies of the stomach, I need scarcely remark, have long attracted the attention of medical men; they were known nearly two thousand years ago to Celsus, who observes, that when the stomach is disordered, the whole system is disturbed, and that the weaker parts more especially suffer. He pointed out its influence upon the heart's action, and its tendency to produce various local diseases in remote parts of the body, as also its capability of maintaining a state of general irritation of the nervous system. But it is more especially to the industry and genius of Hunter, that we are indebted for nearly all that is at present known upon the subject. He taught us, that through this principle, all the actions in an animal have a connexion with one another; the living principle of one part sympathising with the living principle of another; the nerves of one part sympathising with the action of the nerves in another; and the mind sympathising with the mind; that, as a consequence of this principle, no considerable disorder can take place in one part of the body without producing correspondent derangement in others; that, as another consequence of this principle, an action may arise secondarily, without any immediate impression; the part so secondarily impressed, either acting in conjunction with that primarily acted on, or taking the whole action on

itself; or, as he otherwise expressed it, one part under the stimulus of irritation or disease, is capable of stimulating another into sensation, action, etc. He maintained, moreover, that sympathy is a principle in animal bodies, so intimately connected with every possible impression, affection, and action, that we cannot have a proper conception of the animal economy respecting diseases, without taking it into consideration. It arises, he observes, from every part of the body being ready to fall into affections and actions in consequence of an impression, affection, or action, taking place in some other part, and it consists essentially in one part participating in the impressions, affections, and actions of another.

But we are more especially indebted to him for pointing out the importance of this subject in connexion with the stomach and digestive organs on the one hand, and morbid states of the constitution, on the other. From an attentive consideration of many facts, he was led to believe that the stomach had a direct sympathy with all parts of the body, and thus might be regarded as the seat of universal sympathy; that when the stomach sympathised strongly with any part, this state of the stomach produced a morbid condition of the constitution, from which, however, some organs would suffer more than others, and whence it followed, that various local and apparently unimportant diseases of remote parts of the body might, through the medium of this organ, produce a state of constitution favourable to the causation of various secondary diseases, the precise nature of which would, in a great measure, depend upon the peculiar sympathies subsisting between the stomach and particular organs. The correctness of these doctrines, and the importance of their application to medical practice, have been especially dwelt upon by Mr. Abernethy, who has shown, that if the disordered feelings and functions of the digestive organs thus induced be removed, the greatest degrees of nervous disorder in remote organs and parts will sometimes cease suddenly; at other times, they will be greatly mitigated and subside, proving that, in such cases, the one derangement is the cause of the other.

From a careful consideration of this subject, we may, I think, deduce some practical conclusions which bear immediately upon the pathology and treatment of uterine diseases. We may learn, in the first place, that impressions made upon the stomach and digestive organs may be so reflected upon the uterus as to give rise to uterine disorder, without the stomach and digestive organs themselves being very manifestly disturbed. Thus it often happens, that trifling irregularities of diet, and other causes, which can only act, at least primarily, upon the digestive organs, frequently occasion feelings of pain, discomfort, or uneasiness in the uterus, when the former organs would appear to have been but slightly disturbed; and in some cases, the uterine disorder may be very considerable, while that of the stomach is scarcely perceptible. The same thing is observed also in the instance of a loaded, flatulent, or disordered state of the colon, which may be unattended by any pain or discomfort in the immediate seat of the disorder, while considerable pain and uneasiness may be felt in the uterine and ovarian regions as its consequence. Now these circumstances are precisely in accordance with what has been laid down by

Hunter as a law or principle of sympathy; for he taught, that when disorders and consequent diseases thus arise, the organ sympathetically disturbed may suffer more than that originally affected; or that the part secondarily impressed may take the whole action on itself. As regards the uterine organs, this principle is of the utmost importance, and admits of an extensive application; for there are none which are so ready to fall into morbid actions and affections, as a consequence of the morbid actions and affections of other organs; and whilst the sympathetic disorder of these, thus induced, may assume considerable importance, the actual causes from which it springs, and by which it is continued, may be altogether lost sight of, if not carefully looked for. I had on one occasion a striking illustration of this form of sympathy, in the instance of a parturient patient, in whom, of course, the uterine organs are more than usually susceptible to impression, and, consequently, in whom the effects of various causes are more easily appreciated.

Case. Mrs. C., aged 34, was confined on the 12th August; she went on favourably until the seventh day after her confinement, when she drank a small quantity of cold toast-water, being at the time not very strong, and somewhat heated and perspiring. This was immediately followed by a sensation of extreme coldness in the uterus, which continued for a period of two days persistently. From the first, she felt no sensation of cold in the stomach, the impression having been entirely reflected from this organ upon the uterus. Had the sensation experienced been that of pain instead of cold, it might have led to the conclusion that there was uterine disorder or disease, and thus to the adoption of measures which, as the result proved, would have been altogether unnecessary.

Secondly, we may learn how all the circumstances which have been referred to, as calculated to give rise to gastro-intestinal derangement, may be regarded, in one sense, as the causes of uterine disorders also. For though the operation of these is primarily upon the stomach and digestive organs, or the ganglia connected with them, and derangement of these is first produced, yet this, by a sympathetic or reflected kind of operation, may, and frequently does, become the cause of secondary uterine affections. Hence it is that many circumstances, not apparently having any connexion with the uterus or its diseases, thus become so, and require to be carefully considered in their treatment. We can thus see how the causes previously spoken of, such as depressed states of the constitution, irritable conditions of the nervous system, morbid conditions of the blood, constitutional derangement of any kind, local irritation or disease, irregularities of diet, sedentary pursuits, anxiety of mind, a residence in warm climates, want, privation, etc., may indirectly affect the uterine organs, and either originate or maintain a state of uterine irritation or disease.

Thirdly, it will follow, that when causes have primarily and directly acted upon the uterine organs, as when cold or sudden fright have checked or interfered with the menstrual secretion, such arrest or interference will speedily be followed by corresponding disorder of the stomach and digestive organs, which will, in turn, sympathetically augment the former, and variously disturb the whole constitution. If we carefully inquire into the history of such cases, this, in fact, will be

generally found to be the usual order and sequence of the morbid actions which take place. Almost invariably the digestive organs become disturbed concurrently with the constitution; and the disorder of these, while it increases the constitutional disturbance, interferes with the return of healthy uterine action. It is well known, for instance, that anæmia is a frequent consequence of suddenly suppressed menstruation; and it has generally been attributed to the direct action of the uterus upon the blood, or the constitution: but I believe that in nearly all cases it will be found to be immediately dependent upon an intermediate disorder of the stomach and digestive organs, which, although occasioned by the suppression, is continued independently of it. This may not always be very obvious, whilst sometimes it is very considerable, and consequent upon it the blood becomes impoverished, which, together with the chylopoietic disorder, keeps up a state of irritation of the uterine organs, which is altogether incompatible with the return of healthy functional action. By correcting the disorder of the digestive organs, however, together with any other that may have been simultaneously produced, as also the condition of the blood, it will generally happen that healthy uterine action will spontaneously return without any specific treatment. Of this I have seen numerous instances.

Lastly, seeing how readily gastro-intestinal disorders may be occasioned by uterine disease, and how painfully they react again upon the constitution and the uterine organs, we may learn the importance of maintaining tranquillity of the stomach and digestive organs in the treatment of those cases of organic uterine disease which are not susceptible of radical cure. Almost all such diseases may be said to occur in two forms—the one being active, the other quiescent—and in the latter state they are often compatible with a considerable degree of health and freedom from local uneasiness. For of no organs can it so truly be said as of the uterine, that a very great amount of organic disease is not inconsistent with a tolerably healthy performance of function, if incidental causes of disorder or irritation are removed. The causes, then, of such incidental disorder or irritation, deserve to be carefully investigated; and they will, I am persuaded, be more frequently found in connexion with the derangements in question than is generally supposed. Upon these, indeed, have appeared to me to depend, for the most part, those dangerous consequences which so often occur in connexion with organic uterine diseases, and which are so fraught with injury to the health and constitution of the patient. To take fibrous tumours in the walls of the uterus as an example, we find them in some cases altogether unproductive of any particular symptoms; and even when of considerable size, they may continue for many years without being even recognised either by the patient or practitioner. Menstruation may go on normally; pregnancy may take place, and proceed favourably; and parturition may be safely accomplished. But in other cases we find them attended with much irritation of the uterus, and great functional disorder, such as pain, hæmorrhage, leucorrhœa, etc. Now that which determines the difference in these cases, appears to me to be altogether independent of the uterus and of these particular growths, and may in a great measure be traced to irritative disorder of other organs which sympathetically

disturb the uterus, morbid conditions of the blood, and disturbed states of the nervous system generally; and that such is really the case is proved by the fact, that if these incidental sources of uterine irritation be removed, such active forms of uterine disease will become quiescent, and cease to endanger the health or comfort of the patient. Of this I have also seen numerous examples.

When again we consider the relations of the stomach and digestive organs to the ganglia and nerves of organic lfe; when we bear in mind that the uterus is principally supplied with nerves from this source; that its ganglia and nervous endowments are very considerable, and that they have intimate connexions through filaments and plexuses with the great ganglia which immediately preside over the functions of the stomach and digestive organs, we must admit that there are ample reasons for believing that morbid conditions of the one organ should be rapidly propagated to the other; for it is a well-established physiological dogma, that when organs are supplied with nerves from the same ganglia, they more readily participate in each other's actions, impressions, and affections, both morbid and physiological, than when they are supplied with nerves from a different source. From a consideration of this principle, it would appear obvious, that not only do the whole of the chylopoietic viscera sympathise intimately with one another, but that this sympathy is extended to the whole of the organs contained in the pelvis, of which the uterine may be considered as the most important. From the earliest periods, the sympathies of the uterus with the stomach have attracted the attention of medical men; but the *reciprocal* nature of these sympathies have not been as carefully attended to, although it admits of easy demonstration that the uterus is more readily affected by morbid conditions of the stomach, than is the latter affected by morbid and peculiar conditions of the former; and accordingly it may be laid down as a sound pathological axiom, that in general the stomach cannot be much disordered without giving rise to correspondent disorder of the uterus. When severe gastric irritation exists, the sympathetic uterine disorder may, and often is, equally severe; but in slighter forms of disorder of the stomach and digestive organs, the same principle holds equally good, and hence from such causes various subdued forms of uterine disorder may arise. It is to this point I am anxious more especially to direct attention, because whilst, on the one hand, the influence of uterine derangement upon the stomach is generally admitted, as is also that of severe gastric disorder upon the uterus, the reciprocal relations which subsist between the slighter forms of irritative disorder of both, do not appear to have been sufficiently recognised, or if recognised, they have not been duly regarded in practice by the generality of practitioners.

Looking again to the circumstances in which gastro-intestinal derangements originate, seeing that they may be perpetuated by an endless variety of causes, we cannot be surprised that consecutive disorders, uterine as well as others, should often be protracted, and difficult of removal. For whilst disorders of the digestive organs, in some form or other, are probably the most frequent of the maladies which prevail in social life, they are at the same time those which it is most difficult to rectify. In some cases, they are dependent upon

habits or modes of life, which the patient cannot, or will not, relinquish. In others they arise from mental or moral causes, which in the varied forms of disquietude of mind, anxiety, trouble, or affliction, are almost inseparable from our social existence. In one grade of society they are met with as a consequence of indolence, dissipation, or excess; in another, as a result of want, penury, and destitution; and such disorders, however induced, by their reaction upon the constitution and the nervous system, are rendered additionally complex and proportionately difficult of cure. On this subject, an eminent writer says,—"Of late I have been inclined to regard these circumstances as the cause of the complicated diseases which are met with in man so much more frequently than in animals. In man the brain is more sensitive, and liable to be disordered by mental affections. In man the digestive organs are liable to be disordered by stimulating and unnatural diet. Sedentary habits and impure air cooperate to aggravate these disorders. The affections of the brain and digestive organs mutually increase each other, and thus a state of constitution arises which is productive of the most general and complex diseases. But even these do not seem to me to be the most calamitous terminations of such causes. The disorder of the sensorium, excited and aggravated by the means which have been described, frequently affects the mind. The operations of the intellect become enfeebled, perplexed, and perverted. The temper and disposition irritable, unbenevolent, and desponding. The moral character and conduct appears even liable to be affected by these circumstances. The individual in this case is not the only sufferer, but the evil extends to his connexions and to society."[1]

Impressed with the importance of these and similar considerations, I have for many years been accustomed to study uterine diseases with especial reference to their constitutional origin and causes; and in taking the histories of cases, I have more particularly sought for information on this point, which I have carefully noted down. The result of doing so has been to convince me that constitutional causes have more to do with the origin and continuance of uterine diseases than is commonly supposed; that chylopoietic disorders—sometimes singly, but more frequently associated with others—do, in the great majority, precede and give rise, first, to uterine irritation, and, secondly, to various uterine diseases; and farther, that a proper and full appreciation of this circumstance is indispensably necessary to their successful treatment. The extent to which chylopoietic derangement is met with in connexion with this class of disorders, either as a cause, a consequence, or an accidental complication, would be altogether incredible, if facts did not directly support the observation. Thus of the hundred cases referred to, and tabulated in the earlier part of this paper, chylopoietic disorder existed as an antecedent in 82, and as a concomitant in 97. In 33 it coexisted with spinal irritation; in 87, with anæmia; and in 20, anæmia; spinal irritation and chylopoietic disorder were met with concurrently. It is surely then unnecessary to adduce any further evidence in support of the opinion that such disorders, either singly or combined, do, in a large proportion of cases, precede and give rise

[1] Abernethy. Surgical Works, vol. i, p. 265.

to uterine derangement, and are also the chief causes by which these derangements are both complicated and perpetuated.

In proceeding to illustrate these views by a reference to practical examples, I shall, in the first place, adduce cases which show the severe consequences which may be occasioned by chylopoietic disorder when this is of a marked character, or the uterine organs are in a state of undue susceptibility. This latter condition is best exemplified in the instance of parturient females, in whom the uterine organs, from being in functional activity, are unusually susceptible to impressions, and in whom, consequently, the operation of causes calculated to disturb them is best studied and observed. But another purpose will also be served by doing so; for by showing the disastrous consequences which may result under these circumstances from such causes, we may learn to appreciate the injurious tendency of similar causes upon the uterine organs when occurring in a slighter degree, or when these are in a less susceptible state. For, if in the former case it can be shown that sudden or violent irritation or derangement of the stomach and digestive organs can so affect the uterus, when it is thus susceptible, as to give rise to considerable disturbance of this organ, or of the constitution in connexion with it, then it appears to me that it will follow as a necessary corollary from such facts, that slighter forms of continued gastro-intestinal disorder may so affect the uterine organs as to give rise to less violent, but more persistent forms of uterine derangement.

The consequences to be apprehended from violent or sudden gastro-intestinal disorder in the instance of pregnant females, are convulsions, premature labour, the death of the child, and various untoward occurrences during the puerperal period. I shall, in the first place, select two cases to illustrate this influence, and the consequences which may sometimes happen from omitting to recognise and to remedy such antecedent disorder. I shall then add two others, in which similar disasters were to be apprehended, but were averted by adopting prompt measures for the relief of the chylopoietic derangement.

Case. A young lady of considerable fortune, within a month of her confinement, entertained a party of friends in the Christmas of 1845. She had on a former occasion been prematurely brought to bed of a still-born child, and this circumstance, together with the anxiety felt for her by her husband and friends, had induced them to place her under the care of an experienced practitioner, who for a month previously had almost daily visited her, and on the day in question, reported that he considered her health and prospects to be as favourable as could be wished. The dinner consisted of the usual rich fare which is customary at that season of the year, and although she partook of it moderately, it was evident that her stomach had become disordered. On leaving the dinner table, she felt faint, sick, and indisposed, and her medical attendant was sent for; previously, however, to his arrival, frequent efforts at vomiting had taken place, in some of which portions of food had been thrown up. She was somewhat relieved by this, and he, on his arrival, finding her better, and considering the case to be one rather of irritability of the stomach than of positive disorder, and believing that the vomiting which had taken place had sufficiently unloaded the stomach

of obnoxious matters, contented himself by prescribing effervescing salines, with small doses of laudanum. Towards midnight the symptoms were relieved, the opiates had produced a disposition to sleep, and he left with the conviction that no farther bad consequences would ensue. About five the next morning she was attacked with convulsions, and, as I was in the house on a visit, I was called up to see her. As soon as a lancet could be obtained, I took a basin of blood from her arm, and her medical attendant, who had been sent for, arrived shortly afterwards with another practitioner. The bleeding had somewhat relieved the convulsions, and consciousness returned, but only for a short time. In consultation, it was not thought advisable to carry depletion any further, and soothing calmative measures were considered to be indicated. The head was shaved and kept cool; salines were given, containing small doses of opium, and the utmost tranquillity was enjoined; nevertheless the convulsions continued to recur; in the course of the next day, labour-pains were observed: which were assisted as far as it was possible, in the hope that when labour had taken place, the convulsions would cease. But this was delusive; in due time the patient was delivered of a still-born child, but there was no remission of the convulsions. The patient gradually became comatose, and died on the third day. On a *post-mortem* examination, it was found that the sinuses of the brain were congested, and that the brain itself was more vascular than natural. The ventricles contained about two ounces of serum, and a small quantity was effused at the base of the brain. No examination was made of the stomach or alimentary canal.

Whether a different result would have followed a different mode of treatment at the onset of this case; whether, in fact, if the state of the stomach and bowels had been carefully investigated, and they had been thoroughly unloaded of their obnoxious contents by evacuant measures, the patient would have survived, I am unwilling to express an opinion; but there can be no doubt, that the train of events which ended in the death of this lady, originated in a disordered state of the stomach and digestive organs, together with an advanced period of pregnancy. Looking, indeed, to the fact that the nervous system is almost morbidly susceptible to impressions during this state from a variety of circumstances, we cannot be surprised that when additional disturbing causes come into operation, and more particularly gastro-intestinal irritation, that violent consequences should sometimes ensue, and such as were observed in the present case. That a disordered state of the stomach and bowels existed, and immediately gave rise to the attack in this case, is shown by the fact of the patient having been particularly well up to the period of her partaking of a rich indigestible meal, by the occurrence of nausea and vomiting shortly afterwards, and by the convulsions beginning almost immediately after the spontaneous efforts at vomiting had been subdued by opiates. Such cases are extremely but painfully instructive, and should teach us the necessity of examining carefully the state of the stomach and digestive organs whenever nervous disorder is threatened during pregnancy, or the puerperal state.

Case. A lady of extremely nervous temperament, aged 27, and whose general health had been for many years very delicate, had

arrived at the latter part of the eighth month of pregnancy, when she began to suffer rather severely from gastric irritation. She had throughout her pregnancy suffered much from nausea and irritability of the stomach; and at first the additional symptom was not thought to be of much importance; but as it continued persistently, and was the cause of great uneasiness, an eminent obstetric physician was consulted about her case. He saw her on the 15th of April, and took a very favourable view of it, considering that the gastric irritation was rather dependent upon the very nervous temperament of the patient, together with the period of pregnancy to which she had arrived, than anything else, and he advised a trial of sedatives, such as the hydrocyanic acid, the tincture of henbane and hop, in small doses, with the sesquicarbonate of soda. He did not consider that any unfavourable consequences would ensue. The remedies suggested were tried in various forms, without any material benefit resulting. On the other hand, the gastric irritation became more decided, and at times was very intense. Leeches and sinapisms to the epigastrium were now had recourse to, and other combinations of the remedies proposed were tried, together with opiates and purgative enemata, but still without much positive advantage. On the morning of the 18th of April, she complained of headache and symptoms of cerebral irritation, which were speedily followed by violent convulsions. Free depletion was now practised, and after a considerable quantity of blood had been abstracted, the convulsions were subdued; and although the patient continued throughout the day in a most precarious state, she gradually rallied, and towards the close of the following had greatly recovered, and appeared upon the whole to be going on very favourably. On the 20th her condition was still satisfactory; no convulsions had returned for thirty-six hours; the epigastric pain had ceased, and the patient complained only of depression and weakness. Towards evening symptoms of labour were observed, and in a short time she was safely delivered of a still-born child, without any hæmorrhage or any other unfavourable circumstance occurring.

Now here I would pause in the narrative, and would inquire whether these calamitous consequences, viz., convulsions, premature labour, and the death of the child, did not remotely and immediately spring out of gastro-intestinal irritation or disorder? and whether all the antecedent symptoms were not referrible to this cause, which had existed in a marked manner for many days before these occurrences took place? Can it then be doubted, that if this had been properly recognised and removed, that all the untoward events which were afterwards developed would have been averted? But in this case it is evident, that the gastric irritation was regarded too lightly; and the inevitable consequence of continued irritation in an organ so vital as the stomach, and possessed of so many sympathies, when concurring with pregnancy, was soon displayed in sympathetic irritation of the brain, and its usual sequelæ, cerebral congestion and puerperal convulsions. From this history, we may at least learn, that gastro-intestinal irritation cannot remain long in a severe or persistent form in a pregnant female, without being fraught with much danger; that vascular disease will sooner or later supervene upon such irritation, either in the organ primarily affected, or in some other which has sym-

pathetic relations with it—and this more especially in the brain and the uterus. Hence such consequences should, if possible, be anticipated; and if after the removal of applied causes of irritation in the stomach and alimentary canal by emetics and purgatives, and after fomentations, sinapisms, and sedatives, have been fairly tried and proved to be unsuccessful, it becomes imperatively necessary in these cases to abstract blood from the arm as a precautionary measure, proportioning the quantity to the strength of the patient's constitution, and the intensity of the local irritation, for thus only can vascular disease and its consequences be averted. Nor again is delicacy of constitution any objection to this proceeding; for, as a general rule, it is in the weakly, the delicate, and the anæmic, that local irritation most readily passes into congestive or vascular disease.

But to resume the narrative: the patient had been safely delivered, and for several days subsequently went on very well, much better indeed than could have been expected. Her appetite was good, she enjoyed her food, and slept well at night: the tongue was clean, and the bowels regular. Everything thus progressed favourably, until the seventh day after her confinement. She then saw some friends in the morning, with whom she conversed rather freely, and to whom she expressed herself highly pleased with her very favourable progress. At two P.M. she had dinner, which consisted, as on the preceding days, of fish, bread, and vegetables. This she appeared to enjoy very much, and it was afterwards ascertained, she partook of it very largely. Soon afterwards she felt faint and sick, complained of headache and became very nervous and excitable; so much so that the slightest noise occasioned her to start and feel alarmed. After a time she had uneasy sensations in the pelvic region, in the right hip more particularly, and back, and these soon extended down the whole of the right extremity. Unfortunately, the causes of these symptoms were not at first recognised, the state of the stomach and bowels was not carefully investigated, and the proper remedies were consequently withheld. The symptoms were attributed rather to the excitement and fatigue which had been produced by seeing her friends in the morning, and to her having exerted herself disproportiontely to her strength. It was not then sufficiently considered that a large meal, eaten under circumstances of much physical exhaustion consequent upon the loss of a great quantity of blood, could have led to these results; and accordingly, under the impression I have mentioned, soothing calmative measures were adopted. Ice was applied to the head, and the patient was kept very quiet, in the hope that by rest and tranquillity her symptoms would pass away; but at the end of twenty-four hours she was not materially better: on the other hand, the headache and nervous excitability had increased, and the pain in the pelvic and abdominal region continued to be very intense. After the measures mentioned had been employed for some time, together with aperients, a trial of the Indian hemp was determined upon, at the suggestion of a very experienced practitioner. At first it appeared to have a good effect, subduing the pain and nervous excitement; but afterwards it became more and more questionable in its efficacy. The nervous symptoms, on the other hand, increased the restlessness, and sleeplessness became greater; and the whole of

the pelvic and abdominal organs were greatly disturbed. The pulse became quick, the tongue dry and brown, and there was occasionally a disposition to delirium. Additional advice was now sought for, and an eminent obstetric physician visited the case. The opinion he at first expressed was that no danger need be apprehended, and that the symptoms depended mainly upon weakness and nervous irritability consequent upon the previous loss of blood. Opium was especially recommended and given; but as the symptoms continued unrelieved after forty-eight hours, it was feared that the pelvic irritation had led, or would lead shortly, to the formation of a pelvic abscess. For some days the condition of the patient was most critical, and her sufferings were very great, notwithstanding the regular administration of opium. The whole of the chylopoietic and pelvic viscera were greatly disordered; the abdomen was tense, painful, and tumid; and the patient often delirious. After a time, throughout which there was much pain in the right hip, the superficial veins about the groin began to enlarge, and the corresponding extremity to swell, and this was followed by increased pain in the hip and groin of this side. In a short time, the symptoms of phlegmasia dolens became manifest, attended with excruciating suffering and additional constitutional derangement. The treatment throughout was of a soothing and sustaining nature. Opium was administered rather freely—the bowels and secretions generally were regulated—food and stimulants were regularly given—and local pain and suffering were relieved by fomentations and soothing applications. The progress of the case was slow, but upon the whole satisfactory; and after a protracted illness and convalescence, the patient may be said to have perfectly recovered, although still somewhat weak and depressed in health.

I have not attempted, in the foregoing details, to give more than a very general outline of this case, for to do more would be altogether incompatible with the limits of this paper. It has rather been my object to point out the order and sequence of the actions which followed upon gastro-intestinal derangement, and to show how readily even trivial errors of diet, in persons whose constitution or uterine organs are unduly susceptible, may lead to very serious consequences; and at the same time to show how necessary and important it is to discern and rectify such errors promptly and decisively, in order to avert these calamitous effects. Had the patient taken an emetic, and had the stomach been thoroughly disburthened of its load on the accession of the symptoms, which commenced after the dinner taken on the seventh day after labour, I am convinced that all the ulterior consequences which supervened would have been prevented. Of this I am more and more satisfied, the more I reflect upon the history and progress of the case, and consider it in connexion with others of which I have personal knowledge. That all the untoward consequences which followed in this case mainly depended upon, and arose from chylopoietic disorder, is, it appears to me, sufficiently evident; for the patient had been progressing most favourably up to this date, and gastric symptoms in the first place, and intestinal in the second, were the first to declare themselves, whilst all the subsequent phenomena which occurred may be readily and legitimately deduced from such

chylopoietic disorder. Nothing, indeed, appears to me more certain than that if food be eaten incautiously, when the digestive organs are much enfeebled, either by disease or constitutional causes, that digestion will not properly go on, and that the undigested food will become an irritant to the alimentary canal, and as such, a cause of various constitutional disorders, their severity being proportioned to the degree of general weakness or irritability which may prevail.

Let it then be remembered, that whether during pregnancy or the puerperal period, whenever it is possible or likely that applied causes of irritation exist in the stomach or alimentary canal, that evacuant measures should precede and take the place of all others; for nothing can compensate for their omission when such causes exist. The employment of emetics during both these periods, when circumstances require them, is perfectly safe, as I have verified in a number of cases. Indeed, the action of full vomiting during pregnancy is infinitely less trying or dangerous to the patient, than the incessant retchings with which some females are tormented throughout the greater part of pregnancy, and in spite of which they do well. In illustration of this, and in order to place the results of such practice in apposition with those in which these measures have been omitted, I subjoin the particulars of the following cases.

Case. Mrs. R—ll, seven months advanced in pregnancy, was attended by me, October 5th, 1849. She had been suffering throughout the day from headache, flushing of the face, tension of the forehead, noises in the ears, occasional numbness and convulsive catchings in the fingers. These symptoms were attended with, and had been preceded by, nausea and a disposition to sickness, from which she had suffered, more or less, for several days. The stomach was so irritable, that scarcely anything would stay upon it; the bowels were constipated and flatulent, and she had uneasy sensations in the uterus, back, and hips, with occasional forcing pains, which threatened to end in premature labour. These symptoms appeared to have been connected with, and were remotely attributable to, mental anxiety and trouble, consequent upon which, and the co-existence of pregnancy, the stomach and digestive organs had become irritable and disordered. The presence of marked gastro-intestinal derangement under these circumstances, suggested to me the necessity of giving at once an emetic, after which an alterative was ordered, and subsequently she was directed to take a mixture containing Epsom salts, in an acidulated infusion of roses, by teaspoonfuls, until purging should take place. The next day, the patient was in every respect better, and tranquillity had been restored to the digestive organs, and to the constitution generally. The emetic had occasioned profuse vomiting, and a great quantity of sour offensive matter had been thrown up, which was followed by a subsidence of the sickness and gastric irritation. Subsequently the alterative and aperient were taken, and when purging had taken place, she was relieved of all cerebral and uterine uneasiness. She had no further recurrence of either, but continued to progress favourably, and at the full period was safely delivered of a healthy child, without any unfavourable occurrence taking place.

Case. I visited a lady at 3 A. M. on the 28th December 1847, who was four months advanced in pregnancy with her first child, and

who, it was reported, had been suddenly taken ill. She had fainted away, and had entirely lost all consciousness, and this without any very obvious cause. When I saw her, she was in a state of profound coma; her head was hot, the pupils contracted, and her pulse quick. She moaned frequently, and occasionally threw her hands instinctively to her head: she was, however, incapable of speaking, and no information could be obtained as to the history or cause of the attack. A medical gentleman, who had seen her before I arrived, and who was still in attendence, had given a full dose of calomel, had applied cold lotions to the head, and had also administered sal volatile in water, but hitherto without any beneficial effect. The absence of vascularity of the conjunctivæ, the contraction of the pupils, the quickness of the pulse, together with the youth of the patient, her age not exceeding twenty-two, led me to regard the cerebral affection as one of irritation rather than of congestion; and after repeated inquiries, it was elicited from her friends that she had partaken during the day of some rather indigestible food. I had no hesitation, therefore, under these circumstances, in prescribing an emetic, which with some difficulty was administered, but the result was very satisfactory, and profuse vomiting of a large quantity of undigested food soon followed, after which the consciousness of the patient returned. She suffered for some days from the effects of the attack, but upon the whole may be said to have recovered very favourably, and at the full period was safely delivered of a fine healthy child. It should be mentioned, that while she was unconscious, she had occasional convulsive catchings of the fingers; and I afterwards learnt, that before she became unconscious, she had very uneasy feelings in the uterine region—circumstances which appear to point on the one hand to a threatening of convulsions, and on the other to miscarriage, which were both averted by the administration of the emetic.

I have placed these four cases in juxta-position, for the double purpose of pointing out the serious consequences which may ensue from gastro-intestinal disorder when the uterine organs are in a susceptible condition, and of exemplifying the safety and advantage of the particular treatment which I have recommended. In the two former cases, the consequences of omitting this were painfully evident, whilst in the two latter the advantages derived from it would appear less obvious if the contrast were less striking. My object, however, is not so much to pursue this subject as to make it subservient to another purpose, viz., that of directing professional attention to the influence of slighter and less obvious forms of chylopoietic derangement in the causation of uterine disorders. For if it is admitted that violent irritation of the digestive organs, such as was met with in these cases, can be reflected upon the uterine organs so as to give rise to the consequences which followed in the first and second and were threatened in the third and fourth, viz., premature labour or miscarriage, the death of the child and puerperal convulsions, then it appears to me reasonable to conclude from such facts, that slighter forms of irritative disorder of the stomach and digestive organs may also affect the uterine organs when in a less susceptible state, and so give rise to uterine derangement of a more subdued, but, at the same time, more persistent character.

The disorders in question present themselves in almost endless variety, from a degree of irritation which is so slight as to be scarcely perceptible to the patient or practitioner, to one which is so severe as to disturb the whole constitution. Between these opposite extremes there is every possible gradation, and each, in its particular degree, may occasion secondary disease of corresponding severity. In the uterine organs, we observe consequences which are commensurate with their intensity; and whilst these are sometimes so slight as to amount to little more than mere irritability of the uterus, leucorrhœa, and irregularity of the menstrual functions, in other cases we observe distressing forms of hysteralgia, profuse leucorrhœa, and excessive, irregular, painful, or defective menstruation, occurring as a consequence of similar causes, when of a more decided character.

But in the instance of the slighter of these forms of chylopoietic disorder, it too frequently happens that their existence, or relations to the uterine malady, are altogether overlooked; and the latter continues thus silently, but steadily, to progress, until vascular disease may have supervened, and rendered it painfully manifest. On the other hand, when the chylopoietic derangement is of a marked and prominent character, and cannot be overlooked, it equally happens that it is often considered to be a mere accidental or tributary complement to the uterine affection. By one it is regarded as a consequence, by another as an accidental complication, whilst by a third it may be altogether disregarded; and hence it follows, that its importance and its relations to the uterine affection are often lost sight of, or at least imperfectly appreciated. If I were, however, to state the impression which many inquiries on this subject have left upon my mind, I should say that, in at least fifteen out of every twenty cases in which uterine and chylopoietic disorders coexist, the latter is not only the antecedent, but the cause of the former, whilst in the remainder only, or in a like proportion, can it be regarded as a sequence, or an effect. I am perfectly aware of the difficulty which attends any investigation having for its object the determination of the relations of power, cause, and effect, in regard to any given phenomena. But I take it, that that which is invariably, or nearly so, the antecedent to any particular event, has strong claims to be regarded as its cause; that this claim is increased, if no other circumstance can be shown to stand in such relationship to the event; and that it is still further demonstrated that this antecedent is the cause, when the event by which it has been followed ceases for the most part with its removal. Upon these grounds then more particularly, am I led to uphold the correctness of the opinion which I have expressed, in regard to the relations which subsist between uterine and chylopoietic disorders when both coexist; for I believe careful and properly directed inquiries will tend to show that, in such cases, the latter has nearly in all cases preceded the former, and has often accompanied it throughout: whilst in the great majority it will be found, that the correction of this disorder will be followed by the cessation of the uterine, unless, indeed, vascular or organic disease shall have supervened in the latter, and so rendered it independent of the former.

In support of the correctness of this opinion, I would refer to the

table published in the earlier part of this paper,[1] from which it will appear that chylopoietic preceded uterine disorder in 82 cases out of the 100, and that no other circumstance can be found which has such relations to it. And it will hereafter be shown, that the results of treatment confirm the general inferences which are deducible from these facts: for it will appear, that the removal of the chylopoietic disorder is generally followed either by the cessation of the uterine, or by a marked improvement taking place in regard to it.

We have, however, various forms and degrees of chylopoietic disorders to consider in connexion with uterine diseases; some being so slight and insidious as scarcely to be recognised without very careful investigation, whilst others are of a very marked and serious character. And, before proceeding to adduce the cases upon which the views advocated in this paper are more particularly founded, it may be well to describe the more general symptoms by which these disorders are attended; to state the pathological conditions on which they may be supposed to depend, and the principles upon which their treatment should be conducted. This is the more necessary, because, if the truth and accuracy of the opinions contained in this paper are to be tested, as they should be, by the results of similar treatment in other cases, it is manifestly important that the symptoms of such disorders should be readily recognised on the one hand, and adequately treated on the other.

Symptoms. The more common forms of chylopoietic disorder which occur in connexion with uterine diseases, and which are perhaps the most frequently overlooked, are characterised by the following symptoms: by certain deviations from the healthy state of the tongue, more especially on awaking in the morning; by a degree of fretfulness of temper or despondency of mind, which is unusual to the patient, and unwarranted by her circumstances; by some uneasy sensation, either constant or occasional, about the epigastrium; by some degree of irregularity in regard to the action of the bowels; by some unnatural appearances in the urine or stools; by variability of the appetite, which may be either excessive, defective, or depraved; by restlessness at night, and broken and unrefreshing sleep, whence patients arise in the morning with a feeling of weariness or fatigue. There is, also, often a disposition to blotches and eruptions on the skin; the feet and hands are often cold and clammy, and perspiration is readily induced by exercise.

Now, in regard to these symptoms generally, it should be observed that, unless they are carefully and diligently inquired for, the practitioner will often be led into error by the representations of the patient. In some, indeed, disorder of the digestive organs may have existed so long, as to have become habitual; and even when this is very considerable, it may be, and often is, set down by the patient as being natural or constitutional, and such as cannot have the least connexion with any coexisting local complaint. Again, when the gastro-intestinal disorder is less marked, the practitioner may be readily misled by the appearance of the tongue during the day, and the general statement of the patient, who may declare herself to be perfectly well, when she

[1] London Journal of Medicine, November 1851, p. 985.

may be found on inquiry to have all the symptoms which denote chylopoietic disorder. Hence it becomes necessary to direct the patient's attention to those particular symptoms in detail, which, in the aggregate, indicate the presence of such disorder; and it will thus often be found, that the tongue is habitually dry, furred, or unpleasant, on awaking in the morning; that the appetite is uncertain and capricious, and the bowels irregular; that the patient is languid and listless, anxious and despondent; that the pulse is frequent and feeble, the heart's action readily disturbed; and that other symptoms exist, equally characteristic of an irritable or disordered condition of the stomach and digestive organs, although the patient may have represented herself as being in good health.

Of the several indications, perhaps the appearances of the tongue furnish the least fallacious and most ready test of the presence of gastro-intestinal derangement. Its condition, however, under different circumstances, requires to be carefully investigated, for it will often be found to be furred at the back part, when it is tolerably clean at the front and edges; its appearance, again, will vary at different periods of the day, according to the different states of the stomach, and various states of mind which may arise. Hence any casual examination of the organ may, and often does, lead to erroneous conclusions; and it becomes indispensably necessary to ascertain its general condition when the patient first awakes in the morning, when it will often be found to be dry, furred, or unpleasant, and this even persistently, although during the day it is tolerably clean. Such abnormal deviations, however, demand to be carefully attended to, for they are certain and conclusive indications of the presence of gastric irritation or disorder. If, for instance, the tongue is simply dry, and this habitually on awaking in the morning, we have evidence that there is at least a deficiency of the secretions of this organ; and if there is no local cause for this deficiency, or constitutional febrile disturbance coexisting, we may reasonably infer that there is a corresponding deficiency of the gastric and hepatic secretions, the consequence of gastric or hepatic irritation, of which this is probably but a sympathetic effect. When, again, the tongue is habitually furred or unpleasant, as well as dry, we may equally deduce from these circumstances, that the gastric and hepatic secretions are not only deficient, but at the same time unhealthy. And such scanty, irregular, or unhealthy conditions in regard to the secretions of the stomach and liver, may again be legitimately attributed to an irritable or disordered state of the nervous ganglia of the sympathetic, which are more directly in relation with these organs, and which more immediately influence or regulate their secretions.

Pathology and Treatment. Thus we may, I think, correctly deduce, from a consideration of these circumstances, that the symptoms in question are more or less significant of a state of nervous irritability and weakness of the ganglionic nervous centres, whence the stomach, liver, and digestive organs are immediately supplied with nervous energy; that one of the primary consequences of this weakness and irritability, is a deficiency or depravity of the secretions which are ordinarily furnished by these organs, and upon which the healthy and proper performance of their functions mainly depends; whilst another consequence is, the production of various forms of disorder in regard

to these organs, as shown, perhaps, by pain, uneasiness, or some other kind of functional disturbance. Hence the indications of treatment, in such cases, should be to impart tone and vigour to the nervous system on the one hand, and to appease irritability and correct disorder on the other; whilst, at the same time, we adopt such measures as are calculated to improve and promote the secretions of the irritable organs.

But, in the first place, it is necessary that we should investigate the particular circumstances in which such weakness, irritability, and disorder may have originated; for these will often be found to have arisen from, or to be associated with, various constitutional causes, habits, customs, and modes of life, which will be but little amenable to medicinal treatment: and these must therefore be looked for and removed, before we attempt any specific treatment for the morbid conditions themselves. This, again, should be of a comprehensive character, having reference not only to the local affection, but also to the constitutional causes or disorders from which it may have sprung, and should comprise not merely medicinal measures, but these combined with proper care and attention to diet and regimen.

But, having premised such attention to the remote causes from which these disorders may have originated, and having removed these so far as they admit of being removed; having urged the necessity of relinquishing various habits, pursuits, and customs, which may have been prejudicial to health; having enjoined due attention to matters connected with regimen, the necessity of taking regular exercise, of keeping early hours, and having adequate rest and sleep; having also inculcated the necessity of proper dietetic measures, of adapting the quality and quantity of the food to the wants of the system and the powers of the digestive organs, and of observing regularity in regard to the periods of taking it,—it becomes a question to consider what therapeutic measures are indicated in these particular cases: and these can only be determined by considering what are the precise pathological states upon which these disorders depend. I have already expressed an opinion, that, in these cases, there is weakness and irritability of the ganglionic portion of the nervous system, leading to various functional disorders of the organs, and more especially to a deficiency or depravity of the secretions which they are destined to furnish, and upon which the proper performance of their functions depends. Hence it appears to me, that the indications of treatment should have reference more particularly to these circumstances, to weakness and irritability, on the one hand, and disordered action on the other; and the measures which are required for the cure of such pathological conditions, are more especially alteratives, tonics, and sedatives, which should be variously combined and exhibited according as these morbid states may more or less respectively coexist in different cases. On each of these remedies I will therefore proceed to make a few remarks, so far as they relate to my present subject.

1. Alteratives. The employment of alteratives, so long as disorder continues, and more especially when this is denoted by a faulty or defective state of the secretions, appears to me to be of the first importance in the medical treatment of these cases; for, so long as this continues, so long it is hopeless to anticipate benefit from

tonics, or strength or vigour of constitution from food; for, inasmuch as digestion in a great measure depends upon the purity and sufficiency of the secretions, which are poured out by the digestive organs during the digestive process, it must follow that, when these are defective or depraved, it will be proportionately disturbed, and that the food, instead of being converted into healthy blood, will pass into various crude, hurtful, or unassimilable matters, which, instead of nourishing the body, will be a source of irritation to the nervous system, and of injury to the constitution. But, in the use of alteratives, the utmost caution is required; and the greater the weakness which may coexist with disorder, the more sparingly should they be given. Mercurials, judiciously administered, appear to subserve this purpose better and more certainly, perhaps, than any other medicines; but there are many cases in which their utility is questionable, and others in which their employment would be fraught with positive harm. The circumstances, then, which tend respectively to these results, require to be carefully noted and considered.

The action of mercury on the constitution as a remedial agent, has been a fruitful source of controversy in the profession, and cannot even yet be said to have been satisfactorily determined. It has been variously considered as a stimulant or sedative, both stimulant and sedative, an alterative and tonic; but its action and effects differ essentially from any of these, and must be regarded as *sui generis*. That its action, however, is primarily upon the nervous system, and more especially upon the organic or sympathetic portion of it, is, it appears to me, the most legitimate inference which can be drawn from a consideration of the various circumstances which attend and follow its administration. This action, at the same time, is of a peculiar and specific character; calculated, on the one hand, to produce irritative disorder where none exists, but to correct, neutralise, or antagonise such irritation when already existing. Thus, for instance, when mercury is administered, even in the mildest form and the most moderate dose, to persons whose digestive organs are in a perfectly healthy and tranquil state, and who have not been accustomed to its stimulus, it seldom fails to produce considerable disturbance in them, such as would arise ordinarily from a variety of causes, of which again, when so produced, it is eminently curative. The following case, which occurs to me, illustrates this remark. A rather delicate little boy was attacked with a feverish cold, attended with a furred tongue, and much disorder of the biliary and digestive organs: he had a good deal of fever, was restless, constipated, and had entire loss of appetite. On account of the evident disorder of the liver and digestive organs, three grains of calomel were at once given him, and with the most decided benefit. Before any purgative action had taken place, the tongue had become clean, the fever had subsided, and the child slept comfortably for the first time for several nights. The benefit attending the administration of the medicine on this occasion, led to its being subsequently given under other circumstances, and here with a very different result. The child was not now suffering from any manifest disorder of the stomach and digestive organs, the tongue was clean, and the appetite was tolerably good; but his bowels were somewhat torpid, and there was a degree of weakness and delicacy of health which was attributed in part to a torpid or irregular action of

the liver. Upon this view of the case, the same dose of calomel was given, which had been so salutary on the former occasion; but the effects were now of a very different nature, and violent irritative disorder of the stomach, liver, and alimentary canal were the consequences. The little patient became sick, purged, and extremely uncomfortable, the tongue furred, and much general prostration ensued. Now here it is impossible to suppose otherwise, than that these different effects were mainly dependent upon the absence or presence of irritative disorder previously to the administration of the medicine; for, where such irritative disorder exists, the specific irritation set up by mercury tends, as it were, to neutralise or antagonise it, and thus to restore a state of nervous equilibrium or tranquillity. Whereas, in the absence of such antecedent irritation or disorder, the action of mercury is productive of many disagreeable and often injurious consequences.

This principle of action is also shown in a variety of instances: thus, when there is restlessness or sleeplessness at night, as a consequence of digestive disorder—an effect which is of frequent occurrence—the administration of a few grains of blue-pill will often procure sound and refreshing sleep, such, indeed, as to impress the patient with the idea that some form of opium had been taken. But this effect appears to me to be only from the specific action of the mercurial having been antagonistic or curative of the irritation previously existing; for, if the same dose of the same mercurial preparation be given to the same patient, in the absence of such irritative disorder, it seldom fails to produce the most opposite consequences—to produce restlessness and sleeplessness, a dry, furred, or unpleasant tongue, and an uneasy condition of the stomach and digestive organs, together with disorder of the biliary and other secretions. Hence, it appears to me, we may deduce, from careful attention to these circumstances, some rules which should guide us in its administration in the treatment of those disorders of the stomach and digestive organs, which are under consideration.

And, first, we may learn that mercurial medicines should never be given in these cases, unless there is positive evidence of the existence of disorder, as shown more particularly by an irregular, faulty, or morbid condition in regard to the secretions; for it must be borne in mind, that many morbid states of the chylopoietic organs, which are unquestionably conducive to uterine disease, depend rather upon weakness and irritability than upon actual disorder. If, then, the tongue is clean and moist, especially on awaking in the morning, and the alvine discharges do not indicate a deficiency of biliary or intestinal secretions, the use of mercury will be found to be very questionable, if not fraught with positive injury.

Secondly, we may learn that, in the administration of mercury, the form of this medicine, and the dose, and the frequency of its exhibition, should be mainly regulated by the degree of irritative disorder which may exist. In proportion as this is slight, should the dose of the mercurial be small; whilst, in the severer kinds of disorder, it may be given freely, and with the utmost benefit. In the more trivial forms of these disorders, I believe that an occasional dose of grey powder or blue pill at bed-time will be sufficient; but this should be

continued until the disordered state of the secretions shall have been rectified; whilst, in the more decided forms of these disorders, it will be necessary to administer the medicine in larger doses and at short intervals. And so long as the condition of the digestive organs is carefully watched, and disorder is found to continue, so long may it be given with perfect safety and advantage.

Again; in those cases in which there is great disturbance of the stomach, liver, and intestinal canal, as indicated by incessant nausea and retching, by very manifest derangement of the secretory functions of the liver and stomach, and by much irritative disorder of the small and large intestines, together with febrile disturbance, the administration of calomel is far preferable to that of any milder preparation of mercury. It often, by its specific action upon the nervous system, or rather upon its ganglionic portion, produces such antagonism to the existing irritation or disorder, as to restore tranquillity speedily both to the digestive organs and the constitution, and thus to justify the remark which has sometimes been made, that calomel in large doses is a powerful sedative.

I infer then, from a consideration of these circumstances, that mercurial medicines are only useful in the treatment of dyspeptic affections, when there is clear and unmistakeable evidence of the existence of disorder, and this not dependent upon merely applied causes within the alimentary canal which admit of removal, or on mental or other causes which are of a transient character; that the particular form of the medicine to be employed must be chiefly dependent upon the *degree* in which this disorder exists; that it may be continuously administered for longer or shorter periods, in doses proportionate to the severity of the disorder and its persistency or continuance; that in the slighter forms the mildest preparations, such as grey powder or blue-pill, are the best; whilst, in the severer and more acute forms of these disorders, calomel is preferable, often possessing a specific power of arresting or controlling such violent actions, and thus appearing to have the properties of a powerful sedative in such cases.

But, as I have remarked, it must be ascertained, in the first place, that such gastro-intestinal disorder does not depend upon the presence of applied causes of irritation, in any part of the alimentary canal; for the employment of mercurials in such cases is not only often unnecessary, but is sometimes prejudicial. To remove such causes, therefore, or, in other words, to ensure the regular evacuation of the fæcal contents of the bowels, becomes an important indication in the management of these cases; and this should be fulfilled by the most simple and lenient medicines. In all cases in which the constitution is weakly, the blood impoverished, or the digestive organs irritable, active purging is for the most part injurious, and is often attended by a marked aggravation of the uterine disorder. It often happens, too, that the bowels may be purged without being cleared of the fæcal matter which may be detained in them, and thus much harm may be done by the employment of purgatives, without this being compensated by the least possible good. The precise medicine, or combination of medicines, which will best effect the object in view, cannot always be determined in different persons, and therefore it is often better to leave it to the patient,

whose experience may enable her to decide best as to the particular form of aperient that should be employed. In one, a little castor-oil, taken at bed-time, will ensure the desired result; and in another, the milk of sulphur; whilst in some an aloetic or rhubarb pill, taken before or after dinner, will be found to be the most serviceable. Active purging, however, must in all these cases be avoided; and we may safely interdict the habitual use of such medicines as jalap, calomel, salts, senna, black draughts, etc.

II. TONICS. In the next place, it is necessary to adopt measures which are calculated to diminish weakness, on the one hand, and allay morbid irritability on the other; for many of these affections of the digestive organs may be said to be constituted almost entirely of these pathological elements, the amount of disorder being sometimes comparatively trivial, and such as would spontaneously cease, if weakness and irritability were removed. These conditions, then, require to be carefully attended to and corrected; and we have fortunately remedies at our command which subserve both these purposes. The first indication we can fulfil by the administration of various tonics; the latter, by medicines which have a sedative or tranquillising action upon the nerves, or upon the ganglia, whence the nerves of the disordered viscera are derived.

The administration of tonics in these cases is, for the most part, imperatively demanded; not only because the digestive organs themselves are weak and irritable, but because the tone of the nervous system generally is impaired, and because these conditions, for the most part, either originate from, or are kept up by, an impoverished state of the blood. From this cause, the constitution at large is depressed and enfeebled, the nervous system is morbidly irritable, and the digestive organs, participating in this general weakness and irritability, become either spontaneously or readily disordered by the operation of trivial disturbing causes. In the table, published in the former part of this paper, the proportion of cases in which anæmia coexisted with chylopoietic disorders is very considerable, amounting to 87 out of the entire 100; and if the statements and representations of patients could be implicitly trusted to, and correctly interpreted, it would appear that anæmia is a frequent antecedent, as well as concomitant of such disorders. Whether, then, we look to the pathological condition of the digestive organs in these cases, to the state of the nervous system with which they are associated, or to the character of the blood, we see in each and all of these circumstances, individually as well as collectively, a necessity for these measures, or such as are calculated to impart strength and vigour to the constitution, and improve the quality of the blood.

But the exhibition of tonics, just as the exhibition of alteratives and of aperients, requires much circumspection. They are, for the most part, inadmissible, when there is much coexisting disorder; they should be given guardedly when this exists in a moderate degree only; while they are most beneficially given where weakness and irritability are the sole pathological conditions which prevail. Again, the form of tonic to be given requires some consideration, as well as its dose, the periods at which it should be taken, and the nature of the concomitant uterine affection. In simple irritability and weakness of the

digestive organs, with which the uterine organs may have participated, and which would be characterised by slight uterine uneasiness, moderate leucorrhœa, and irregular or scanty menstruation, the use of iron is decidedly indicated, and it may be given largely. Probably of all forms, the citrate is the most eligible and efficient, and it should be given in doses averaging from ten to twenty grains, after each principal meal, daily. Where anæmia exists in a marked manner, as is often the case, the latter dose is by no means too large, and, taken as directed, it will sit easily upon the stomach, and occasion no unpleasant effects, whereas one-fourth the quantity, taken before meals, will often produce feverish excitement and headache. Concurrently with this medicine, it is necessary to give an occasional alterative at bed-time, when the tongue has been dry or furred on awaking in the morning; and the bowels should be regulated by some gentle aperient. Besides the direct action of iron upon the blood, which it tends rapidly to improve, it would appear, when so given, to have a specific action upon the nervous system, and more particularly upon the ganglionic portion; hence it will often happen, that the digestive organs will have acquired increased tone and vigour, and that the appetite and digestion will have improved, before the blood has become proportionately altered; and hence, also, an improvement will be observed in the condition of the uterine organs, before any correspondent change can have occurred in the blood.

Irritability and weakness, however, which chiefly indicate, and are benefited by the employment of tonics, seldom continue long without being associated with disorder; and this, if unattended to, will compromise the advantages which would otherwise result from their employment. Weakness and disorder are, in fact, distinct pathological conditions, and often opposed to one another; so much so, that what is curative of the one, will often aggravate or increase the other. In these cases, then, it is necessary to adopt a medium course; and when both weakness and disorder coexist, and require to be concurrently rectified, it is best to combine alteratives and tonics, adapting their relative proportion to the particular requirements of each case, according as either weakness or disorder may preponderate. When disorder greatly preponderates, it will often be the best practice to premise alteratives, aperients, and a restricted regimen and diet, before venturing on the exhibition of tonics. When, again, this is less severe, the two modes of treatment may be combined, alteratives being given at bed-time, while tonics are administered during the day; or, what will often be found to be more useful will be to give the milder tonics, such as the mineral acids, with small doses of the liquor hydrargyri bichloridi, until circumstances will permit the employment of the more powerful. Alteratives and tonics may, indeed, be combined in nearly all these cases with advantage; for weakness and irritability cannot long continue without being followed by disorder; and disorder, for the most part, arises from some antecedent weakness, either of the part or the constitution. Many cases appear to me to have been but little benefited by treatment, because the coexistence of these opposite pathological conditions had either been lost sight of, or not properly attended to or acted upon, in practice.

But the employment of tonics in these cases must be also regulated, in some measure, by the nature of the concomitant uterine affection; for it may happen that this may be such as to forbid their use altogether. In the case, for instance, of active congestion, in that of increased vascular action, and in that of hæmorrhage or menorrhagia, it may be that the use of tonics will be fraught with much danger, notwithstanding the existence of anæmia, by their tendency to perpetuate or increase such vascular actions. Again, there are other instances in which one form of tonic will be useful, while another may be detrimental. Thus in passive forms of congestion of the uterus, in similar forms of leucorrhœa, and in relaxed states of the uterine organs, the most useful tonics are those which are of an astringent character. In such cases, I have found the muriated tincture of iron of extreme efficacy; and it may be rendered less stimulating and more astringent by giving it in combination with the dilute muriatic acid; whilst neither of these medicines, separately or combined, is incompatible, chemically, with the liquor hydrargyri bichloridi. In such a combination, then, we have an efficient tonic and astringent suited to many forms of uterine disease, and calculated to give tone to the capillary system, when congestion or hæmorrhage depends upon local or constitutional weakness; whilst the addition of the liquor hydrargyri bichloridi renders it a mild alterative, suited also to those slighter forms of irritability and disorder of the digestive organs, which so often initiate and maintain similar pathological conditions of the uterine organs.

But lastly, there are cases in which extreme disorder of the digestive organs may coexist with extreme weakness, and in which the one morbid element cannot be treated altogether irrespectively of the other. On the one hand, the amount of disorder renders the use of the more powerful tonics, such as steel, quinine, and the vegetable bitters, altogether inadmissible, whilst the great weakness which coexists, renders the use of alteratives and aperients in some degree hazardous. Take, for instance, the case of a delicate, anæmic girl, whose menstruation has been checked by cold or fright. In such it will almost invariably happen, that the digestive organs will, in the first place, be very greatly disturbed, and that much constitutional derangement will follow upon this, and that it will also maintain a state of general irritation, which will be incompatible with a return of healthy uterine action. Here, if we have recourse to active treatment, such as the free use of mercury and purgatives, for the cure of the disorder, we shall do much harm to the constitution, by increasing the general weakness and irritability. Tonics, on the other hand, are equally inadmissible, from the coexisting disorder, the bad state of the tongue, and the presence of febrile symptoms. In such cases, however, we may do much good by adapting our remedies to the peculiar requirements of such cases. Thus in the mineral acids (and I refer more especially to the nitro-muriatic and the sulphuric), we have sometimes useful and appropriate remedies. With the former, the liquor hydrargyri bichloridi may be beneficially combined; with the latter, the sulphate of magnesia; and, in such combinations, we have a mild alterative and tonic, which is especially suited to those forms of disorder which are under consideration. In farther recommendation of these medicines, it may be added, that the former, given in lemon water, with syrup of

ginger, is almost as palatable as lemonade, and the latter, in the compound infusion of roses, is rather a grateful and agreeable medicine than otherwise.

III. SEDATIVES. The above measures comprehend, then, as it appears to me, those which are especially necessary for the fulfilment of two out of the three indications, which require attention in these cases. I observed that they were constituted, in a great measure, of three pathological elements, viz., weakness, irritability, and disorder. I have referred to the measures which are generally necessary for the purpose of diminishing the former, and correcting the latter; but it yet remains to consider what additional means can be had recourse to for the purpose of allaying morbid irritability; for, in many cases, this will continue in spite of alteratives and aperients on the one hand, or of tonics on the other, and will thus require to be specifically treated —if, indeed, we are possessed of any specific remedies for it. In some cases of the kind to which I refer, there may be acute pain at the epigastrium, or in various parts of the abdomen, constituting, in the first case, gastrodynia, and in the latter, enterodynia. But morbid irritability of the digestive organs may be manifested in other ways than by absolute pain: there may be simply disquietude or discomfort; a sensation of extreme weakness, or sinking at the epigastrium; the sensation of crawling within the intestines, together with many other sensations of an equally unusual character; or there may be an irregular performance of the alimentary functions, and a great disposition to flatulency, or eructations. These symptoms appear to be directly referrible to some peculiar form of gastro-intestinal irritation, not always dependent upon either applied causes of irritation, mere weakness, or positive disorder, and they are, therefore, not readily amenable to measures which would be curative of these. Fortunately, we have a class of remedies which meet the requirements of these cases; and which, in the absence of direct causes of irritation, extreme weakness, or positive disorder, are eminently efficacious. I speak of such remedies as bismuth, hydrocyanic acid, the oxides of various metals, and more particularly those of silver and zinc.

But of all these, there is none which appears to me to be so generally efficacious, and so curative of these forms of disorder, as bismuth. I have found it to allay nervous irritability of the stomach and digestive organs generally, more certainly and expeditiously than any other medicine; and, singular to relate, there is none which exercises such a sedative influence upon irritable conditions of the uterine organs, when these are met with as a consequence of gastro-intestinal disorder—a fact which alone tends to show, that uterine irritability and disorder is often but a reflected consequence of such gastro-intestinal derangement. In uterine hæmorrhages in particular, I have found it strikingly efficacious, and often curative of them, when styptics of various kinds had been tried, and had failed. This therapeutical fact is in accordance with another, which has been observed by Sir J. Eyre, who has found that the oxide of silver has also a powerful influence in restraining uterine hæmorrhages of various kinds—a power which it can only possess in virtue of its sedative action upon the gastro-intestinal mucous membrane, or more properly, perhaps, upon the nervous ganglia, whence this membrane derives its nerves. I cannot

doubt its efficacy in such cases, looking alone to the utility of bismuth in them; while it must be quite obvious that the action or *modus operandi* of both medicines, in the cure of these affections, must be of an analogous character. The efficacy of bismuth, again, is not confined simply to irritable or neuralgic conditions of the stomach. It is equally curative of irritable affections of the intestinal canal, such as pain, cramp, spasm, flatus, colic, or diarrhœa, when these are not dependent upon applied causes of irritation, or mere weakness or disorder, but depend upon morbid irritability of the mucous membrane, which, although not always, is, sometimes, a consequence of these causes, and as such, may continue long after they may have passed away.

The oxides of the metals are also serviceable in these cases, but more especially those of silver and zinc.

Hydrocyanic acid has enjoyed a considerable reputation in painful and irritable states of the stomach; but, as my experience of it has been more extended, I have become more and more sceptical as to its actual value. I was at one time impressed strongly with a sense of its utility, from the testimony born to its efficacy by numerous authors; but I have been so frequently disappointed in its effects, that I seldom trust to it alone, or administer it except in combination with medicines calculated to serve the same purposes. It is, however, a favourite remedy with many practitioners of deserved reputation, and therefore should not be hastily condemned: possibly its uncertainty may depend upon the manner in which it is prepared by different chemists, and its ready tendency to decompose, rather than upon any positive deficiency of curative power which it may possess.

I have thus noticed the chief indications which appear to me to require attention in the treatment of the disorders of the digestive organs which are under consideration, and the particular means by which these indications should be fulfilled. I have pointed out the coexistence of at least three pathological elements in these cases, namely, weakness, irritability, and disorder. I have, moreover, endeavoured to show that each of these conditions requires to be concurrently attended to and corrected; and I have expressed the opinion, that in proportion as these requirements are more or less perfectly accomplished, will our success in the treatment of co-existing or consequent disorders of the uterus be more or less perfect. But, it must be added, that the exclusive treatment of disorders of the digestive organs will not alone be curative of such diseases; because they often originate from, and are kept up by others, which, concurrently with those of the digestive organs, maintain a state of general irritability of the system which is incompatible with the return of healthy uterine action; and, if these causes in the aggregate are not adequately attended to and removed, their effects cannot be expected to cease. If anæmia, for instance, coexists with functional disorders of the digestive organs, its removal is as necessary for the cure of the uterine malady, as that of the former. The same remark applies to the coexistence of spinal irritation, which may, and often does, complicate these cases. To show that the disorders in question do really occur in the manner represented, that is to say, for

the most, in an associated form, I subjoin the following analysis of the cases previously tabulated, which gives the following result. Of the 100 cases of uterine disorders of various kinds, 97 co-existed with evident derangement of the digestive organs. Of these 97, in one this co-existed with spinal irritation alone,—in 64 with anæmia; in 22 with anæmia and spinal irritation; and in ten only did it occur without either spinal irritation or anæmia. Such facts point to the necessity of taking a comprehensive view of the causes of uterine disorders, and indicate one source of the difficulty and uncertainty which often attends their treatment.

But, before quitting this part of the subject, there is one pathological state of the alimentary canal which it is necessary briefly to advert to, because, either as a cause or a complication, it occasions or simulates uterine or ovarian disease. I refer to morbid conditions of the colon, whether dependent upon an accumulation of fæcal matter in it, flatus, or other causes. In these, the symptoms which are met with so closely resemble those of disease of the uterus or ovaria, that it is not always easy to discriminate between them; and it was only after having repeatedly seen the apparent symptoms of ovarian or uterine disease disappear by thoroughly unloading the colon, that I became convinced of the importance of this affection in connexion with uterine diseases. The particular condition of the colon to which I refer, has been treated of under the designation of "torpor of the colon". It sometimes depends upon a more general disorder of the digestive organs at large, sometimes upon a deficiency of bile, or, again, upon general constitutional weakness, induced by sedentary habits, night-watching, anxiety of mind, and more especially anæmia. The consequences of these causes frequently is, that the tone and muscular power of the intestine become diminished and insufficient, by its peristaltic action, to overcome the resistance of the sphincter; and hence the evacuations are scanty, and never such as to thoroughly empty the bowel of its contents, although in some cases there may be diarrhœa. This state of the colon is denoted by uneasiness in the iliac regions, by much pelvic pain, which is more especially felt in one or both of the ovarian regions; there is also tenderness on pressure, and a feeling of fulness and resistance from the tension, or accumulation of fæcal matter or flatus in the colon, which will often give the idea of ovarian enlargement: there is, moreover, a weight and dragging in the back, a bearing-down sensation often felt in the uterus, and other symptoms, which clearly point to an irritable condition of this organ as the consequence of this affection. By the use, however, of appropriate aperients and tonics, tepid bathing, and a suitable diet and regimen, the evil may generally be overcome, and tranquillity will be restored to the uterine organs, notwithstanding that the condition of the colon may have existed for many months, and throughout have been the cause of much uterine uneasiness.

I shall next proceed to adduce those practical proofs of the correctness of the preceding views, without which what I have advanced might be very properly received with doubt and hesitation. I have hitherto, in treating of chylopoietic disorders as the cause of uterine affections, confined myself to an examination of those theoretical

considerations which support the views which I have expressed; and I have endeavoured to show that these are not only reconcileable with, but perfectly in harmony with, the facts and principles which have been observed and taught by Hunter, and some of the greatest masters of our art. I have also showed that many circumstances tend clearly to prove that these chylopoietic disorders not only accompany, but, for the most part precede, uterine derangements, and therefore that such antecedence was presumably not merely accidental, but that the former disorder was, in some degree, the cause of the latter. I now propose to strengthen this view, by relating the histories of various uterine diseases which have been treated in accordance with these views; and they will, I think, conclusively establish the fact, that many and dissimilar affections of the uterine organs, some apparently structural, will entirely disappear under the influence of constitutional measures alone, or with very little specific treatment: whilst others, in which extensive organic disease existed, may be rendered so far quiescent as not to disturb the health or comfort of the patient. I had at first intended to attempt some order in the arrangement of these cases; but as I proceeded with the task, I found this more and more difficult, and have finally relinquished it altogether. The fact is, we do not observe those conventional forms of disease in nature which are described in our systems of nosology; irritative disease, for instance, of the uterus, will in one case be manifested by pain, inquietude, and various uncomfortable sensations of the organ. In another, it will be chiefly manifested by leucorrhœal discharges, with little comparative uneasiness; whilst in a third case, irritation will be chiefly manifested by menstrual disorders. I have therefore relinquished the idea of arranging these cases according to their nosological characters.

But believing that irritative disorder is, for the most part, the cause of those particular actions, feelings, or sensations, by which disease of an organ is, for the most part, rendered manifest; and believing also, that even in those instances in which organic or structural changes have taken place, that an organ may yet perform its functions tolerably well, if such irritative disorder be corrected, I have made this consideration the basis of a distribution of these cases; and I have classified them in groups, according to the particular symptoms by which such irritative disorder was manifested. In the first group, I have placed those in which uterine disorder was chiefly indicated by leucorrhœal discharges; in the second, those in which it was principally shown by menstrual disorders; and, in the third, I have placed those in which irritative disorder co-existed with organic or structural disease of the uterus. I shall proceed to narrate cases in this order; and shall commence with those in which leucorrhœa more particularly preponderated over the other uterine symptoms.

(To be continued.)

Chester Place, Hyde Park Gardens, October 1851.

ON THE ARREST OF TYPHUS FEVER BY QUININE.

By ROBERT DUNDAS, M.D., Physician to the Northern Hospital, Liverpool; formerly Surgeon to H.M. 60th Regiment; and late Medical Superintendent of the British Hospital, Bahia.

In the *Medical Times*, I recently endeavoured to impress my professional brethren with the evidence in favour of the efficacy of large and repeated doses of quinine, in arresting the course of typhus fever. My observations have called forth several valuable communications from different correspondents; to many of whom I have not the honour of being personally known. Some have fully admitted the soundness and the importance of the principles which I have laid down; others demand more extended statistical proof; and a third class state, that the quinine treatment had, in their experience, failed, in several instances, to arrest the disease. Such are the chief points in the correspondence with which I have been favoured.

Instead of replying to each inquirer individually, I am anxious to be allowed to make the present explanatory communication to the London Journal of Medicine, as an answer to all.

I have reason to think that my observations on the specific powers of quinine in typhus fever have been to some extent misapprehended. I do not believe, nor have I ever asserted, that large and repeated doses of quinine will *always* cure or arrest typhus fever. I have stated the contrary. And I now ask:—Will quinine always arrest ague? will calomel always salivate? or will opium always induce sleep? Assuredly they will not. Yet notwithstanding exceptional cases, who will question the general—not universal—specific action of these agents? If we take, as an illustration of the failure of quinine in typhus, some unhappy patient from the noisome and unhealthy courts or cellars of a large city — his constitution broken down by intemperance, by "poverty, sorrow, and dirt"—what remedy, or what treatment, can snatch, with certainty, that wretched being from the grave? What I say, and what experience will I believe confirm, is, not that quinine will certainly cure such cases as the above:—no, nor those in whom, from a fatal trifling with worse than useless remedies, the vital fluids have become vitiated, or some vital organ already irrecoverably damaged;—but I do distinctly state, that quinine will, *generally*, cure every case of typhus fever curable by medicine, including a large number of those who would sink under any other form of treatment. I say that quinine, administered as I have directed, will, in the vast majority of cases, stay or avert the symptoms that threaten life,—will, in the forcible words of Mr. Eddowes, as proved at the Liverpool Fever Hospital, "*either cut the fever short, or prevent the accession or increase of the more formidable symptoms.*" And such also are the results in the hands of Dr. Goolden, the experienced physician of St. Thomas's Hospital; of the practice at the Liverpool Northern Hospital; and in the private practice of myself and others.

The dogma so tersely laid down by Pitcairn, and adopted, probably, more from its antithesis than its truth, that "*you may guide a fever—*

you cannot cure it", was obviously based on the hypothesis, that fever originates in a specific poison, and must consequently run a specific course. What wonder, then, that the efforts founded on such premises should have so satisfactorily issued in proving the *incurability* of the disease? The prophecy insured its own fulfilment! Strange, too, that this generally received maxim, so far from being true, ought in fact to be precisely reversed; namely, that you "may *cure*, but cannot *guide* a fever." No human agency can guide a fever. While it continues, some of the symptoms may indeed be moderated, and death, from certain complications, may be averted; but the course of the disease will ever be fraught with danger, particularly if it be long continued, or if any system or any vital organ be predisposed, accidentally or hereditarily, to morbid action. Herein lies the chief danger in fever.

The methods of treatment—if, indeed, some of them deserve this name—have been legion, and of every degree of activity. Irish patients, in their cabins, have been abandoned to cold water: distinguished physicians have, under other circumstances, deliberately adopted and practised the expectant method; while the more heroic and imposing measures of bleeding, brandy, or mercury, have been pursued in clinical hospitals, or in the mansions of the rich. Typhus patients have recovered under each of these modes; but this fact only points out more strikingly the tenacity of life under the most disadvantageous circumstances.

As regards the demand for more extended evidence, and more numerous cases, I must at once confess, that, having observed how all new theories and modes of practice—from Hippocrates, the father of rational medicine, down to the visionary Hahnemann—have been ushered into life by a vast parade of successful cases, I have long regarded this kind of evidence with suspicion, and have avoided it on the present occasion, under the impression that many others might feel as I do. Moreover, when, as in the present instance, any principle admits of ready and conclusive proof, the cumbrous accumulation of cases is a downright imposition on the time and patience of the profession,—supposing, which I much doubt, that they would be read. Is your principle sound? *one* apposite case affords the illustration. Is it false? *a thousand* will not establish its truth. Let it be tested. Perhaps I may be allowed, in imitation of a celebrated northern surgeon, to introduce one other, though somewhat an unusual medical witness. A hospital nurse, E. McCartney, had been so employed for thirty years, and to her was entrusted the administration of the quinine to the patients in the Fever Hospital. Whilst I was discussing in the ward, with Dr. Gee and Mr. Eddowes, the relative results of the treatment, this woman voluntarily observed to us,—"I don't know, but the patients that take the powders (the quinine) get well the fastest. I never saw the patients get well so fast before." So much for a "nurse's tale".

Influenced by the considerations above stated, I have introduced only one case on my own authority; and in that the notes were taken, and the treatment carried out, not by myself, but by Mr. C. J. Evans, then house-surgeon to the hospital, and now apothecary to the Liverpool Infirmary—a gentleman whose competency few will question. I may be allowed to add, that

all the witnesses whom I am about to cite were equally impartial, and thoroughly competent observers.

I shall now submit the valuable evidence of Dr. Goolden, who has also touched on some practical points, to which I shall afterwards briefly advert. In answer to my letter, requesting him to communicate to me the result of his experience of the quinine treatment in typhus fever, he replies:—

"I have only to state that it is so satisfactory, that I should not feel myself justified in treating any serious case of typhus without it. Of eight cases admitted under my care in St. Thomas's in one week—five adults and three children—all with the characteristics of typhus gravior, with one exception, the effect was well marked. Each dose of quinine produced a sensible effect; ten grains in solution, every two hours, to an adult, produced some giddiness and deafness in about thirty-six hours, when it was discontinued; and it was only necessary to give a few doses of nitre and a slight aperient, and nothing remained of the fever but slight debility—debility varied according to the previous duration of the disease. In one case in the hospital, there was so much headache and excitement after each dose, that after the third time it was discontinued, but there was no permanent ill effect; and I am satisfied the course is quite safe to adopt.

"I have met with several opportunities of trying it in private practice.

"In one case, a young gentleman had been travelling with his tutor in Germany, and, when at Giessen, was observed to be out of health; he had loss of appetite, shivering, debility, thirst, and feverish nights. Still, he was able to make the journey home. When at home, he was attacked with severe typhoid symptoms, and I visited him with his medical attendant. I found him with *a black dry tongue, hot dry skin, petechiæ, pulse* 140 *and full, delirium, deafness, and diarrhœa.* He had been in this state several days, when I suggested the large doses of quinine. After an emetic, he took eight grains every two hours. I saw him after the *fourth dose,* and found him *sensible, but rather deaf, the skin bathed in perspiration, pulse sunk down to* 80, *and the diarrhœa checked.* The medicine was continued during the night, and discontinued the next morning, as the surgeon in attendance had had no experience in the quinine treatment, and did not like to carry it on upon his own responsibility. I saw him two days afterwards, and found that he had had no sleep, and the diarrhœa was returning. He took some opium, and repeated the quinine in smaller doses. After a good sleep he awoke much better, and was apparently going on well, when after some days I was sent for, in consequence of a congested state of the left lung, and slight cough. The apex of that lung was quite dull on percussion; no respiratory movement was observed on that side, and bronchophony was distinct, and much large moist crepitation, which made me fear the result, as his mother was the only one of a large family who had not died of consumption. A blister was applied under the clavicle, and he was ordered port wine and nutritious food; and I am happy to say that he is now quite recovered, and the lung perfectly sound. I do not attribute the congested lung to the quinine, but to the fever; but I should be wrong to omit it in making a report.

"I requested the opinion of Mr. Hine, who has the care of the servants of the Great Western Railway at Swindon, including 2,000

families of artizans, etc., among whom typhus is prevalent,—perhaps from want of drainage in the new town,—and his report to me was, that for some time the result was most satisfactory; but latterly he had found that the head symptoms had prevented his using it. He thought that there had been some change in the type of the fever.

"The only drawback that I see to the use of the large doses of quinine, is the necessity for frequently visiting the patients, say several times a-day, which is almost impossible in country practice, and very difficult in town when one is much occupied, and patients may consider such frequent visits to arise from the *nimia diligentia medici*, when the danger is over, and perhaps hardly apparent."

The above statement needs little comment. Of the eight hospital cases of typhus gravior, the treatment was conclusively satisfactory in seven; the exceptional case was also valuable, as proving the perfect safety of the remedy in those individuals where some peculiar condition or idiosyncracy interferes with its curative power. In one case, Dr. Goolden pushed the remedy, not only with perfect safety, but with entire success, beyond what I have ever done, or found necessary; and this fact is very important.

The case of the private patient is highly instructive, as proving, beyond all rational doubt, the specific power of quinine in arresting, *within the short period of eight hours*, the most formidable and alarming symptoms incident to typhus fever: and it is especially important in another sense,—had the fever been prolonged, considering the patient's constitutional tendency, fatal disease of the lungs was inevitable. No other form of treatment, I firmly believe, could have saved this youth's life.

Though deficient in the necessary details, the report of Mr. Hine will fix attention; and I trust that this gentleman, as well as others, who enjoy such extensive and favourable opportunities for observation, will favour the profession with the results of their future experience. I must not pass over the "*only drawback*" urged by Dr. Goolden against the quinine treatment of typhus—and its practical difficulty is indisputable—namely, the necessity for frequently visiting the patient. To ensure success, he should, undoubtedly, be frequently seen, whilst the large doses are being administered; and this, as Dr. Goolden observes, is almost impossible in country practice, and very inconvenient to the well-employed town physician. This difficulty, however, affects in no degree the intrinsic value of the quinine system of practice, or the rationality and truth of the theory on which it is based. At the same time, it must be admitted, that the efficacy of this method of treatment cannot be fairly and fully tried, unless the practitioner, or some competent substitute, exercise a frequent, even though an inconvenient, supervision.

Neither in my own experience, nor in that of others, so far as I am aware, have the large doses of quinine caused congestion of any important organ. On the contrary, by cutting short, or moderating the febrile excitement, they prevent all such congestions, and in this consists the great value of the treatment; seeing that the vast majority of fever cases are carried off by these local affections. In the event of any important organ being involved, I have, with great advantage, resorted to extensive dry cupping, either alone, or followed by a blister.

When the first large doses of quinine have failed to produce their usual curative effect, and the practitioner is obliged to discontinue them, an emetic ought to be administered, as formerly pointed out; and if, after this, the febrile excitement still continue, a full dose of the liquor opii sedativus, with a few drops of nitric acid, will frequently afford the most signal relief, and enable the patient to resume the quinine with every prospect of success.

I would here observe, that the large doses of quinine are not only safe, but advantageous in every stage, and in every form of typhus fever, and that the action assigned to it by Dr. Pereira and others is altogether erroneous. The presence of intense headache, quick and strong pulse, dry and burning skin, dry, chapped and black tongue, intense thirst, hurried respiration, abdominal tenderness, and diarrhœa, do not contraindicate its use. On the contrary, under large and repeated doses, the headache will subside, the pulse calm down, the breathing become less frequent, perspiration will return, the tongue will become moist, and the diarrhœa will be checked.

After the first decided impression has been made on the disease by the quinine, it is invariably necessary to support the patient's strength by good beef-tea, and a moderate allowance of wine. Purgatives, without some decided necessity, should be avoided. When the head continues much involved, a strong capsicum enema—a drachm of the *powder* to ten ounces of water—will often afford relief. The minor adjuvants in fever may also occasionally be resorted to with comfort and advantage.

In these observations I have confined myself to the exposition of general principles, and altogether avoided cases, as I entirely concur with that eminent physician, Dr. William Stokes, whose *Lectures on Fever* are unexcelled in the English or any other language, "that you might as well expect to find two human beings exactly alike, as to find two cases of fever perfectly similar":—the varieties are infinite.

I may here state, that I have repeatedly witnessed in Brazil, seasons of ague, (for the disease prevails in seasons), when quinine, though always curative, appeared less efficient in controlling the disease than at others; and similar modifications will doubtless occasionally occur in the fever of this country. Modifications in the quinine treatment, and probably very important ones, will also, I am satisfied, be introduced through the more extended experience of the profession, though I believe the *principle* will be only confirmed by being tried and tested by different observers.

I shall now briefly repeat the principles I have here, and elsewhere, laid down. The evidence on which I adopted them is embodied in my *Sketches of Brazil*, now in the press, and which in a short time will be laid before the profession.

1. Ague and remittent fever do not originate in malaria or marsh miasm. The doctrine of a special marsh poison I hope to show to be altogether unfounded.
2. Intermittent, remittent, and continued fever, are mere varieties of the same disease. The intermittent constantly merges into the remittent or continued type; and continued fever assumes still more frequently (in Brazil) the intermittent form; and all are curable by the same agents. By the same agents we can arrest

them all. Could this be done if they originated in different *specific* poisons? or, can we ever arrest, by any power, the course of a truly specific disease, as small-pox, etc.?

3. The notion of typhus fever being unknown in the tropics, is altogether ill-founded. The intermittent, remittent, and continued fevers of tropical climates often run into genuine typhus. In Brazil, when the disease takes this course, it is popularly termed "maligna", or "malina", and, in some seasons, is very frequent and very fatal.
4. Bark, duly administered, will generally arrest the intermittent and remittent fever; and typhus fever being essentially the same disease, bark ought to, and will, generally arrest it.
5. Ague will occasionally resist, for many days, the most judicious application of quinine—and finally yield: the same remark applies to typhus.
6. Quinine is more certain in its results in proportion to its early administration; but it is less to be depended on with the aged.
7. The administration of large doses of quinine in typhus, when not curative, is *never* followed by the slightest ill effects.
8. As typhus is, commonly, the more severe form of fever, and the subjects of its attack generally less favourably disposed, so we shall find considerable discrepancy in the several results.
9. Typhus will occasionally resist quinine, and yield to other remedies, and the same holds good with ague; yet who ever associates the latter disease with any other remedy than quinine? And I am firmly of opinion, that the time approaches when the treatment of typhus fever, after ages of vacillation, will be established on the same sure and satisfactory basis as that on which the treatment of ague now rests.

Mr. Eddowes continues to adopt the quinine treatment *universally* with the patients in his section of the Fever Hospital: and Dr. Gee in his wards of the same establishment is now giving it a trial. From two such able observers in such an extensive field, we cannot fail to obtain valuable and correct information.

Since the above was written, my attention has been called to an interesting report, in the last number of the *Medical Gazette*, by Dr. Humble, on fever, as it appeared during the last year, in the Newcastle Fever Hospital. The symptoms, indeed, are pretty much those which commonly characterise the fevers of this country; and I notice the report, chiefly, from the "relapsing" type assigned to the disease.[1]

After alluding to the different periods at which the "relapse" occurred, Dr. H. goes on to state: "In general, this came on after convalescence had commenced, and it did so in spite of any precaution which could be devised against it. . . . . A boy became convalescent, and was ordered to keep his bed until the usual period of relapse had passed over. This was accomplished with considerable difficulty, *as*

[1] Upon Relapsing Fever, so well described, in 1843, by Dr. Cormack, and more recently by Dr. Jenner and others, I have made some remarks in my forthcoming volume.

he felt himself perfectly well; but on the evening of the fifteenth day, the relapse, or, as it might be called, *the second attack*, of fever came on." Alluding to the class of patients, Dr. H. states: "A large importation of Irish were huddled together in great numbers, in a few lodging-houses, situated in the lower parts of the town. . . . . In one family, fever seemed to have been occasioned, or at any rate aggravated, by the want of the common necessaries of life . . . . two of the children presented all the symptoms described as belonging to the famine fever of Ireland. Four cases, after presenting the usual symptoms of continued fever for several days, took on the character of *regular ague;* in one, after twelve days, where the type was tertian; and in three, after ten days, in which it was quotidian", precisely as continued fevers often terminate in Brazil and other southern countries.

What, I ask, would large doses of quinine have done in these Newcastle fevers? But the *word* "relapse" unhappily presents itself, and all reasoning ceases. Speaking of fever, generally, that most accurate of observers, Dr. Stokes, writes: "We seldom meet with a case of typhus without morning remissions; and in some cases the symptoms are aggravated on alternate days, so as to bear some resemblance to double tertian." I have already stated what large doses of quinine would effect in *these* cases.

I now subjoin a letter from Mr. A. B. Steele, late surgeon to the Liverpool Fever Hospital, and medical superintendent of Irish Quarantine and Fever Ships in the Mersey. I had learned, at the hospital, that Mr. Steele had tested the quinine treatment in typhus, and was anxious to obtain the opinion of an authority so competent to decide on its merits. This opinion was kindly and promptly given as follows:

"49, *Russell-street, 24th Oct.* 1851.

"Dear Sir,—At your request, I have much pleasure in furnishing the following brief notes of my experience in the treatment of continued fever with large doses of quinine, as recommended by you, and of which I was only informed a few days ago.

"The first case was an Irishman, named Lawrence Connor, aged 40, living in 4 Court, Grosvenor-street, one of the very worst streets in Liverpool, and scarcely ever free from fever. I visited him here on Saturday the 18th instant, and found him labouring under the usual symptoms of the low type of continued fever; had been ill seven days; was lying on straw in a corner of the floor, destitute of all comforts, or even necessaries.

"I gave an order for his removal to the Fever Hospital, but he did not go. On Monday the 20th, I was again called to him. He was now so much prostrated, that I should have considered it hazardous to remove him. There was great nervous and muscular debility; skin hot and dry; suffusion of conjunctivæ; pulse small and frequent; tongue protruded with difficulty, very dry and brown; delirious, especially at night; can scarcely answer questions. I ordered one drachm of disulphate of quinine in six powders, one to be taken every two hours.

"On the 21st, I found the patient considerably better. The skin was moist; pulse softer, fuller, and less frequent; tongue readily protruded, moist, and whitish; the brown fur had quite disappeared; delirium stated to be quite removed; expresses himself better. The quinine

in ten-grain doses was ordered to be continued, and wine and beef tea to be given. These directions were not properly carried out during the following days, and a partial relapse has been the result; the tongue becoming rather dry and brown; the prostration returning; but still the patient is now (25th) in a far more favourable condition than he was anterior to the administration of the quinine.

"The second case, a woman named Galagher, 14 Collingwood-street, had been labouring under fever for several days. On the 20th, I found her in a state of great prostration, with well marked symptoms of low fever, with, I believe, pleuritic complication. The condition of the patient did not admit of auscultation, or a minute examination. General symptoms very similar to the first case. I ordered quinine in ten-grain doses, and a blister to the chest. The next day, she expressed herself much better; the symptoms had evidently given way. The quinine was continued, and she is now in a fair way of recovery.

"I have tried the plan in a third case of low continued fever, with dry brown tongue, etc.; but unfortunately, from the first, the medicine was not given regularly, or in the quantities ordered; still, what would be considered a large quantity of quinine was taken, and with a decidedly beneficial effect, although not to the same extent as in the other two cases.

"In the first case, the decided effect on the objective symptoms of the disease, *in twenty-four hours*, was so striking as at once to convince me of the value and importance of the remedy; and this improved condition was produced without the collateral advantages of *ventilation, cleanliness, nursing, nutritious diet, or stimulants*,—a fact which greatly enhances the value of this mode of treatment, in the hands of those who, unhappily, have to contend with the disease under the most unfavourable circumstances.

"I have witnessed the results of various methods of treating fever, in several hundreds of cases, during the epidemic of 1847, in our Fever Hospital, and on board the Fever Ships in the Mersey, and subsequently in the town; but I have never found any remedy, or remedies, which appeared to me to cut short the disease, or modify the symptoms, in the same decided manner in which the quinine has done when fairly tried.

"I hope shortly to be able to give you reports of more cases, as I shall continue to adopt your system, the importance of which cannot, I think, be overrated. "I remain, etc.,

"A. B. Steele,

"Late Surgeon to the Fever Hospital, Medical Superintendent of the Irish Quarantine and Fever Ships in the Mersey."

"P.S. I forgot to state that Lawrence Connor had, by mistake, fifteen grains instead of ten grains of quinine for the first four doses."

I have just received the following communication from my accomplished friend, Mr. Eddowes, which, with his valuable cases, prevents the necessity of my adverting (as was otherwise my intention) to the very important question of *typhus with complications*. By the kindness of Dr. Gee and Mr. Eddowes, I observed these cases whilst under treatment, and to both gentlemen I am, for this advantage, very deeply indebted.

"*Liverpool Fever Hospital, Nov.* 8, 1851.

"DEAR SIR,—In reply to your note of yesterday, I beg to state that my opinion of the quinine treatment is unchanged.

"In one important practical point, I entirely differ from Dr. Goolden and yourself. I do not consider that the quinine treatment requires, for its successful employment, any special supervision. For all practical purposes, *one* visit daily to the patient has been found sufficient in the hospital, where the ten grain doses have been given every two hours, for many days, without any inconvenience.

"I quite agree with Dr. Goolden (judging from the cases under Dr. Gee, and in my own charge), that the treatment appears to be altogether free from danger.

"The quinine has been used here in fevers, complicated with chest affections, etc. I enclose for your satisfaction the notes of two cases (*ex multis aliis*), and should you desire any more, you can have them.

"To Dr. Dundas. "I remain, etc., W. EDDOWES."

"CASE I. TYPHUS IN AN EPILEPTIC—ERYSIPELAS SUPERVENING—CONVALESCENCE ON THE FIFTH DAY OF TREATMENT. Richard Lewis, aged 30, a painter, has had colic and wrist-drop; has had epilepsy for seven years, having two fits a month. The epilepsy occurred a month after the attack of colic. His general health is good.

"*Present Attack.* Has been ill more or less for three weeks, but confined to bed for five days only: he had been under treatment, and had got worse.

"*October* 18. *Present State.* He complains of deafness and frontal cephalalgia; is propped up in bed, which, he says, eases the great headache. He passes restless nights; the countenance is flushed; the respiration hurried, 32; the pulse 106, jerking and weak; skin hot and dry; tongue dry, and brown in the centre, moist at the edges: there is tenderness upon firm pressure over the hepatic region. He was directed to have ten grains of the disulphate of quinine every two hours; four ounces of brandy daily; milk diet, beef-tea, and arrowroot.

"*October* 19. He sleeps better; the head is easier than yesterday; is not propped up as before; the breathing is easier; the tongue as before; a dusky erysipelatous flush is appearing on the cheeks and forehead. He was ordered to continue the remedies, and apply flour to the erysipelas.

"*October* 20. The headache is less, but he spent the night restlessly; the face is swollen; the breathing natural; pulse 96; tongue as before. He says that he "feels quite well, except the soreness of the head and face." To continue the quinine, etc.

"*October* 21. The deafness is nearly gone; the tongue moist; he was restless at night; headache quite gone; pulse 80, natural; skin cool, covered with a perspiration; the erysipelas is better. The medicines were continued.

"*October* 23. He was convalescent; and was directed to take ten grains of quinine three times a day.

"CASE II. PETECHIAL TYPHUS—PLEURITIS AND BRONCHITIS—CONVALESCENCE ON THE FIFTH DAY OF TREATMENT. *October* 23. Mary Maloney, aged 15, of good general health, has been ill five days; the skin is hot and dry, with petechiæ; she has great thirst; restless nights; slight headache; tongue coated with a white fur; loss

of appetite. The pulse is 100, natural. ℞ Ipecac. gr. xv., antimon. potass. tart. gr. i., statim sumendus. Postea sumat quinæ disulph. gr. v., secundis horis. To have milk diet, arrow-root, and beef-tea.

"*October* 14. She is breathing quickly; the pulse is 120, jerking and weak; the tongue white at the base; she has pain in the left inferior mammary region. In front, the chest is clear on percussion; there is sibilus on the right side, also on the left, with occasional cooing rhonchi. To the left of the cardiac region, is a dry friction sound, loudest during expiration. Behind, the left base is resonant, but less so than the right; the respiratory murmur is faint throughout. The friction sound is audible from the supra-spinous fossa to the base; mucous rhonchi are audible over the whole of the right side. To continue the quina. ℞ Ung. hydrargyri fort. ʒij., pulv. camphoræ ʒ ss., p. opii. ʒj. M. Sæpe lateri sinistro infricandum.[1]

"*October* 15. The pain in the side is easier; the respirations lower; pulse 118; skin hot; friction sound behind as before; no increase of dulness; friction sound in front moister. Continue the quina.

"*October* 16. The breathing is easier; the pulse softer and more natural; the countenance improving.

"*October* 17. Pulse 112, soft and natural; the skin moist; no cough; no headache; breathing natural; petechiæ fading; she takes food, and says her tongue is sore. The quinine was continued.

"*October* 18. She is convalescent; the tongue is clear; the countenance natural; pulse 84. She says she feels well. The friction sound is still audible. She had no relapse.

"There were two other patients in the same ward with the same complication: the above treatment was adopted, and the recovery was as speedy.

"Perhaps it may not be uninteresting to you to know, that there have been two cases of typhus occurring in pregnant women. The quinine was administered—in the one case five, and the other ten grains—every two hours. They both recovered without any ill effects."

I have lately conversed with several able men of great experience—Dr. Ewing Whittle of the South Dispensary, amongst others—who have observed fever on a large scale, and who are of opinion that no reliance can be placed on the "eruptions", to which many distinguished authors attach so much value, as diagnostic of the different fevers. They consider the character of the eruption as dependent on epidemic constitutions, idiosyncrasy, and atmospheric and other influences. All are aware of the numerous "rashes" which supervene on derangement of the digestive functions from the use of certain medicines, articles of diet, etc., in different constitutions, and at different seasons.

As regards the rosy lenticular rash, deemed peculiar to typhoid fever, all tropical practitioners must repeatedly have observed these spots in protracted cases of dysentery; and I have myself witnessed all the eruptions described by authors as *pathognomonic* of the several fevers, displayed, in the same patient, at one period or other of his disease. There is now a patient in the Liverpool Fever Hospital, A. B., who presents an abundant "*mulberry rash*", which quite disappears on pressure.

[1] From a formula recommended by Dr. Blakiston.

There is, also, at the present moment, another patient in the Hospital (James Moore), in whom we have conjoined the mulberry rash, the rosy lenticular rash, and "true erysipelas"—the latter classed by Dr. Watson, one of the latest and best authorities, with the contagious exanthemata—as "a specific disease, running a definite course, and attended with an eruption".

Now, in this instance we have, according to authority, three distinct morbid poisons—the typhus, the typhoid, and the erysipelatous—contending for mastery in the same unhappy individual, and all running their regular course, unchecked and unmodified in the slightest degree. Does the history of other morbid poisons present us with anything analogous?

On the authority, indeed, of Carmichael, a "plurality of venereal poisons" was at one time pretty generally admitted by the profession; but was finally exploded by M. Ricord, of Paris, who, on one occasion, exhibited, with a smile, to Mr. Carmichael himself, his *four* distinctive eruptions classically designed on one and the same patient.

This *argumentum ad hominem* did not, I believe, prove altogether conclusive to Mr. C., but perfectly so to every one else; and the "plurality of venereal poisons" soon disappeared.

All must admit that our lot is cast in revolutionary times. I, however, as a loyal citizen of the republic of medicine, have now discharged my duty in handing over "the quinine system", and the principles on which it is based, for trial before the "legal and constituted authorities".

Like other arch-revolutionists, the present doctrine is earnest in its *promises* to "benefit the public": I have not, however, allowed its justification to rest solely on my own testimony to character—naturally open to challenge—but have adduced other, and unimpeachable evidence, and I now await with confidence the verdict; for although the profession be a republic, and its decrees too often tinged by human infirmity, I firmly believe that its final judgments are never wanting in calmness, and justice, and truth.

An incidental interest attaches to the doctrine now advocated, namely, that it will afford an opportunity for testing the value of the infinitesimal doses of homœopathy with doses even larger than those commonly employed by regular physicians. Let an adequate number of fever cases be selected; place them side by side in the same room; let six be treated on my plan; six infinitesimally; let competent individuals (not including myself) be appointed on either side to take the notes, day by day, administer the remedies, and report the results; and on these results I am willing to stake, absolutely, my own professional reputation, and the reputation of legitimate medicine, so far as that can be staked by such an humble individual as myself. I entertain no doubt that the authorities of the Fever Hospital, or of the Infirmary, the Northern or the Southern Hospitals, or the Dispensaries, will readily afford the means of testing by direct comparison, that which I believe, with the rest of the profession, to be a dangerous delusion, but which has obtained sufficient extension to render its refutation an object of public interest. To this "experimentum crucis" no honest homœopath can object.

Canning-street, Liverpool, November 1851.

BIBLIOGRAPHICAL RECORD.

A Practical Treatise on the Diseases of the Lungs and Heart; including the Principles of Physical Diagnosis. By Walter Hayle Walshe, M.D., Professor of the Principles and Practice of Medicine, and of Clinical Medicine, in University College, London; Physician to University College Hospital, etc. pp. 580. London: 1851.

This work is divided into two parts; the first treats of the Physical Examination of the Lungs, Heart, and Great Vessels; and the second is devoted to the Diseases of these organs.

The first part is divided into two chapters. The first chapter treats of the Physical Examination of the Lungs, by inspection, application of the hand, mensuration in rest and in motion, percussion, auscultation, and succussion; and concludes with remarks on the determination of the situation of surrounding parts and organs. Dr. Walshe has written it in an instructive style; and has, as in the rest of his work, condensed a good deal of information in a small space. We can afford room for only a few extracts.

Under the head of Motion, the author observes that, "in *ordinary* breathing, which is mainly effected by the descent of the arch of the diaphragm, the amount of abdominal is greater than that of thoracic-expansion movement; and the former commences sensibly before the latter. This is true, however, only of adult males; in females, the costal expansion (especially superiorly) is greater than the abdominal—a difference which I presume to depend on the constraint of the lower chest and upper abdomen by stays, and other articles of dress.[1] In *forced* breathing, in both sexes, the thoracic movement is greater out of all proportion than the abdominal; and, even in the male, the expansile action commences superiorly." (p. 17.)

Mensuration is treated of as applied in rest and during motion. In mensuration during motion, Dr. Walshe regards Dr. Sibson's chest-measurer, though liable to fallacies, from the forward motion not always accurately expressing the expansibility of the chest, and from other causes, as furnishing superior indications to those furnished by application of the hand, in localising with precision deficiency or excess of antero-posterior motion. The amount of inspiratory expansion and expiratory retraction of the chest and abdomen is measured by a graduated double tape: the expansion, in the healthy male adult, with a circumference of thirty-three inches, is about a quarter of an inch, which is shared equally between the two sides. "In forced inspiration, the circumference is increased by from one and a half to three inches, and is somewhat greater on the right than on the left side—the deficiency on the latter side mainly depending on the heart. The total circular difference between forced inspiration and forced expiration, ranges between two and a half and five inches." Forced breathing has scarcely any influence in expanding the abdomen.

In disease, mensuration ascertains the amount of deficiency of expansion; and is considered by Dr. Walshe as a valuable means of examination. In

[1] In an Appendix, Dr. Walshe says: "The observation of a considerable number of female children, between the ages of four and ten, who had never worn stays, leads me to the conclusion that, independently of any extraneous influence, there is proportionally more infra-clavicular movement in the female than in the male. But indubitably the main source of the excess of infra-clavicular movement, in the adult female, is due to the use of apparatuses interfering with inferior costal and phrenic action. The male dog breathes exactly like the human male, almost wholly with the abdomen, the chest rising inferiorly after the abdomen; the action in the female dog is very closely the same."

some instances, however, he observes, "the measured range between forced expiration and forced inspiration may be the same on the two sides, and yet the accompanying change of volume of the two lungs may be very different in kind. On one side, the play may be chiefly effected by the ready inspiratory expansion of the lung; on the other, by the great efficiency of expiratory contraction. In the former case, the lung maintains its relative efficiency by the power of taking in beyond its medium quantity of air; in the latter, by its power of expressing air, which in ordinary breathing stagnates within it: in the former case expansibility, in the latter elasticity, predominates. Here are two very different conditions of lung, most important to be distinguished, but which have hitherto never been made the subject of *clinical* study. The difficulty of the study is, it is true, extreme, from the nicety required in fixing the standard of comparison, namely, the medium or tranquil state of the chest. My observations on this matter are as yet too limited to justify me in announcing general conclusions; but they prove to me that, with care, the inquiry may become rich in results." (p. 35.)

Percussion. Dr. Walshe objects to the terms *dull* and *clear*, as applied to the percussion sounds; but retains them, because they are generally understood, and because it is very difficult, if not impossible, to substitute correct scientific terms for them. He also objects to the use of the term *dull*, as applied to "little" or "no" sound; for it is not in intensity that dull sounds differ from clear ones, but in duration and pitch. Hence he understands by what is practically called clearness, continuousness of sound; and by dulness, non-continuousness; and, as continuousness of sound depends on the elastic vibratile character of the material furnishing it, the inference is, that when dulness exists, the material struck is either inelastic, or the vibration is suddenly stopped by some extrinsic influence. Clear sounds, as those of the chest, approach in character to tones; and, under certain circumstances, the pitch can even be assigned—they become notes.

Passing over the author's instructions for the method of performing percussion, and the nature of the sounds elicited in various parts of the chest in a state of rest, we find the following remarks on the modification of the results of pulmonary percussion by inspiration and expiration.

This may occur in three ways. "1. By altering the volume of the lungs; 2. By altering their density; 3. By altering the position of the heart and abdominal viscera. 1. At the close of an ordinary expiration, the right lung extends downwards as far as the sixth rib in front, and the eighth laterally. The lower edge of the left organ, sloping abruptly outwards and downwards from the middle line on the level of the fourth cartilage, again turns inwards a little, and then passes outwards, reaching laterally the eighth rib or interspace. From numerous trials on the dead subject, where no cause existed to modify materially the volume of the lungs, I infer that, in expiration, the lungs are from one to one and a half inches apart on the level of the second cartilage, and four and a half inches apart on the level of the fifth. From their lateral aspect, the lower edges curve downwards and backwards, reaching the ninth interspace or tenth rib, especially close to the spine. During full inspiration, the lungs extend downwards in all directions somewhat further than the limits just mentioned; the inferior edge is then carried about an intercostal space and half lower than after ordinary expiration, and proportionally still lower, when the lungs have been forcibly emptied of their air. At the same time, the space on the left of the sternum, where, after expiration, the heart is in contact with the thoracic walls, becomes filled with lung.

"2. The density of the pulmonary tissue being in the inverse ratio of the air it contains, it is plain that the percussion-sound must be rendered duller in any given point of the chest by a full expiration. In other words, the sound yielded will vary in clearness according as percussion is performed at the close of inspiration or of expiration. The duration of the sound, and the

sensation of elasticity perceived, vary, in the ordinary way, as the modifications of clearness.

"3. The depression of the dull-sounding spleen and liver attending inspiration, replaced as they are by expanding lung, tends during that act to increase the clearness of the percussion-sound in the lower regions of the thorax; the influence of the similar locomotion of the stomach and intestines will vary with the filled or empty state of these viscera. The heart, pushed downwards and inwards, and receding somewhat from the chest-wall during inspiration, where its place is taken by the inflated lung, gives dulness of less extent and lower site than in expiration." (pp. 53-5.)

In consequence of this triple influence of the respiratory acts on the results of percussion, it is advisable in all cases, and absolutely necessary in delicate ones, that the respiration be at the same stage, when the two sides of the chest are percussed comparatively. The end of a full inspiration is best; when the patient can be made to hold his breath.

The alterations in the percussion-sound, produced by disease, are considered under the heads of statical signs, and dynamic signs.

The statical signs are: 1. *Diminution of clearness*, gradually passing into perfect dulness,—the *duration* of the sound being proportionally *shortened*, and the *sense of resistance increased*. It occurs whenever the density of the materials underneath the part struck is increased. 2. *Increase of clearness and of duration*, with *decrease of resistance*, or excess of elasticity. This is noted, where the relative quantity of air in the chest is increased, but not so far as to interfere, by tension of the walls, with their vibration; as in pneumo-thorax, hydro-pneumo-thorax (acting here in the upper part of the chest), in atrophy, hypertrophy, and emphysema of the lung. Extreme anæmia also, by lessening the relative quantity of blood in the lung, may, as suggested by Dr. Stokes, increase the clearness of the percussion-sound. 3. *Increase of clearness and of duration of sound*, with *increased resistance of walls*, is observed where there is a surplus of air in the subjacent part, with considerable induration of tissue between the surface and the part containing that surplus,—a combination of conditions met with where a superficial cavity in the lung has a thin, indurated, and adherent external wall. 4. Alterations in quality are referred to these types: (*a*) Wooden; (*b*) Hollow; (*c*) Tympanitic. These are described at length by the author. The dynamic signs arise from perversions or impediments of the natural modifications of percussion by the act of respiration. Few of these signs are of practical importance, but some of them occasionally prove valuable.

1. The volume of the lung will not be increased during inspiration in cases of hydrothorax, pleuritic effusion, and pneumothorax; in emphysema, and in obstruction of the chief bronchus, either from external or from internal causes. In these cases, also, the air, which in health should escape, still stagnates within the chest, and hence there will not be a sufficient reduction of the area over which pulmonary resonance is heard.

2. The clearness of percussion, as increased during full inspiration, may be affected. Certain states of disease give rise to a comparatively deficient increase of clearness at the end of a full inspiration on either side, the sound being equally clear on both in ordinary respiration. Again, the percussion-sound on expiration may be disproportionately dull on one side. Both these signs sometimes give very satisfactory results in cases of small irregularly scattered indurations, tuberculous or otherwise, of either apex. Other states of the lung—as emphysema and dilated bronchus—interfering with the expulsion of air from the vesicles, give rise to a comparatively deficient diminution of clearness at the end of full expiration: and the same result will occur if there be air in the pleura.

Resistance. Dr. Walshe believes the amount of resistance offered by the chest during percussion to be often of practical importance in diagnosis "There are cases", he says, "of not very rare occurrence, in which erroneous

inferences would almost inevitably be drawn from the sound elicited by percussion, were not these corrected by the information derived from the degree of resistance felt by the fingers. Take the case of a cavity seated close to the surface ; the unnatural clearness of sound which sometimes distinctly exists over such cavities (quite independently of tubular or amphoric quality) might not only lead to an incorrect estimate of the state of the subjacent part, but also to the inference that the lung, in reality least affected, was the most diseased. The sensation of hardness and firm resistance experienced by the fingers at once discloses the true cause of the unusual clearness. Besides, the cases are extremely numerous in which it is satisfactory to have the corroborative evidence, furnished by the state of resistance, in favour of the evidence drawn from the sound. That doubt often exists as to the state of the sound on the two sides, is unquestionable ; and, in these cases, the condition of the subjacent parts may frequently be settled by taking into consideration the amount of resistance. To those persons whose sense of touch is more delicate than that of hearing, this source of diagnosis is of especial value.

" The resistance depends on the state of the contents and of the walls of the chest. All conditions lessening the relative quantity of air in the lung, while they deaden the sound, increase the resistance. All conditions which conversely increase the relative quantity of air, decrease the resistance, while they increase the clearness of the sound: pneumo-thorax is the principal disease. But the walls of the chest may be so stretched in that very affection by excessive accumulation of air, that the resistance becomes extreme, though the sound continues clear. Here the state of the walls themselves modifies the resistance ; as it does likewise where solid or liquid matters accumulate in their substance, where the periosteum thickens, or the ribs either enlarge, or (as in the retraction period of chronic pleurisy) become unduly approximated to each other." (pp. 66-7.)

Auscultation. Dr. Walshe thus concisely states his views on the much debated question—the relative merits of hollow and of solid stethoscopes. " From trials with hollow and solid cedar and ebony stethoscopes, I have come to the following conclusions :—That, with the hollow instrument, the respiratory murmurs appear stronger and more open in quality,—with the solid, weaker and sharper, so much so, that a bronchial character may be simulated ; that cavernous phenomena lose, in some measure, their hollow quality with the solid instrument ; that friction phenomena are sometimes materially better heard with this ; that the natural vocal resonance over the trachea is hollower, graver, and better articulated with the hollow cylinder ; and that the resonance of the observer's own voice, as he speaks, while auscultating the chest of another person (autophonia) is materially more intense with the solid than with the hollow instrument." (pp. 69, 70.) Dr. Walshe points out the precautions to be observed in the performance of auscultation, both as regards the observer and the patient.

The sounds discoverable by auscultation of the lung in disease are described under the following heads, which we exhibit in a tabular form, for the sake of conciseness.

A. 1. Modified Pulmonary Murmurs, or species of unhealthy respiration distinguished by changes of

- (α) Duration and intensity
  - (a) exaggerated respiration
  - (b) weak respiration
  - (c) suppressed respiration
- (β) Rhythm
  - (d) jerking respiration
  - (e) divided respiration
  - (f) altered ratio of inspiration to expiration.
- (γ) Quality, and other properties
  - (g) harsh respiration.
  - (h) blowing
    1. simple
    2. cavernous
    3. amphoric

- A. 2. Adventitious sounds, produced within the thorax by the act of breathing
  - (*a*) Originating in the air-passages — Rhonchi or rattles
    1. Sibilant
    2. Sonorous
    3. Crepitant — (*a*) Primary; (*b*) Redux
    4. Subcrepitant — (*a*) True; (*b*) Liquid
    5. Dry crackling
    6. Humid crackling
    7. Mucous
    8. Cavernous
    9. Dry crepitant, with large bubbles
  - (*b*) Originating in the lung-substance (Pseudo-rhonchi)
  - (*c*) Originating in
    1. The Pleuræ — Friction sounds: grazing, rubbing, grating, creaking, rumbling; Pseudo-rhonchi
    2. The Mediastina
- B. Modified vocal resonance
  - (*a*) diminished — weak; suppressed
  - (*b*) increased — exaggerated bronchophony; *pectoriloquy*; *ægophony*[1]
- C. Modified resonance of the cough (Tussive Resonance) — Bronchial; Cavernous; Amphoric
- D. Phenomena common to the respiratory murmurs, to rhonchi, and to the resonance of the voice and cough — Amphoric echo; Metallic tinkling
- E. Sounds of the Heart, and Murmurs, as transmitted through the substance of the lungs.

We must refer our readers to the original work for Dr. Walshe's remarks on the modified breath-sounds and rhonchi—subjects to which, as is well known, he has devoted much attention, and which he has enjoyed extensive opportunities of investigating. The following is his description of PLEURAL PSEUDO-RHONCHI—a phenomenon, we believe, not previously described.

"In the winter of 1842, I made the following observations. In a male adult presenting the most evident signs, both in front and behind, of a cavity at the left apex, an extremely abundant subcrepitant rhonchus occurring almost in puffs, and having the liquid character in a most marked manner, was day after day (during the week previous to death) detected in the entire height of the left side posteriorly. The rhonchus was, however, distinctly more abundant and more liquid (as noted in writing during life) in the upper scapular, and upper part of the lower scapular regions, than elsewhere. As the patient was anasarcous to a high degree (the urine albuminous), and as he constantly lay on the left side, the explanation of the subcrepitant rhonchus naturally suggesting itself was, that it depended on œdema of the pulmonary tissue generally, but most marked at the apex, and there of course affecting tissue between the cavity and the surface of the lung. At the post-mortem examination, however, I found this explanation was inadmissible; for the thin lamella of tissue between the cavity and the surface was as hard as cartilage, and contained not a particle of serosity; nor was

[1] These two sounds are considered by Dr. Walshe to be varieties of bronchophony.

the organ in any part distinctly infiltrated with fluid, being, on the contrary, particularly dry from its excessive induration. But all along the posterior surface of the pulmonary pleura there appeared (in addition to ordinary dense pseudo-membrane) a quantity of fine adventitious cellular tissue, abundantly infiltrated with fluid. Masses of some size were formed from place to place by the accumulation of fluid in the meshes of this cellular tissue, and it was observed by those present (who had not seen the patient during life) that they were much larger than elsewhere at the apex. There was no air either in the cavity of the pleura, or intermixed with the serosity. Now, although it was possible to suggest another explanation, it seemed most reasonable to suppose, under the circumstances, that the rhonchal sound was actually produced in the masses of infiltrated tissue referred to, and therefore outside the lung, and independently of air.

"Subsequent experience has amply proved the correctness of this explanation, and shown that sounds, perfectly rhonchal in properties, are producible whenever adventitious tissue within the pleura is infiltrated with serosity, and the movements of the chest are sufficiently free. The sounds occur in two forms, squashy and crackling. The character of the first is represented by its name, and, coupled with the sensation of extremely superficial site, suffices for its diagnosis.[1] The crackling form, in itself indistinguishable from some conditions of subcrepitant rhonchus, may be diagnosticated by the coexistence of friction-sounds, constant or occasional, and by its being unaffected by coughing. Mere moisture in the plastic matter within the pleura seems enough to give a rhonchoid character to friction sound." (pp. 120, 121.)

Dr. Walshe enters at some length into the theories of the production of Bronchophony, as laid down by Laennec and Skoda. The latter observer opposed Laennec's view that the bronchophony of hepatisation was explicable by the increased conducting power of the solidified parenchyma, on the ground that (1.) bronchophony may in a few minutes appear and disappear over solidified lung, the other physical signs undergoing no change; (2.) when vocal resonance has temporarily disappeared, it may be restored by making the patient breathe deeply; (3.) in pleuritic effusion, the resonance weakens as the effusion (and the solidity of the lung) increases; (4.) if a healthy and a hepatised lung be taken from the body, and, while one person speaks through a stethoscope placed in contact with each organ successively, a second listens through another stethoscope, it will be found that more intense resonance reaches the ear through the healthy than through the diseased lung. Dr. Skoda believes that "bronchophony is really produced by consonance of the air, within the bronchial tubes, with the laryngeal voice"; and he excludes the walls of the trachea and bronchi from all share in the conduction of the sonorous vibrations of the chordæ vocales.

In criticising Dr. Skoda's observations, Dr. Walshe objects to the comparison instituted between healthy and hepatised lung-tissue when removed from the body: hepatised lungs, under this condition, *do* sometimes conduct sound with much intensity. Again, during life, the laryngeal and tracheal walls obviously conduct vibrations; but this is not the case when the lung is removed from the body: and further, "within the body, the contact of a hepatised lung with the chest-wall is more perfect than that of a healthy one; and, admitting that the former is a worse conductor in regard of the condition of its substance, it may be a much better one through the *closeness of its union (especially if adhesive) with the parietes.*

"In seeking for a theory of bronchophony, there are three points to be considered: the conduction of laryngeal voice; its possible intensification within the chest; and the distance at which that intensification (if real)

[1] "The precise spot where infiltrated false membrane exists may be pointed out during life by this sound."

occurs from the part of the chest-walls examined. In regard of conduction, theory would say that, as the human voice is best propagated in air, the more the lungs were rarefied, the higher would its conducting power become ; and, in accordance with this, it is certain that intense bronchophony is sometimes heard over highly emphysematous tissue. But, on the other hand, as the tracheal and bronchial walls themselves vibrate during speaking, any *really solid* material directly connecting a large bronchus with the surface of the chest, must conduct those vibrations forcibly ; and, in accordance with this, we find that wherever solid fibrous structure is seated in the manner supposed, bronchophony of the most intense character is audible. But if the union of the solid material with the bronchus on the one hand, and the chest-wall on the other, be not perfect—if there be any interruption at the planes of union of the conducting materials—the acoustic conditions are completely changed, inasmuch as interruption at the union of media of different densities most deeply impairs the conducting faculty of the series. Here is one clue to the differences in vocal resonance, observed where the physical conditions appear, on superficial view, identical. On the other hand, theory, for the reasons just now adduced, does not teach that, in the variable semi-solid states comprised under the title of ' hepatisation,' conducting power should be affected in an uniform manner, and experiment shews that it actually is not. Experiment, in truth, alone can teach what the force of conduction really is in the various complicated conditions of physical change in the lungs.

" Next, in regard of intensification within the thorax. The thoracic resonance is sometimes stronger than the laryngeal voice ; hence intensification of sound within the chest is real. How is it to be explained ? Skoda's theory of consonance does not seem to meet the difficulty, or rather to go beyond it. For, in the first place, the air in any enclosed space does not consonate with every sound produced at its orifice, but only with the fundamental note of that space, or certain others having a fixed harmonical relation to that fundamental note. Now, when well marked bronchophony exists, it is audible, as I have assured myself, with the various notes of the octave, though most with the low ones. Again, bodies consonate only in unison, or in certain fixed harmony, with the original sound. Now, the pitch of the bronchophonic voice varies irregularly from that of the laryngeal, with which it coexists. Further, it seems doubtful whether consonance could occur in a system of branching tubes, such as the bronchi : and lastly, Dr. Skoda's exclusion of the tracheal and bronchial walls from all participation in the phenomenon is at variance both with theory and experiment. But there is another way in which sounds may be intensified at a greater or less distance from their places of production—by reflection, and by reflections brought to a focus, or *echo*. Now, the conditions of reflection are fulfilled in the hepatised lung ; the tubes along which the voice is transmitted from the larynx are surrounded by semi-solid material, proper (when compared with healthy tissue) to reflect and concentrate the sound ; the air-cells and minute bronchi are closed, to a variable distance, and prevent its divergence. The tubes resemble so many speaking trumpets, and, just as in these instruments, the augmentation of sound (intensification) is produced by reflection from their quivering walls. . . . But, if the reflected vibrations chance to be brought to a focus within a larger tube, then echo will occur, and, as under ordinary circumstances, the echoed may be materially louder than the original sound. But it may be inquired how, upon this theory, is the temporary disappearance of bronchophony explicable ? In the first place, I disagree with Skoda as to the frequency of the occurrence ; I believe intermittent bronchophony to be a most rare phenomenon,—in this respect assimilable to intermittent bronchial respiration. In the second, where it does occur, it may depend on the deadening influence of mucus or blood in the tubes, or an obstruction of a chief bronchus by fluid, or by accidental pressure (glandular

or other) on its external surface. Under the latter circumstances, bronchophony would, probably, (I have not verified this conjecture) be heard at some point of the chest nearer the bifurcation of the trachea ; or it is possible that certain changes of posture, altering the relationship of the reflecting surfaces, might interfere with the production of echo, by preventing the reflected sounds from coming to their usual focus ; or, the position of the auscultator in respect of the focal point might prevent him from hearing an echo really existing. The force of the echo will also rise, the smoother the bronchial walls, and the larger the tubes in which it occurs ; and numerous other circumstances may be conceived, but scarcely proved, to affect the phenomenon. Among these, the composition of the gases within the bronchi (or in the pleura) may, for aught that is known, hold an important place : hydrogen has been proved to deaden sound greatly ; the effect of carbonic acid, when mixed with other gases and aqueous vapour, can only be learned by experiment.

" Lastly, as concerns the distance from the point of auscultation at which the intensification within the thorax occurs ;—the farther away, the less of the resonance will reach the surface ; the amount, however, will be modified by the conducting property of the interposed media.

" These three conditions of bronchophony—conduction of laryngeal sound, intensification of this within the thorax, and proximity of site of the intensification, may or may not be directly as each other ; one may be in a state favourable to, the rest unfavourable to, the production of bronchophony." (pp. 127-31.

Pectoriloquy and Ægophony are next treated of by Dr. Walshe, who considers them as " important varieties of vocal resonance within the chest (bronchophony)."

In speaking of Metallic Tinkling and Amphoric Echo, Dr. Walshe states his belief that these phenomena are fundamentally one and the same. Amphoric echo is produced artificially by blowing, coughing, etc., into a glass decanter, either empty, or containing a little water, so long as the fluid is not agitated ; but, if drops of water, slowly, and at distinct intervals, fall on the surface of the fluid, the ear, applied to the surface of the vessel, recognises the most perfect imitation of metallic tinkling.

The remainder of the observations on the Physical Examination of the Lungs, including some interesting observations on the position of the diaphragm, we must pass over.

The Second Chapter treats of the Physical Examination of the Heart and Great Vessels. It is divided into the following sections : 1. Inspection ; 2. Application of the Hand ; 3. Mensuration ; 4. Percussion ; 5. Auscultation ;—all as applied to the examination of the heart.

In preference to attempting to give an imperfect idea of the contents of this chapter by condensing it, we will extract entire some of the author's observations on the Sounds of the Heart, contained in the section on Auscultation.

" The first of these two sounds, coincident with the systole of the ventricles, the heart's shock against the side, and the pulse (or diastole) of the arteries nearly adjoining the heart, is called the first, or systolic, or (because of maximum force at the lower part of the cardiac region) inferior, sound of the heart. The second of the two sounds, synchronous with the diastole of the ventricles, the recedence of the heart from the side, and the pulseless state (or systole) of the large arteries, is known as the second, diastolic, or (because of maximum loudness at the upper part of the cardiac region) superior, sound of the heart. The soundless period succeeding to the first sound may be called the first, or post-systolic silence ; that succeeding the second sound, the second, or post-diastolic silence.

" If the period of an entire revolution of the heart, that is from the com-

mencement of one first sound to the commencement of the next succeeding first sound, be divided into ten equal parts, about four of these will be found to be occupied by the first sound, one by the post-systolic silence, two by the second sound, and three by the post-diastolic silence. This estimate is, however, only to be taken as approximatively true. When the pulse beats even as much as from seventy to eighty times in the minute, the post-systolic silence is difficult enough of detection; but it becomes obvious, where the pulse does not exceed sixty in a minute.

"An accurate idea of the character of the heart's sounds cannot be given by a single description of them, as heard in any one particular spot: they vary materially at different parts of the cardiac region, both in their positive and relative properties. The least study of the healthy chest will convince the student that the description which it is the habit to apply to the sounds of the heart generally, holds good only when these are heard at the left apex. The sounds require comparative analysis: (*a*) at both sides of the apex-region, and at both sides of the base-region: (*b*) at base and apex on the same sides of the organ; (*c*) at base and apex on opposite sides. Now this is the most difficult of all studies connected with the healthy heart; but it is essential as the basis of observation of the organ in a state of disease.

"(*a*) At the left apex the first sound is dull, measured, booming, prolonged, and strongly accentuated; its commencement pretty sharply defined; its close much less so. Double the length of the second, deeply seated, and of lower pitch than this, it attains its maximum at this apex, in regard of accentuation, prolongation, and measured, booming character, but not habitually in amount of sonorousness. The second sound, only half as long as the first—clear, abrupt, flapping, and short—is more sonorous, more superficial, and of higher pitch than its predecessor. At the right apex-region, the first sound is considerably clearer, shorter, more abrupt, less strongly accentuated, and of somewhat higher pitch than at the left apex-region. This difference of character depends, probably, both on the thinness of the walls of the right, as compared with the left ventricle, and on the parietes being of different conducting power in the two situations: at all events the sound, audible at the end of the sternum, may be fairly referred more particularly to the right ventricle; that near the nipple, to the left ventricle. So, too, the second sound is habitually clearer, and sometimes even of higher pitch, at the end of the sternum, than towards the left apex; this is, however, less constantly true, and I have known the converse to be the case, where no suspicion existed of the existence of dilatation of the left ventricle—where, indeed, the first sound possessed to the full its natural share of dull, prolonged, booming character.

"Passing from the apex to the base, the same kind of dissimilitude, laterally, in the sounds, may be heard,—not indeed precisely at the base, but a little above this, opposite the second interspace, where the aorta and pulmonary artery are placed side by side. The first sound at the right second interspace is commonly duller, of slightly lower pitch, and more prolonged than at the left corresponding point: in neither is it accentuated. The second sounds differ here in the same characters and in the same manner, but to a less degree: they are accentuated in both places, more on the right side than the left.

"(*b*) Let us now examine the two sounds comparatively at base and apex on the same sides of the heart. The first sound, strongly accentuated at the left apex,—prolonged, booming, and dull,—at the left base loses the accent, which passes to the second sound, while this become louder, more ringing, and sometimes even of higher pitch than that at apex. At apex and base on the right side, the characters of the first sound are very similar; it has more accent in the former than in the latter spot, however, both positively, and *à fortiori* as compared with the second sound.

"(*c*) The relative characters of the two sounds at base and apex at oppo-

site sides of the heart (crucially taken, as it were), may easily be deduced from the foregoing account.

"Now, if these statements be correct, it appears obvious that no *single* articulate symbol can be devised, applicable to the heart's sounds in more than one point. The subjoined series is offered for the four points of prominent clinical interest. The acute accent-mark is used to show where the accent falls (twice, when it falls very strongly); the marks of long and short where one or other character is prominent.

	First sound.	Second sound.
At the left apex	ŭ̋bb	dŭp
At the right apex	úp	tŭp
At the left base[1]	up	túp
At the right base[1]	ub	tŭ̋pp

"The eye gathers from these symbols the tendency to equalisation in length of the sounds observable at the bases, as well as the transference of the accent from the first to the second sound at the apices and bases respectively.

"The extent to which the heart's sounds are audible in health, is not subject to any fixed rule. One great mistake,[2] commonly committed by authors who attempt to define it, is not considering separately the first and second sounds. From this omission, the ordinary starting proposition, that 'the heart's sounds are heard at their maximum in the præcordial region,' becomes an error: the second sound is, in truth, heard in nine people out of ten, more clearly at mid-sternum, on the level of the second interspace, than at any point of the præcordial region,—even limiting that region to the space in which the heart is uncovered by lung during tranquil breathing. The thickness of the soft parts, the form of the chest, and many other physical conditions, perfectly independent of disease of any of the thoracic organs, modify the extent of propagation so variously, that there can be no practical utility in laying down rules subject to perpetual exceptions. But the lines of propagation of the two sounds severally agree in most healthy persons, whatever be their absolute intensity at their seat of production; changes in these lines point positively to some modifying cause, and hence their establishment is clinically valuable. Now, the first sound passes slantingly upwards to the left acromial angle, growing weaker and weaker on the way; it loses much more on the way to, and at, the right acromial angle: its propagation backwards is clearest and fullest to the left,—so that while audible at the left back, it may be inaudible at the right. The second sound, with the base-region as its centre, radiates to the right and left acromial angles, with greater clearness to the left than the right; posteriorly it reaches the surface at the right side less clearly than at the left." pp. 189—192.

Great attention has been devoted by Dr. Walshe to the morbid modifications of the sounds of the heart, and to adventitious sounds or murmurs. We quote his remarks on Inorganic Endocardial Murmurs.

"Endocardial murmurs, that cannot be traced to any organic cause after death, or that disappear so completely and permanently during life as to preclude the idea of structural change in their production, are termed inorganic. They are divisible into two sub-classes—murmurs of blood origin, and of dynamic origin.

"1. *Cardiac blood-murmurs.*—An intra-cardiac blood-murmur is of mo-

[1] "The left and right second interspaces close to the edge of the sternum."

[2] "Some authors speak of the sounds being audible in healthy male adults, of moderate stoutness, even *at the right side posteriorly*; others hold that the space over which they are heard *seldom exceeds two square inches!*"

derate or very slight intensity, commonly of medium or low pitch, short or moderately prolonged, of whiffing quality, very easily rendered temporarily harsh by excitement of the heart, and modified in intensity by certain changes of posture. This murmur is, as far as I have observed, invariably basic in seat and systolic in time, produced at the orifices of the aorta and of the pulmonary artery,—with a force at each proportional to the power of its communicating ventricle; scarcely conducted along the aorta at all; frequently audible, on the contrary, at the second left (or pulmonary) cartilage; only in exceptional cases audible below the nipple; and never, within my experience, perceptible as far as the left apex. The site and rhythm of these murmurs, excluding all those of diastolic time and seat at either apex, are of great value in their distinction. To their quality and pitch I attach but moderate importance; for organic murmurs may be soft, and inorganic ones are not very unfrequently rather harsh: while the latter may be shrill, whistling, and of high pitch, and the former are of course frequently of low pitch. Unfortunately there is no character in a systolic basic blood-murmur which positively proves its nature, and distinguishes it, *under all circumstances*, from one of organic source. The distinction is often rather to be made through the absence or presence of venous hum (I do not remember ever to have observed an intra-cardiac spanæmic murmur unattended with venous hum) and the course and duration of the phenomenon, than through its own immediate characters: *permanent* harshness and high pitch are never associated with murmur of blood-origin. If the arteries be the seat, extensively, of strong blowing murmur, without artificial pressure (as, for example, the arch of the aorta, the innominate and subclavian arteries), a co-existing systolic murmur at the mid-sternal base is, in part at least, inorganic; but, on the other hand, the cardiac murmur may be truly inorganic, and yet the arteries be perfectly free from abnormal sonorousness.

"The morbid state of the blood which acts as the most frequent cause of these murmurs is spanæmia,—whether it be that of chlorosis, of malaria, of starvation, of deficient insolation, of hæmorrhage and over-venæsection, of carcinoma, of convalescence from acute diseases, etc. I have occasionally observed it in uræmia; so, too, it occasionally occurs (though to a very slight amount) in the hypinosis of continued fever and the exanthemata, and in the hyperinosis of pneumonia and acute rheumatism, under circumstances excluding more or less positively its dependence on endocarditis. It has been affirmed that plethora, rendering the quantity of blood too great for the cavities of the heart, produces murmur within it: confirmation of the statement is wanting; more especially if we agree with those chemists who maintain that the relative quantity of red corpuscles is increased in plethora.

"The mechanism of these blood-murmurs will be considered with that of the venous class.

"2. *Dynamic cardiac murmurs.*—Under this head murmurs occurring in the heart, through some abnormal state of its action, range themselves. Violent excitement of the organ, whether it act merely by increasing the force of the current, or by disturbing its direction, occasionally produces for the time systolic murmur at the base. I have observed this not only in hysterical females (who, though of florid countenance, might have been slightly spanæmic), but in males with palpitating heart. If the organ be the subject of dilated hypertrophy, palpitation is sometimes, but certainly not always, attended with the same murmur. In hypertrophy with dilatation there is possibly another dynamic source of systolic murmur: from the altered form of the cavities of the ventricles, their contained blood is probably propelled against the edges of the arterial orifices, instead of directly through them; and this misdirection of the current may, very possibly, generate murmur.

"The heart may, probably, also undergo dynamic changes interfering with the closure of its valves, and giving rise to murmurs of the regurgitant

class. A systolic murmur at the left apex is occasionally audible in chorea, disappearing as the disease disappears,—which cannot be referred to inflammation or organic disease of the mitral valve; which cannot be of blood-origin, but which does seem plausibly ascribable to disordered action of the muscular apparatus connected with the valve. The same kind of disorder may conceivably be the cause of certain mitral regurgitant murmurs, attending dilated hypertrophy of the left ventricle, which disappear under treatment.

"In seeking the causes and seat of any given endocardial murmur, the essential points in the inquiry are its relationship to the systole or diastole, and the spot of its maximum intensity on the surface of the chest. Subsidiary conditions of great importance are the direction of transmission, duration, clinical progress, quality, and pitch of the murmur; and, beyond itself, the state of the heart's natural sounds, and the presence or absence of certain audible phenomena in the arteries and veins, or both." (pp. 218-221.)

Having thus glanced at the scientific part of Dr. Walsh's book, we will now proceed to an examination of the practical portion.

The second part is devoted to diseases of the Lungs, Heart, and Great Vessels; and is divided into three chapters.

The First Chapter contains an account of the Diseases of the Lungs and Appendages.

Neuralgia of the Lungs, Pleurodynia, and Intercostal Neuralgia, are briefly treated of, and are followed by an instructive description of the symptoms, physical signs, and treatment of Bronchitis, in its acute and chronic forms. Two pages of the work are also occupied with a description of plastic bronchitis, a rare affection, anatomically characterised by the formation of solid or tubular concretions of exudation matter of low type (sometimes containing exudation cells) within the bronchial tubes, reaching, more or less extensively, from their finest to their largest divisions. A case of this kind has been recorded, with an illustration of the casts of the bronchial tubes, in a recent volume of the *Transactions of the Provincial Medical and Surgical Association.*

Hay Asthma is briefly noticed; and a concise view of Influenza is given. Dr. Walshe is evidently unwilling to remove this disease from the place which it has so long occupied among chest affections; but he appears nevertheless convinced that it is "even in its local manifestations, an affection *sui generis*, and of much more extensive seat (even anatomically speaking), than its classification with bronchitis would seem to signify". And a little farther on he observes: "There are exceptional cases (the same poison evidently being at work), where violent headache, flushing of the face, and delirium with fever, mark its action; others, where the digestive organs alone suffer, and in the upper parts; others, marked by diarrhœa or pseudo-dysentery; and yet others, where erethism or actual catarrhal inflammation of the urinary organs is the main phenomenon." We can scarcely agree with Dr. Walshe, in calling these complications of a febrile disease "exceptional". On the treatment of influenza, the author makes the following concise and judicious remarks:

"The experience of centuries has established beyond question the impropriety of depletory measures in the *treatment* of influenza. The czar of Russia was justified, by the mortality clearly traceable, not only in his own dominions, but in various countries of Europe (England, France, Spain, Italy) to blood-letting, in issuing his Ukase against its employment. I doubt if the occurrence of consolidation-signs even warrants the use of the lancet: such signs are observed chiefly in the aged and exhausted: and I know, from experience, that dry cupping and carbonate of ammonia will remove these signs in such cases; whereas I have never seen any benefit derived from abstraction of blood, either by leeches or cups. Such consolidation is very positively *passively congestive* in the aged and infirm, and is

increased by depressing measures. Should well-marked signs of sthenic pneumonia occur in a young or middle-aged person, leeching or cupping may be advisable; but even then caution is requisite; a dozen leeches have, within my experience, produced successive fainting fits in a previously healthy and robust individual. I have never seen a case (perhaps such may be met with in the provinces) where venesection was advisable. Neither should tartar emetic, active purgatives, nor (I think, in spite of the encomiums of Dr. J. Davies) mercury, with a view to its constitutional effects, be employed. The treatment I have found most successful, is as follows:—keep the patient in bed; open the bowels by some gentle laxative; give some slightly diaphoretic medicine, in combination (if there be rheumatic pains especially) with colchicum and an alkali; procure sleep by extract of lettuce or of hyoscyamus; and allow diluents freely. After the first three or four days, if bronchitic rhonchi exist, a blister should be applied between the shoulder-blades or to the sternum, and an expectorant mixture prescribed. This mixture may with advantage be made somewhat stimulant; let the vehicle, for example, be partly ammoniacum mixture, or decoction of senega; lobelia inflata, or paregoric, should enter into its composition. Tonics, iron, and quinine may be given daily during convalescence, unless the stomach have been implicated to any amount. If there be much exhaustion, from the first, sesquicarbonate of ammonia and strong beef-tea should be given without hesitation." (pp. 276-7.)

Syphilitic Bronchitis, and the Narrowing or Obliteration of Bronchi, are next noticed by Dr. Walshe.

Pleurisy. This subject is elaborately treated of. The *physical signs* are referrible to four periods: that of hyperæmia and dryness; of plastic exudation; of sero-purulent effusion, with or without dilatation of the side; and of absorption, with or without retraction of the side. The *diagnosis* is in general simple: but there are several diseases with which pleurisy may be confounded. From plastic pericarditis, plastic pleurisy is distinguished by the respiratory rhythm of its friction-sounds. Friction in the peritoneum, especially at the upper part, is with difficulty distinguished from similar sounds in the lower part of the pleura, as the rhythm is respiratory in both. From pneumonic solidification, acute pleuritic effusion is diagnosed by the disappearance of vocal fremitus; by the absence of crepitant rhonchus, and of *true* tubular, sniffling, metallic respiration; by the vocal resonance being dull, or weakly bronchophonic; by the displacement of the heart and intercostal planes, and the extension of dulness—affected by change of position—across the mediastinum: by the absence of rusty sputa, of acrid heat of skin, and, above all, by the state of the pulse-respiration ratio, which will never be so disturbed as in pneumonia. An enlarged liver will be distinguished by non-protrusion of the lower intercostal spaces, although they are rendered more prominent; by the clear percussion-sound superiorly, and by the tolerably full amount of respiration audible at the posterior base of the chest. An enlarged spleen, if it be sufficiently large to increase the width of the left base of the thorax, raises the heart, but does not push it aside: it extends far into the lumbar region, and as far as or beyond the middle line of the abdomen: it affects but very slightly the respiration at the posterior base of the chest; and causes no protrusion of the intercostal spaces. Leucohæmia, if present, may assist in the diagnosis. The distinctive marks of hydrothorax, intra-thoracic tumour, cancerous infiltration of the lung, and tubercle, are also given.

Under the head of *treatment*, Dr. Walshe enters rather fully into the subject of paracentesis thoracis; an operation which he pronounces as worthy of "being numbered among the valuable gifts of surgery". With regard to the probable success of the operation, the condition of other organs, and the presence or absence of pulmonary tuberculisation, are most important to be taken into consideration: and the operation has been much more successful

in young persons than in those of advanced years. With respect to the period of the disease most favourable for operating, Dr. Walshe makes the following remarks:

"Experience proves, as might have been anticipated, that, when performed at an advanced period, paracentesis is rarely successful; the local changes which then have had time to arise in the pleura, pernicious as these are, are even less subversive of success than the deep constitutional distress entailed by the disease. And yet, to this period, puncture of the chest is often, I might almost say commonly, postponed; it can hardly be matter of surprise, that in some such cases it has appeared to do little more than hasten death. There can be no question that the fitting time for operation has come, when a tendency, insuperable by medical means, exists either to increase or to non-absorption of the fluid. The practical difficulty is, to determine the precise period at which such tendency may be considered to be developed. On the one hand, perseverance in a given mode of treatment has sometimes proved successful, when everything seemed to foretell its probable inefficacy; and, on the other hand, valuable time may be frittered away, and the period at which paracentesis affords real chance of permanent relief but too easily suffered to pass by, from the procrastination caused by a very natural anxiety to give more gentle measures a full trial. A thorough consideration of the whole history of the case, as also of the existing local and constitutional states, is required to enable the practitioner to seize the propitious moment for surgical interference. This difficulty is, unfortunately, not confined to the operation for empyema." (pp. 305-6.)

In operating, as a measure of precaution, a grooved needle may be first introduced; and the best instrument is the trochar, if it be desired to evacuate the fluid by degrees. Under ordinary circumstances, the integuments and pleura should be first incised with a bistoury.

"The first point to be ascertained, in selecting the place for the performance of the operation, is the adherence or non-adherence of the lung to the chest, and, in the former case, the precise limits of the adhesions. It is scarcely necessary to say, that the site of these must be carefully eschewed. When the entire side is free from adhesion, the common advice of surgical writers has been, that the opening be made at the most dependent part of the antero-lateral part of the chest. But undiscriminating attention to this advice, given with the sole view of securing free egress for the pleural fluid, has occasionally led to perforation of the diaphragm and abdominal viscera; even the kidney has been extensively wounded by operators whose practice is to adhere too scrupulously to such injunctions. Laennec recommended the space between the fifth and sixth ribs, a little in front of the digitations of the serratus magnus muscle, as the fittest site for puncture. The importance of opening the fifth instead of a lower space, has been justly insisted on by Drs. Townsend and Stokes, who draw a fair analogical argument in favour of high puncture, from the elevated position in which the discharge commonly occurs, when spontaneous or preceded by the formation of abscess. The opening has sometimes taken place even above the clavicle. If the ribs cannot be clearly distinguished, on account of the presence of marked œdema, some difficulty may arise in fixing upon the spot for incision. Steady and continued pressure with the pulps of the fingers will sometimes enable the operator to discover the edges of the bones, in cases where this would on first view have appeared altogether impossible.

"The place for operation having been duly determined on, an incision of about two inches in length is to be made through the integuments, and the intercostal muscles carefully divided to the same extent. The cutting instrument should not be carried too close to the borders of the ribs, lest the corresponding branches of the intercostal artery be wounded; this statement applies especially to the lower border of the upper of each pair of ribs, along which the superior, and of the two the much larger, twig runs. The division of the

costal pleura itself is by some recommended to be performed with a lancet, but such caution seems useless. When the flow of matter announces the pleura to have been divided, the opening in that membrane should be enlarged sufficiently to give free outlet to the contained fluid.

"If the operator have been unfortunate enough to incise the pleura over the site of firm, thick, and strongly-adherent pseudo-membrane, and in consequence no fluid appear, the line of conduct to be further pursued must vary with the practitioner's confidence in the correctness of his diagnosis in other respects. If he still remain satisfied of the presence of the liquid effusion, the attempt to evacuate this may be proceeded with; if he be apprehensive of having altogether erred, the obvious course is to dress the wound, and avert, as effectually as possible, the ill effects of the unnecessary suffering to which the patient has submitted. In the former case, surgeons have attempted to tear asunder the pleural adhesions,—a procedure utterly unjustifiable: the only admissible modes of acting are, to enlarge the existing opening with the bistoury, or to make a new one. The opening may be enlarged, if the free border of the membranous mass interfering with the escape of the fluid be ascertained to be perfectly close to the angle of the existing wound; under other circumstances, a new incision must be made." (pp. 306-308.)

"Some writers lay very great stress upon the importance of preventing the occurrence of pneumothorax; and there can be little question that the entry of air through the wound is a circumstance which it would be well, if possible, to prevent. But the efficacy of any plan devised for its prevention is extremely questionable. Thus the modifications of the common canula, constructed for the purpose of preventing the occurrence of pneumothorax, have invariably been found failures. The proposal to puncture the chest under water is worth trial. It seems, in truth, well to prevent the ingress of air into the pleural cavity, if possible; and this because the existence of pneumothorax must interfere with the expansion of the lung; and the contact of air with the diseased surface is likely to entail increase of inflammation and decomposition of the fluid retained or resecreted by the pleura. Nevertheless, the prevention of pneumothorax does not by any means appear to be a matter of such importance as considerations of this kind might lead us to expect. In numerous instances, where the physical signs of pneumothorax were distinctly detected after the operation, recovery has ensued.

"Laennec appears to me, as already stated, to have correctly pointed out the description of cases in which it may be advisable to evacuate the contents of the chest, by degrees, and upon successive occasions. Under other circumstances, experience shows that no apprehension need be entertained of ill effects following complete evacuation. Speculative reasons may and have been, by various persons, adduced in numbers in favour of each mode of evacuation; the important point to remember is, that *experience* is in favour of as complete evacuation as possible. Curiously enough, many of the advocates of successive evacuations are at the same time energetic in denouncing the ill effects of pneumothorax; how they reconcile to themselves the recommendation of a mode of operating which doubles, trebles, quadruples, or even still further increases the chances of the entry of air, does not very clearly appear.

"The proposal to ensure the removal of the entire collection of fluid, by drawing off with a syringe any portion of it which gravitates below the opening, is as old as Scultetus. Mr. Jowett and others have proposed modifications of the syringe employed by that surgeon. There does not appear to be any reasonable objection to the employment of these instruments, if they be dexterously introduced and managed; and they may, in some cases, be decidedly useful. Laennec proposed the use of a cupping-glass and exhausting syringe, with the view of drawing off the remains of the fluid, and facilitating the expansion of the lung.

"Is it advisable, under all circumstances, to close the wound after the operation? If the contents of the pleura have been completely evacuated, there can scarcely be any motive for leaving the orifice open. If the evacuation have been only partial, still it is better to close the opening than to leave a canula or tent in it, as the constant renewal of the air in the pleura is decidedly detrimental, and may—unlike entry of air at the first—be prevented by immediate closure of the wound. If, however, any species of canula were devised which would admit of the egress of fluid, and successfully oppose the ingress of air, this objection will cease to exist; and the facility afforded by such an instrument, for the removal of any newly-secreted fluid, will be an important motive for its employment.

"The changes induced by the operation are, or may be, of two kinds; *physiological*, and *pathological*. The former, which are local and general, are as follow: the diminution of the contents of the chest, is, of course, attended with decrease in the dimensions of the affected side. In a case observed by Dr. Townsend, the semi-circumference, which reached sixteen and a half inches before the operation, had fallen to thirteen and three-quarter inches on the ninth day after it. The approximation of the pleural surfaces is rendered manifest, sometimes at a very early period, by the occurrence of friction phenomena; the patient is frequently enabled to lie on the affected side on the day, or even a few hours, after the operation; his dyspnœa is immediately relieved; the state of anxiety under which he laboured disappears; and a sound sleep, the first, possibly, enjoyed for weeks, commonly follows the evacuation.

"Of the *pathological* results, as they may be termed, of the operation, pneumothorax is the most inevitable: the question of its influence on the ultimate issue of the case has already been referred to. The continuance of secretion from the pleural surface for a greater or less period, and hence the constant renewal of empyema, is of very common occurrence. In rare instances, the characters of the newly-secreted fluid remain those of that originally evacuated; in the great majority, they change; the general tendency of the change being of the purulent character. The alteration from the almost purely serous appearance to the purulent is sometimes accomplished in twenty-four hours. When the fluid has been originally more or less completely formed of pus, but of a laudable kind, its conversion into a purulent matter, of bad quality and fetid smell, is not unusually observed. Under these circumstances, the injection of warm water or some other unirritating fluid becomes advisable. Should there be much appearance of putrescency, a small quantity of very weak solution of chloride of sodium may be added. The notion of giving tone to, and diminishing the irritation of the pleura, by injecting tonic preparations, seems of very questionable justness; nor has the practice been attended with sufficiently favourable results to warrant its general employment. Iodureted solutions, or one of nitrate of silver, have more *à priori* reason in their favour.

"In the ordinary course of things, when the case is destined to end by the patient's restoration to health, the wound or wounds in the thoracic walls gradually close, and cicatrisation is perfect within a short period; but in some cases, the opening, instead of closing, acquires the characters of a fistula, which it retains for a variable period, and daily gives issue to more or less pus.

"When spontaneous perforation of the costal pleura has occurred, and a portion of the contents of the pleural cavity escaped through this into the subcutaneous cellular membrane, forming an abscess there, this should be opened without delay, in order to prevent the occurrence of sinuses and burrowing: so well established is this point, that the operation is, under these circumstances, termed *empyema of necessity*.

"Cases of *double* empyema are, as a general rule, unfit for operation, unless evacuation be rendered necessary for the prevention of asphyxia. Should

particular circumstances arise, under which paracentesis might on other grounds become admissible, an interval of time, varying in length with the condition of the patient, should be allowed to elapse between the two operations." (pp. 309-312.)

From the author's observations on PNEUMONIA, we can only afford space for the following remarks on the *seat* of the disease.

Of 1430 cases, 742 were of the right lung, 426 of the left, and 262 of both organs. In 264 cases, the upper lobe was affected 101, the lower one 133, the middle part 30 times. (Grisolle.) The cases of double pneumonia, which furnish 18·3 per cent. of the whole series, were in general not so from the outset; the implication of the second lung was secondary in point of time. This is important; for, in doubtful cases, the existence of the phenomenon at one only, or at both sides of the chest, will aid materially in distinguishing the true crepitant rhonchus of pneumonia, from the sub-crepitant rhonchus of capillary bronchitis. And yet it is very probable that, even by Laennec, double capillary bronchitis has been mistaken for a double pneumonia. Again, the proportion of double pneumonia in the adult does not probably exceed one in twelve; whilst, in new-born infants, the disease is almost always double. Pneumonia commencing about the middle of the lung is rarely primary.

The lobular, interlobular, latent, and intercurrent forms of pneumonia, are briefly but instructively noticed.

GANGRENE OF THE LUNG, HÆMORRHAGE and HÆMOPTYSIS, HYDROTHORAX, PNEUMOTHORAX, EMPHYSEMA, and HYPERTROPHY OF THE LUNG, are next treated of in succession: but we must refer our readers to the original work, with regard to these subjects.

CHRONIC PHTHISIS. This is a subject which Dr. Walshe has had most extensive opportunities of investigating; and with regard to which he has earned a high reputation. We may say, then, in general terms,—for we find it rather difficult to condense the matter so as to retain it in an intelligible form,—that this part of the work fully sustains Dr. Walshe's character as a laborious observer. Passing over, then, a great deal of important matter, we quote the following propositions, in which are embodied some of the most interesting facts, of which the author has actually seen illustrations.

"(*a*) A young adult, who has had an obstinate cough, which commenced without coryza and without any very obvious cause, a cough at first dry and subsequently attended for a time with watery or mucilaginous looking expectoration, and who has wandering pains about the chest, and loses flesh even slightly, is in all probability phthisical. (*b*) If there be hæmoptysis to the amount of a drachm even, the diagnosis becomes, if the patient be a male and positively free from aneurism and mitral disease, almost positive. (*c*) If, in addition, there be slight dulness under percussion at one apex, with jerking or divided and harsh respiration, while the resonance at the sternal notch is natural, the diagnosis of the first stage of phthisis becomes next to absolutely certain. (*d*) But not absolutely certain: for I have known every one of the conditions in *a*, *b*, and *c*, exist (except hæmoptysis, the deficiency of which was purely accidental), when one apex was infiltrated with encephaloid cancer, and no cancer had been discovered elsewhere to suggest to the physician its presence in the lung. (*e*) If there be cough, such as described, and permanent weakness and hoarseness of the voice, the chances are very strong (provided he be non-syphilitic) that the patient is phthisical. (*f*) If decidedly harsh respiration exist at the left apex or at the right apex behind, if the rhythm of the act be such as I have called *cogged-wheel*, and there be dulness, so slight even as to require the dynamic test for its discovery, there can be little doubt of the existence of phthisis. (*g*) If with the same combination of circumstances deep inspiration evokes a few clicks of dry crackling rhonchus, the diagnosis of phthisis, so far as I have observed, is absolutely certain. (*h*) If these clicks on subsequent examination grow

more liquid, the transition from the first to the second stage may be positively announced. (*i*) If there be slight flattening under one clavicle, with deficiency of expansion movement, harsh respiration and slight dulness under percussion, without the local or general symptoms of phthisis, the first stage of tuberculisation cannot be diagnosticated with any surety, unless there be incipient signs at the other apex also; the conditions in question limited to one side might depend on chronic pneumonia or on thick induration-matter in the pleura. (*k*) The existence of limited, though marked, dulness under one clavicle, with bronchial respiration and pectoriloquy, so powerful as to be painful to the ear, the other apex giving natural results, will not justify the diagnosis of phthisis. I have known this combination when the apex of the lung was of model health, and a fibrous mass, the size of a walnut, lay between the two laminæ of the pleura. I would even go further, and say that the combination in question is rather hostile than otherwise to the admission of phthisis; as, had tuberculous excavation formed at one side, the other lung would, in infinite probability, have been affected in an earlier stage. (*l*) Pneumonia, limited to the supra and infra-clavicular region on one side, and not extending backwards, is commonly, but not always, tuberculous. (*m*) Subcrepitant rhonchus, limited to one base posteriorly, is not, as has been said, peculiar to tubercle; it may exist in emphysema and in mitral disease. (*n*) Chronic peritonitis, in a person aged more than fifteen years, provided cancer can be excluded, involves as a necessity the existence of tubercles in the lungs. To this law of Louis's, it is necessary to add the qualification, provided Bright's disease be also absent. (*o*) Pleurisy with effusion, which runs a chronic course in spite of ordinary treatment, is, in the majority of cases, tuberculous or cancerous: the character of the symptoms, previously to the pleurisy, will generally decide between the two. (*p*) Double pleurisy, with effusion, is not, as has been said, significant of tubercle; for it may depend on Bright's disease. If the latter disease can be excluded, carcinoma and pyohæmia remain as other possible causes. (*q*) If a young adult, free from dysentery, and who has not resided in tropical climates, suffers from obstinate diarrhœa, which goes on month after month, with slight remissions or intermissions, even though there be no cough, he is in most strong probability phthisical. If physical signs, to the slightest amount, exist at either apex, he is, almost to absolute certainty, phthisical. (*r*) If a young adult, free from secondary syphilis and spermatorrhœa, and not dissolute in his habits, steadily lose weight, without clear cause, he is in all probability phthisical, even though no subjective chest-symptoms exist. (*s*) But he is not by any means certainly so; for he may have latent cancer in some unimportant organ, or he may have chronic pneumonia. (*t*) Nay, more, he may steadily lose weight, have dry cough, occasional diarrhœa, and night-sweats, and present dulness under percussion, and bronchial respiration under both clavicles, and yet be non-phthisical. I have known all this occur in cases, both when the lungs were infiltrated superiorly with primary encephaloid cancer, and when they contained secondary nodules of the same kind. (*u*) Failure of weight becomes less valuable as a sign of phthisis, the longer the thirtieth year has been passed. (*v*) The discovery of cardiac diseases with marked symptoms deposes against, but does not exclude, the existence of active tuberculisation. (*w*) The existence of cancer in any organ is unfavourable to the presence of tuberculous disease; but tubercle and cancer *may* co-exist, even in the same lung.

"I would here add, for the sake of beginners, a few cautions in the applications of physical diagnosis in phthisis. Never attempt to give a positive opinion as to the actual state of the lungs, where there has been recent hæmoptysis, or when pleuritic effusions, bronchitis, or pneumonia is present: I of course refer to cases where there may or may not be signs of the first stage; if excavation exist, its signs may be unravelled positively in spite of these complications. Trust very very little, if at all, to the conditions of

vocal resonance ; accept with great caution the evidence of slight changes in respiration, unless they be corroborated by percussion-changes ; place no confidence in jerking respiration (even though local) in a hysterical woman, —nor in harsh respiration limited to the right apex in any woman, nor in very very slight dulness at the right front apex in man or woman. Lastly, never give a confident opinion, in a nicely-balanced case, from a single examination ; and make examinations in various postures." (pp. 393-6.)

The conclusions at which Dr. Walshe has arrived with regard to the use of cod-liver oil in the treatment of phthisis, are as follows.

" 1. That it more rapidly and effectually induces improvement in the general and local symptoms than any other known agent. 2. That its power of *curing* the disease is undetermined ;—I mean here, by ' curing' the disease, its power of causing, along with suspension of progress, such change in the organism generally, as shall render the lungs less prone to subsequent outbreak of tubercles, than after suspension occurring under other agencies.[1] 3. That the mean amount of permanency of the good effects of the oil is undetermined. 4. That it relatively produces more marked effects in the third, than in the previous stages. Opinions the most diverse have been held on this point ; M. Taufflied[2] taught that it had little or no effect on phthisis, if at all advanced ; M. Péreyra[3] *reduced the size of cavities in a few weeks* by its administration. 5. That it increases weight in favourable cases with singular speed, and out of all proportion with the actual quantity taken;—that hence it must in some unknown way save waste, and render food more readily assimilable. 6. That it sometimes fails to increase weight. 7. That in the great majority of cases, where it fails to increase weight, it does little good in other ways. 8. That it does not relieve dyspnœa out of proportion with other symptoms. 9. That the effects traceable to the oil in the most favourable cases are : increase of weight, suspension of colliquative sweats, improved appetite, diminished cough and expectoration, cessation of sickness with cough, and gradual disappearance of active physical signs. 10. That in some cases it cannot be taken, either because it disagrees with the stomach, impairing the appetite (without itself obviously nourishing), and causing nausea, or because it produces diarrhœa. 11. That in the former case it may be made palateable by association with a mineral acid ; and in the latter prevented from affecting the bowels by combination with astringents. 12. That intra-thoracic inflammations and hæmoptysis are contra-indications to its use, but only temporarily so. I have repeatedly given the oil within a day or two of the cessation of hæmoptysis, without any return taking place. 13. Diarrhœa, if depending on chronic peritonitis, or secretive change, or small ulcerations in the ileum, is no contra-indication to the use of the oil ; even the profuse diarrhœa caused by extensive ulceration of the large bowel is not made worse by it. 14. That the good effects of the oil are *cæteris paribus* directly as the youth of those using it,—a singular fact, which probably may one day (when the textural peculiarities of youth and age are better understood) aid in giving a clue to its mode of action." (pp. 398-400.)

---

[1] " That such cures really occur in rare instances (and they are as perfect as in any other organic disease, when they do occur) is indubitable. It has been the vanity of late years to deny this absolutely, because a scientific (or pseudo-scientific?) explanation of the fact cannot be found. I am not one of those who refuse to accept the evidence of my senses, because I am unable to comprehend what they teach me, and in this matter echo the sentiments of the physician in a recent French tale, speaking of a phthisical recovery :— . . . . ' ces miracles de guérison, auxquels la Science ne croit pas, faute de les comprendre, *et devant lesquels je me prosterne, en priant la bonne et sage Nature d'en être moins avare.*' Pierre, par Madame Reybaud."

Acute Phthisis, and Cancer of the Lung are next treated of.

Spasmodic Asthma. Under this head, Dr. Walshe states the following remarkable and important fact, with regard to the hygienic treatment of the disease. "Change of air is most important; but the kind of change that shall prove most beneficial can only be learned by experience. Some sufferers lose their paroxysms south of the olive line, others are easiest in a cold atmosphere; moisture, the bane of some, greatly mitigates the disease in others. The air of towns suits some, that of the country others; the clear suburban air of London is infinitely more noxious to some asthmatic persons than the foul atmosphere of the worst cleansed and most densely peopled localities of the metropolis;[1] occasionally an individual will be found who is tortured with asthma in one room of a house, free from it in others; and this without any distinct explanation being found in the aspect, the drainage, or any other known condition." (pp. 416-7.)

Hooping-Cough is the next subject; and then follow some remarks on Intra-Thoracic Tumours. We quote Dr. Walshe's description of the latter form of disease; and would also refer for comparison and further illustration, to a clinical lecture by Dr. Burrows, published in the *Medical Times* for June 7, 1851, and quoted at p. 661 of this Journal for July. Dr. Walshe, premising that the local symptoms and physical signs of mediastinal tumour, whether of simple exudation-matter, scirrho-encephaloid, encephaloid, fibrous, or fibro-fatty, are almost identical, observes:—

"When a tumour occupies the mediastina, and encroaches, as it commonly does, mainly in front, bulging of the sternum and costal cartilages, in a variable spot and to a variable superficial extent, may exist; the intercostal spaces, widened and flattened, are then unaffected by respiration; but, on the other hand, no shadow of bulging may exist, and yet from other signs the presence of tumour be indisputable. Wherever a tumour, of any thickness, reaches the surface, vocal fremitus is annulled; fluctuation, simple or peripheric, is not to be detected; and a double impulse is sometimes transmitted from the heart, and may be felt both by observer and patient as a sort of inward succussion. If the tumour encroach pretty equally on both sides of the chest, there may be no alteration in their relative semicircular measurement; the respiration-play is found to be impaired, and the impairment may fall rather on expiratory retraction than inspiratory expansion. If by chance either main bronchus (and it is much more frequently the right that suffers) be seriously obstructed, the respiration-play will be relatively deficient on that side, independently of the influence of any excess of tumour within the right thorax. Should the tumour encroach notably on one side or the other, and be at the same time adherent to the wall of the chest, the space between the middle line and nipple will be lengthened on the same side. Wherever tumour reaches, or closely approaches, the surface, percussion will furnish an excessively dull short sound, with highly-marked parietal resistance; the superficial dimensions of the growth may thus be traced in the front or in the spinal regions behind. The resistance and resonance of the heart and liver commonly differ from those of tumours; and hence, if the natural and morbid structures are in juxtaposition, their neighbouring edges may be defined by simple or by auscultatory percussion. Near the trachea, or

[1] "A man, one of the greatest sufferers from asthma I ever saw, lived in the neighbourhood of Chalk Farm, the pure air of Hampstead blowing across his house. I tried, I believe, almost every known remedy, in vain, for his relief. He was accidentally detained one night in the foul region of the Seven Dials; feeling persuaded he could not possibly survive till morning, so great was his dread of the close air. He not only lived through the night, however, but enjoyed the first uninterrupted sleep he had known for months. He took the hint; removed to the Seven Dials for the *benefit of the air;* and when I last saw him, some six months after the removal, continued, though still a wheezer, perfectly free from serious dyspnœa."

more generally in front, or even in the back, the percussion note may be tubular, or even amphoric. I have known it amphoric over the lower half of the right back. The auscultatory signs vary widely. The respiration may be weak, almost to suppression over the morbid mass, or (from pressure on the main bronchus) over the side generally ; or it may be of diffused or even tubular or hollow blowing type : these differences will depend on the precise relationship of the growth to the bronchial tubes and parietes ; as will the absence or presence of bronchophony or pectoriloquy of the loud form. The heart's sounds are conveyed through the solid mass with undue intensity, and if this press on the aorta or pulmonary artery, there may be systolic murmur, simulating intra-cardiac murmur at the base. Bronchial dry and moist rhonchi may be heard. The position of the heart, and of the wings or of either wing, of the diaphragm, will depend wholly on the direction in which the tumour grows : they may be considerably displaced, or retain their natural positions, even where a large mass occupies the mediastinum.

" Certain symptoms arise, or may arise, mechanically from pressure of the growth. *Eccentric* pressure causes bulging of the thoracic parietes, as we have seen, and depression of the diaphragm. *Concentric* pressure may produce dysphagia, sometimes, though rarely, of excessive pertinacity, by acting on the œsophagus ; playing on the superior cava or innominate veins, it causes distension of the jugular, subclavian, axillary, mammary, and superior epigastric, facial, frontal, and even dorsal veins, coupled with a tumid spongy fulness of the base of the neck, swollen livid discolouration of the face and lips (which look in extreme cases distended almost to bursting), and œdema of the face, arm, and affected side of the thorax or the chest generally ; encroaching on the inferior cava, pressure entails anasarca of the lower extremities ; influencing the innominate or either subclavian artery, it weakens either radial pulse ; forcing backwards, or to either side, the trachea, it induces stridulous breathing and weakness of voice (traction of the recurrent nerve may have something to do with both these symptoms) ; its effects on the main bronchus have already been referred to, and sequential to these, exaggerated respiration may be established in the other lung. Irritation and pressure-action combined may give rise to active hydro-thorax or actual pleurisy with effusion.

" The symptoms of intra-thoracic tumour are pain, very variable in amount ; dyspnœa ; cough, with or without expectoration, of the jelly-like kinds (p. 412), or catarrhal ; hæmoptysis ; inability to lie with the head low, and eventually complete orthopnœa, the patient sometimes, for weeks before death, never daring to go to bed, and never enjoying more than fitful dozes. The constitution may long bear up against the local disease ; but the dyspnœa and insomnia at length affect the appetite, and emaciation sets in. The patient dies gradually, anasarcous and exhausted, or he may perish suddenly from obstruction of the pulmonary artery.

" An intra-thoracic tumour may, according to its seat, be confounded with extensive chronic pneumonia and chronic pleuritic effusion, with chronic pericardial effusion, great enlargement of the heart, or aneurism of the thoracic aorta. The distinctive marks of the cardiac and arterial affections will be found in the descriptions of these.

" Tumour will be distinguished from chronic pneumonia by the tendency to increase, instead of diminution, of bulk of the affected side, by the implication of the mediastinum, by the greater intensity of the dulness under percussion, the failure or the disappearance of vocal fremitus, which remains in chronic pneumonia, and the different characters of the respiration in the two diseases. Hæmoptysis and red jelly-like expectoration never occur in chronic pneumonia ; whereas the emaciation is of earlier appearance, and more marked than in cases of tumour.

" From empyema, tumour will be distinguished by the absence of intercostal fluctuation, simple or parietal ; by the greater intensity of dulness

under percussion; by the limits of the dulness not being changed by altering the patient's position (p. 284); by the interspaces not being convex; occasionally by the intensity of blowing respiration; by the clear transmission of the heart's sounds; by the comparative irregularity of outline of the side, some spots being more prominent than others; by the fact, that in cases of tumour, careful percussion will almost surely detect some spot giving a comparatively clear sound, where, according to the laws of physics, liquid, had this been the cause of the general dulness, must have made its way, and hence caused dulness there as well as elsewhere; by the whole class of concentric pressure-signs; and, if they have occurred, by hæmoptysis, or by the jelly-like expectoration.

"A patient having mediastinal tumour may also have empyema on the side most encroached on, generally the right. If the patient be seen for the first time, when the two diseases are present, and if precise medical information as to the previous course of the complaint be wanting, this combination may be very difficult of diagnosis. But empyema does not produce concentric pressure-signs, nor give rise to hæmoptysis or jelly-like expectoration; if these symptoms be present, there must be, in addition to empyema, either tumour or aneurism. Besides, the test of moveableness of dull sound (p. 284) may be appealed to with considerable confidence.

"Given an intra-thoracic tumour, how may its *nature* be determined? If the signs of infiltration of the lung co-exist, the tumour, as far as I have seen, is either composed of simple exudation-matter (of these I have examined three microscopically) or cancer. If the tumour present externally, it is cancer; if tumours exist elsewhere, either secondary to, or independent of, that in the chest, supposing even *their* nature cannot be established directly, the chances are strong, that the thoracic growth is cancerous. Violent hæmoptysis is more common with cancerous than other growths; expectoration of cancer can, of course, only occur with the former. The constitutional characters of cancerous disease may be wanting.

"Intra-thoracic tumour is, of course, beyond the *permanent* influence of *treatment*. But it is astonishing what marked *temporary* improvement of all the direct symptoms may be effected by cautious cupping, dry-cupping, flying blisters, profuse inunction with an ioduretted liniment, gentle purgation, and diuretics. I have twice, within the last year, known the diagnosis of intra-thoracic tumour contested, on the grounds of the relief produced by such measures; yet, post-mortem examinations, in one instance in three, in the other, in seven weeks, proved the existence of massy growths. Unfortunately, all therapeutical means soon cease to avail us; and I know no more truly painful spectacle than that of the closing sufferings inflicted by mediastinal tumours." (pp. 421-425.)

The Second Chapter of this part is devoted to Diseases of the Heart.

Functional Disease of the Heart is treated of under the head of increased, perverted, and defective action. Functional heart disease, according to Dr. Walshe, is not always readily distinguished from organic disease. Œdema and congestion may result from spanæmia and nervous palpitation.

Angina Pectoris, and Passive and Mechanical Congestions of the Heart, come next in order.

Pericarditis is described as acute and chronic. The acute disease, in its complete evolution, passes through five anatomical stages,—those of vascularity with dryness, of plastic exudation, effusion, absorption, and adhesion, each of which has its own special physical signs. In the diagnosis, the essential signs are friction sound, special præcordial dulness, and twisting upwards of the heart's apex. Friction sound, when thoroughly developed, is next to pathognomonic; but there is a possibility of fallacy from pleural friction with cardiac rhythm. Mediastinal pseudo-rhonchus, and the squashy rhonchoid sound, sometimes produced over the heart, when the integuments

are œdematous, are other possible sources of difficulty. For the remaining remarks on the diagnosis, we must refer our readers to the book.

In the treatment, Dr. Walshe gives the first place to blood letting, the second to mercury. In rheumatic pericarditis, colchicum should never be omitted; it may be given as a draught with the mercurial pill. Opium, purgatives, diuretics, and diaphoretics, are necessary or advisable. Blisters on the cardiac region interfere too much with examination; but the same objection does not apply to sinapisms, which often afford great relief. Digitalis, aconite, and hydrocyanic acid, are dangerous.

Under the term *chronic pericarditis*, are included two different states,—"that in which effusion remains in the sac without apparent inclination to increase or to disappear; and that in which adhesions or agglutinations of the pericardium having formed, a tendency to active congestion in the pericardium itself, and in the substance of those adhesions, is more or less constantly present. The former condition is rare; the latter common." (p. 450.)

Endocarditis, Carditis, Cardiac Hæmorrhages, Hydropericardium, and Atrophy, are next brought under consideration.

Hypertrophy. This affection is described as affecting the compartments of the heart in the following order of frequency: 1. the left ventricle; 2. the right ventricle; 3. the left; and 4. the right auricle. In speaking of the symptoms produced by hypertrophy of the left ventricle, Dr. Walshe contests the opinion, that apoplexy is a sort of appanage of the heart affection; but he thinks that the whole subject calls for fresh investigation. "It may," he says, "eventually be found, that the fatty diathesis is the real link between cerebral hæmorrhage and heart disease,—fatty enlargement of the heart on the one hand, fatty degeneration of the cerebral vessels on the other." (p. 471.) He believes that hypertrophy alone is rarely, and probably never rapidly, the cause of death.

In the treatment, Dr. Walshe prefers moderate local, to general depletion, for tranquillising the heart, by diminishing the quantity of the circulating fluid. "There is no known drug possessing the faculty of directly controlling the growth of the heart: iodine seems quite valueless; general principles alone guide us in attempting to put a term to the increase of its bulk. Purgative medicines, and, I believe, the saline and aloetic, are the most appropriate of the class; and the effects of local bleeding, diuretics, are useful, quite independently of the existence of dropsy. Direct sedatives of the heart, hydrocyanic acid, acetate of lead, digitalis, and belladonna (the latter both internally, and in the form of a plaister to the surface), must be employed, with occasional intermissions, during the entire treatment of the case. Of all medicines of this class, aconite seems the best: the alcoholic extract of the root may be given in doses of one-eighth of a grain with perfect safety: no drug, that I know of, possesses so fully the power of relieving painful sensations and disquietude about the heart." (pp. 473-4.)

From the section on Dilatation, we quote the following propositions, which bear on the general doctrine of the production of dropsy by disease of the heart:—

"1. Mitral regurgitation or obstruction, or aortic regurgitation or obstruction, may severally exist, and, for a lengthened period, without systemic dropsy supervening. 2. This proposition continues true, whether hypertrophy exist behind the obstruction or not. 3. Simple hypertrophy of the left ventricle may reach the highest point without systemic congestive effects of any kind. 4. Dilated hypertrophy, even of the left ventricle, may last for years without any such effect, provided the dilatation be not in notable excess. 5. The heart may be weak and feeble, or actually in a state of fatty disorganisation, and the pulse feeble and irregular, and yet no systemic congestions occur. 6. The natural relationship of width of the arterial orifices, and also of the auriculo-ventricular orifices, may be materially perverted,

without the least systemic dropsy arising.[1] 7. Tricuspid regurgitation, where the right ventricle is in a state of dilated hypertrophy, as shown during life, by swollen and pulsatile jugular veins which fill from below, and as shown after death by actual examination, does not necessarily produce dropsy.[2] 8. It would appear, then, that something beyond all these cardiac conditions is wanting to ensure the occurrence of dropsy, unless on the gratuitous assumption that, were life sufficiently prolonged, they would in themselves of necessity induce it. What that something beyond the heart, conducive to dropsy, probably is, I will by-and-bye state. 9. The cardiac affections most frequently connected, as matter of experience, with systemic dropsy, are dilatation and tricuspid regurgitation; and it is certainly very rare for either of these states to exist for any length of time without the supervention of such dropsy; any hypothesis, explanatory of cardiac dropsy, must look to these states as forming important links in its chain of causes. 10. But the something beyond the heart? This is probably furnished by certain conditions, favourable to transudation of the serosity of the blood, in that fluid itself, in the walls of the capillaries and venous radicles, and in the receiving tissues. As concerns the blood, the influence of an impoverished state of that fluid is too well known to be for a moment contestible. Again, it is readily conceivable that the variable density of texture of the walls of the vessels shall promote or restrain the process of filtration. Lastly, cases occasionally present themselves, in which dropsy, supervening from diseased heart, fails to affect portions of the body, noted, under ordinary circumstances, as the earliest and readiest sufferers,—for instance, the lower extremities. I have observed this where the legs had been the seat of erysipelas and subcutaneous inflammation prior to the occurrence of the cardiac dropsy; the chronic anatomical changes in the cellular tissue in such a case, possibly act as a barrier to its reception of serosity from the vessels. Dilatation of the heart, occurring as a primitive disease through simple weakness, or actual organic alteration of the texture of the organ, may be easily supposed, *à priori*, capable of generating systemic congestion and its results. In a heart so affected, the necessary *vis à tergo* is deficient,—capillary stagnation ensues. Now this very stagnation, becoming habitual, may modify the qualities of the blood, and impair the nutrition of the walls of the vessels through the strain they suffer. But change in the blood is, in all probability, worked out meanwhile by other and more effectual agencies." (pp. 478, 480.)

Passing over several interesting subjects, we come to DISEASE OF THE ORIFICES. Dr. Walshe enumerates each class of signs apart, under the heads of mitral regurgitation, mitral constriction, tricuspid regurgitation, tricuspid constriction, aortic constriction, aortic insufficiency, pulmonary constriction, and pulmonary insufficiency. He makes the following important practical remarks on the physical examination of VALVULAR DISEASE:—

"In fixing the seat of production of any given murmur, the first point for the observer to establish, is the position of the heart itself: if this be abnormal, as it very often is in consequence of changes in its substance, allowance must be made for its influence in altering the maximum position of murmurs. Now, the general tendency is to some form of enlargement of the organ, and as enlargements lower it, the maxima points of murmurs are very commonly slightly lower than the maxima points of the corresponding sounds in health. Certain conditions of the aorta or pulmonary artery, of the lungs, pleura, or

[1] Case of Cyanosis. Med. Chir. Trans., vol. xxv, p. 1.

[2] "W. Hallington, ætat. 53, died at University College Hospital, April 7, 1849, with fatty dilated enlargement of the heart (weight 17½ oz.), dilatation of the tricuspid and mitral orifices, and aortic regurgitation carried to a great extent, and yet not a particle even of œdema about the ankles had appeared. The patient had also an aneurism of the aorta, at its bifurcation; but this could not be held to be *preventive* of dropsy."

mediastinum, also throw murmurs into unnatural sites, by changing the position of the heart. Pleural fluid accumulations have more influence on apex than on basic murmurs, for an obvious reason.

"The state of the heart's substance also may exercise a direct influence on the intensity of the murmurs. Thus hypertrophous texture, lying in the course of the circulation, behind a murmur, will intensify this, if it be direct; exercise little effect on it, if it be regurgitant: take the instance of an hypertrophous left ventricle with severally a constrictive and a regurgitant aortic murmur. Hypertrophous texture, lying in front of a murmur, is without effect upon this, if it be direct; intensifies, if it be regurgitant: take the instance of an hypertrophous left ventricle with severally a constrictive and a regurgitant mitral murmur. Dilatation and weakening affections of the heart's substance weaken any direct murmurs through orifices on which such substance may play. Dilatation lessens the force of a regurgitant murmur, in so far as power of backward propulsion is concerned; but as, on the other hand, it allows of considerable accumulation of blood for regurgitation, the weakening influence is somewhat counterbalanced. The physical conditions of a given murmur positively existing at a given orifice, the character of that murmur may be seriously affected by the anatomical state of other orifices. Thus, aortic constriction may be almost murmurless, if there be any great coexistent regurgitation, the aortic current is so seriously weakened by such regurgitation.

"Of two murmurs produced synchronously at different orifices, one may mask or cover the other. An aortic constrictive and a mitral regurgitant murmur may exercise this influence on each other; and a mitral regurgitant may completely drown a tricuspid regurgitant. In the interspace between the maxima points of two synchronous murmurs, however, a spot may generally be caught where the intensity of murmur is less than at either, and the quality different.

"An hypertrophous and widened state of the aorta will intensify its own regurgitant murmur; and if slight pouching exist at the sinuses of Valsalva, the rippling direction thereby given to the current will intensify both a direct and a regurgitant murmur. The state of the blood, too, is important; spanæmia greatly strengthens the force of murmurs of all kinds. The pulmonary veins and superior cava may be the seat of spanæmic murmur, simulating especially systolic apex and diastolic basic cardiac murmurs.

"Again, modified conducting power of adjoining textures may lead to error: thus an aortic regurgitant murmur may be heard better to the left than to the right of the sternum, if the left lung be solid, and the right emphysematous." (pp. 509, 511.)

Malpositions, Cyanosis, Rupture of the Heart, Aneurism of the Heart, and Polypoid Concretions, are next treated of, and with them the chapter on Diseases of the Heart terminates.

The Third Chapter contains an account of Diseases of the Aorta, arranged under the heads of Aortic Pulsation, Aortitis, Atheroma and Calcification, Coarctation and Obliteration, and Aneurism. We had intended giving some extracts from this chapter, but we find that we have already occupied so much space, that we must bring our analysis to a conclusion.

The general opinion which we have been led to form from a perusal of Dr. Walshe's book, is, that it is the production of a laborious and careful observer of facts, who has been desirous of placing before the profession the results of his own observations. Observation is his *forte;* and in this he is a worthy disciple of his great preceptor, Louis. And we would assure Dr. Walshe, that, though we do not pledge ourselves as yielding an implicit assent to everything he says, yet we meet him here with far more pleasure than when we protested, two years ago, against his sweeping condemnation of physiology

as a guide in medicine. We are sure that both the merits of the book, and the high reputation of the author, will ensure for Dr. Walshe, on the *Diseases of the Lungs and Heart*, an extensive and rapid circulation among the enlightened practitioners of the present age.

Sleep and Dreams. By John Addington Symonds, M.D., Bristol. Bristol: 1851.

Were any apology for the publication of Dr. Symonds' lectures upon Sleep and Dreams necessary, it would be found no less in the interest of the subject than in the author's philosophical mode of handling it. The mystery which yet envelopes the action of the nervous system, and the importance of its solution, must attract all observers of nature to any attempt at discovery undertaken in a proper spirit and with due preparation; and we are bound to say, that in the lectures now under review, there are to be found research, candour, and intelligent information, equal to the generalizing both of facts and doctrines. Further, the style is not such as to repel inquiry into, or acquaintance with, the subject matter of the work; the quotations are apt, adding force and vividness to the descriptive parts, while the language employed is sufficiently precise for the physiologist, yet simple enough for the general reader.

In his first lecture, which is devoted to Sleep, the author begins by a description of its ordinary phenomenon, and then refers to its morbid states, the metaphysics of which he explains upon Bishop Berkely's theory. Our author next sketches the physiology of the brain and nervous system; and in the course of his speculations upon the changes which it undergoes during sleep, he adduces the opinions of the most eminent authorities of the day upon such subjects, and amongst others that of Dr. Snow, who propounds that sensation, motion, and thought are closely connected with certain processes of oxidation going on within the body, which processes are stayed during sleep, whether produced naturally or by narcotics.

The circumstances favourable to sleep are then described, amongst which plethora is particularly insisted upon, and with much propriety, as the experience of all whose attention has been directed to the subject can testify. But the mode in which plethora determines sleep is not described, or rather the description is such, that the impression conveyed to the mind of the reader must lead him to the belief that the cranium actually receives and contains in such circumstances a larger portion of blood than usual, a doctrine which we had supposed to have received its *coup de grâce* long ago in the hands of Abercrombie, Hughes, Reid, Kelly, and more lately from Professor Bennett. The integrity of the principle thus established, is by no means impugned by the fact of passion acting as a cause of sleep; on the contrary, it has been shown that all the effects of plethora are brought on by an opposite state of the system, inducing pressure by an alteration in the balance or proportions of the arterial and venous circulation within the head, which, in all cases connected with extravasation or morbid excess in the fluids of the brain, must be held to be the cause of mechanical compression of that organ. The auxiliaries to healthy sleep are pleasingly dwelt upon and illustrated, and of these we fully agree with the author, that none ranks higher than "a conscience void of offence towards God and towards man", when—

> "Nec lenes somnos timor aut cupido
> Sordidus aufert."

The second lecture is devoted to Dreams, and offers as complete and reasonable an explanation of their occurrence as the present state of physiology can supply. However, if dreamless sleep be dependent partly upon pressure on the brain, it might have been worth while to inquire what parts of the brain are naturally most obnoxious to that influence, and whether any rela-

tion could be traced between immunity from pressure, and activity in those parts of the organ so relieved. With reference to the action of narcotics and the *modus operandi* of indigestion in producing imperfect sleep and dreaming, a little inquiry would have been highly interesting. The psychological aspect of the subject receives a due share of the author's attention, and in truth is that point of view most likely to attract general notice. For its further elucidation, we would suggest to the author, that those classes of observations all tending to confirm a fact observed by himself, viz., the ease with which ideas are suggested during imperfect sleep, are worthy of being minutely considered. The first of these, then, consists of external impressions, as cold, heat, etc.; the second of impressions caused by some irregularity of the nutritive process; and the third of those manipulations of Mesmerists by which certain ideas can be excited or suggested. Whatever notion may be entertained of the nature of mind, it is very certain that mental phenomena are never manifested disassociated from certain forms of nervous matter, and this consideration is favourable to the opinion now almost universally entertained, that the path to discoveries on this subject lies in the investigation of physical action. The treatment of the subject of dreams would not have been complete without a reference to their prophetic import, which is discussed in a thoroughly enlightened manner. We would not flatter the author that his reasoning is likely to convert any considerable number of the old women of either sex who believe in dreams, but we can easily suppose that many of his hearers whose nursery impressions had not been entirely effaced, may have been led to the consideration and ultimate settlement of a question which heretofore they had been content to consider an open one. We must now conclude this hasty notice with a recommendation to all whom it may concern to peruse Dr. Symonds's lectures, and we promise them an antidote to the soporific title of the subject, in the philosophic and entertaining style in which it is treated.

Beasley's Pocket Formulary of the British and Foreign Pharmacopœias. pp. 546. London: 1851.

This small volume is barely within the scope of our Journal, although addressing itself in the advertisement to the medical practitioner and student; for it would prove of but slight use to the former, and none at all to the latter.

It was originally compiled "as a Counter Companion to the Dispensing Chemist", for which purpose it appears to be well adapted, as it contains many of the formulæ of the Foreign as well as of the British Pharmacopœias; and as the daily increasing facilities of travelling multiply our visitors from the Continent and the United States, the necessity of compounding prescriptions according to the Pharmacopœias of various countries will be forced upon Chemists and Druggists, especially in our large towns, in which case this book will prove a useful guide.

It would however be far more useful were it reduced in bulk, and a heap of such rubbish as the following weeded out:—"Electuarium Anticachecticum, *Bath Electuary*", consisting of "the heaviest and bluest clinkers from a blacksmith's forge", powdered and made into a stiff paste with treacle, and then mixed with a little carbonate of magnesia and ginger; Linimentum Zingiberis, a "remedy for *short-sightedness*", and such like stuff with which the book abounds. The nomenclature is also very faulty, ancient and modern terms being indiscriminately used; nor has the author always kept in mind the alterations in the new Pharmacopœias; he thus orders the same quantity as formerly of acid. sulph. dil. to be used in making tartaric and citric acids, whereas it should be increased, this preparation of the London College being weaker than before. So far, however, as we have compared it with the original, the formulæ generally appear to have been carefully extracted; and we think the book is one which may often prove useful to the Dispensing Chemist.

CRITICAL DIGEST OF THE BRITISH AND FOREIGN MEDICAL JOURNALS.

PRACTICE OF MEDICINE AND PATHOLOGY.

DR. E. D. FENNER ON THE FEVERS OF NEW ORLEANS, PARTICULARLY THE YELLOW FEVER OF 1849: ABORTIVE TREATMENT BY QUININE.

THE following is derived from DR. FENNER'S valuable Report on the Fevers of New Orleans, originally published in 1849, in the *Southern Medical Reports*, vol. i, p. 109: and reprinted in the *Edinburgh Med. and Surg. Journal* for October 1851.

In New Orleans, as well as in the surrounding country, the fevers are intermittent, remittent, and continued, "alternating in type, and running into each other." In summer and autumn, they have a decided tendency to crisis by hæmorrhage: "this", says Dr. Fenner, "*makes yellow fever:* it forms the true characteristic difference between the high degrees of summer and autumnal fever in the city and country, and must depend on locality and attendant circumstances. During the healthiest years, it predominates over all other types; but during the sicklier years, in the country, it runs into remittent, bilious, and congestive; whilst in the city, it runs into yellow fever. Dr. Harrison testifies, that he had often observed malignant intermittents immediately to precede the outbreaks of yellow fever epidemics."[1]

Dr. Fenner's observations being drawn from a vast public and private experience; and in particular from observations made in, and from the statistics of, the New Orleans Charity Hospital, which is probably the most extensive fever hospital in the world, the following statement is of peculiar force:—"Physicians may say what they please about being able to distinguish a case of yellow fever, as soon as they examine it: we do not believe it possible, according to their ideas. Rarely does a summer pass, in which we do not hear of some intelligent and experienced practitioner being perfectly asto-

[1] These statements testify to the *general truth* of the opinion, that fevers differ as to their degree but not as to their pathology. Dr. Cormack, writing in December 1843, upon the Edinburgh epidemic fever then prevailing, says:—"From a careful study of two hundred cases, and the casual observation of twice as many more, I have found, that many had an interval of perfect health between the attacks, whereas others had only a remission,—that a number of both of these classes of patients had jaundice, hæmorrhages, and vomiting of black matters,—yet so distinct was the connecting link of cases between these groups, that it never occurred to me (nor to any one else, I suppose) to consider, that these variations in some of the phenomena, constituted two distinct fevers. Symptomatic distinctions are important in the regulation of the treatment; but, were they adopted in speaking of the pathology of the disease, they would lead only to partial, and erroneous views. It is the arbitrary method of classification, and the dressed-up descriptions of systematic authors, which make it appear to the cursory student, that the fevers of tropical climates are different from those of this and other temperate countries; whereas, were epidemics of different climates studied as they actually occur, it would be found that fevers differ as to their degree, but not as to their pathology." . . . As an illustration of the "breaking up of an epidemic into different fevers, for the purpose of making a neat return", Dr. Cormack quotes one of the tables from the Army Reports referring to Jamaica, adding this remark: "The cases styled remittent fevers, might very often with as much propriety have been called yellow fever; and in the other classes, difficulties would occur as to the distribution." *Cormack on Fever*, pp. 99, 100. Edinburgh: 1843.

nished at seeing what he had pronounced a case of intermittent or remittent bilious fever terminate in black vomit or other hæmorrhage."

Dr. Fenner is a very warm advocate in favour of the administration of large doses of quinine for the purpose of cutting short yellow fever. In fact, he urges the excellence of the abortive treatment of yellow fever, with the same confidence that Dr. Dundas recommends the same treatment in the continued fevers of this country. The experience of Dr. Fenner certainly gives additional strength to the important practical doctrine, which Dr. Dundas has brought before the profession.

The following are Dr. Fenner's remarks on the therapeutic action of the sulphate of quinine :—"The sedative powers of large doses of quinine, given during the early exacerbation of our summer and autumnal fevers, remittent, bilious, and yellow, have been proclaimed by some of the physicians of this city, by the army surgeons, and by the physicians of the Southern States, in the medical journals for the last ten years. We perceive that these views are gradually extending to the North, and will certainly take there, if properly tested ; but it will require some time to prepare the minds of our northern brethren for such a revolution in therapeutics, as they must effect when established. The wonderful powers of the sulphate of quinine over the yellow fever of New Orleans, are briefly but forcibly set forth in the essay of the late Professor John Harrison, in the second volume of the New Orleans *Medical and Surgical Journal.* Also by Dr. J. Beagnot, a prominent French practitioner of your city, in the first volume of the same Journal. Dr. Beagnot informs us, in a recent conversation, that notwithstanding the favourable mention he then made of the abortive treatment, by large doses of quinine immediately after free blood-letting, he did not adopt it ; but relied chiefly on the lancet alone." . . . . . " Quinine is given in five or ten grain doses by a number of physicians of this city, and the southern country, who have not yet adopted the abortive method. This is a great improvement; but they will go farther after a while. We saw twenty grains with twenty-five or thirty drops of laudanum given at the Charity Hospital, in the early stages of yellow fever, by physicians, this seasons, who would have shuddered at such a prescription three years ago."

ENLARGEMENT OF THE SPLEEN AS A CONSEQUENCE OF INTERMITTENT AND REMITTENT FEVER: ITS TREATMENT BY IRON AND IODINE.

The Madras Medical Board has published a valuable report, by Dr. G. Smith, " On enlargements of the spleen observed during an epidemic of intermittent fever, which attacked the 18th regiment Madras native infantry, in Goomsoor, in 1847-1848." The facts adduced point out, if that be still necessary, the visionary nature of the doctrine of Piorry, viz., that the enlarged spleen is the cause and not the consequence of intermittent and remittent fever. In the first instance, the enlargement is transient and dependent on simple sanguineous congestion : in chronic cases, we find more or less permanent induration and change of structure, but the nature of the latter has not yet been fully made out. The *Edinburgh Monthly Journal* (October 1851) gives the following summary of Dr. Smith's treatment.

" In some cases, even in persons who had suffered often from intermittent, the mere arrestment of the fever, with the subsequent use of laxatives and diaphoretics, removed very considerable enlargements in periods varying from five to ten days; in one instance, a cure was effected in sixteen days, though the edge of the spleen was at one time an inch and a half below the umbilicus ; and occasionally the cure takes place quite suddenly, the spleen returning to its natural size within four-and-twenty hours, though it may have remained much enlarged for several days after the cessation of fever. When these simple measures do not appear in a few days to promise speedy

recovery, the remedies principally to be depended on are chalybeates, and the stimulus of pressure and kneading. Dr. Smith usually gave iron in the form of sulphate, and along with aloes and iodine. Two grains of sulphate of iron, two of aloes, and one of iodine, were given twice or thrice a day, in the form of pill, made up with aromatic confection; and twice or thrice daily the enlarged organ was subjected to firm kneading with the hands. The efficacy of this treatment was tested by subjecting some severe cases in the first instance to diet, regimen, and laxatives alone, without avail. Even where there is reason to suppose, from the long duration, and great extent of the enlargement, that the disease must have advanced partially to the stage of hypertrophy, a cure may be accomplished by the same means; but then it is tedious, and may extend through several months.

"While it appears that few can resist the tendency to spleen disease, in localities so favourable as Goomsoor to the production of intermittent, Dr. Smith mentions some interesting facts, in proof that some constitutional tendencies must predispose to visceral disease in such circumstances, and others operate as a protection. It is remarkable that in the epidemic he describes, the European constitution seemed less inclined to disease of the spleen than that of the natives. Of twenty-three European officers, twenty had fever; but none of them suffered from enlargement of the spleen. And he adds the case of an officer who had constantly remained exempt during repeated attacks of severe ague, throughout a period of twenty years. Age diminishes the predisposition; for the disease occurred almost entirely among the young and middle-aged sepoys, the old members of the regiment, who suffered from fever, being very rarely observed to suffer from enlargement of the spleen."

PATHOLOGICAL RESULTS OF BRONCHITIS.

1. Primary Results of Bronchitis.

(*a*) *Obstruction of the bronchi from swelling of mucous membrane and from secretion.* The anatomical condition consequent on such obstruction, when long continued, as in the case of inspissated secretion, is collapse of those portions of the lung to which the affected tubes are distributed. The collapsed condition is often termed "carnification", and is identical with the infantile atelectasis; it is denoted by condensation and want of air, without appreciable exudation, comparative increase of weight, an unusually dark colour, the consistence unaltered. This collapse may be diffused, or limited and lobular, the latter being a form which has been so often described as "lobular pneumonia". It is, however, destitute of the minute granular aspect of true lobular pneumonia; under the microscope, scrapings from its surface show only blood-corpuscles, epithelium, and a few pus-cells from the bronchi, instead of the abundant granular elements and cell-forms which are obtained from lungs in which exudation has occurred; and, in the majority of cases, the condensation is removed by inflation.

The general result of Dr. Gairdner's inquiries in this direction is expressed in the following propositions:—

"1. That in all cases of collapse of the lung not caused by external pressure, the bronchi have presented unequivocal appearances of obstruction.

"2. That in most, if not all, the instances of severe and fatal bronchitis, especially if the secretions had become ropy or inspissated, more or less collapse of the pulmonary texture has also been present."

The mechanism of this bronchitic collapse is thus explained: it is argued and shown to be probable, from all the facts that can be brought to bear on the subject, that obstruction in a bronchial tube, even if it be incomplete, leads to diminution in the quantity of air contained in the tubes beyond the obstruction. To account for this, it has even been supposed that the air is absorbed into the vessels; but Dr. Gairdner justly puts aside this hypothesis,

and believes that the comparative greater power of the expiratory over the inspiratory act (as 3 to 2) may account for the diminution of the air. The peculiar nature of the obstruction will also aid the expiratory act, as it is pointed out, that, the bronchi being a series of tapering and dichotomizing tubes, a tough pellet of mucus will fall towards the smaller end, and, during inspiration, will of course pass onwards still deeper into the narrowing tube, and perfectly block it up; while, in expiration, if it can be moved at all, it is forced into the wider portion of the tube, and allows the air to pass. And, in addition to this, if the plug be insufficient to close the main tube, it may be carried against one of the openings of the next bronchial division, and completely block it up. Besides these causes, anything which tends to produce insufficiency of the inspiratory act will aid this.

(*b*) *Bronchial Abscess.* In the centre of a lobule collapsed from bronchial obstruction, a small collection of pus can sometimes be found, varying in size from a hemp-seed to two or three times that size; the pus is sometimes surrounded by a "villous" membrane, at other times lies in contact with the pulmonary tissue; the tubes leading to such abscess are found much inflamed. This lesion is most common in children, but is found in adults, and has often been described as tubercle. The origin of these abscesses appears to be,—first, the collection of pus in the central bronchi of a collapsed lobule; secondly, the retention of this by changes in the bronchus higher up; and, finally, softening, and ulceration of the coats of the central bronchi and escape of the pus among the adjoining parts.

2. Secondary Results of Bronchitis.

Dr. Gairdner remarks, that, notwithstanding the apparently grave nature of bronchitic collapse, many cases get well. In inquiring into the mechanism of recovery, he takes occasion to point out, that the great function of the muscular fibres in the bronchial tubes may be a deobstruent one; that these fibres, which are certainly passive in the respiratory act, may be constantly undergoing a kind of peristaltic action even in health, which tends to force on the secretions in the tubes. Consequently, in collapse, these fibres may succeed in dislodging the thickened mucus, and in rendering the tube again free to the passage of air. He then goes on to remark on the production of

(*a*) *Emphysema.* From an analysis of forty cases of emphysema, it is shown, that 67 per cent of all cases of emphysema are connected with pulmonary collapse of other portions of lung; that 10 per cent. are connected with hepatization; and 20 per cent. with tubercle.[1] There is, therefore, evidently some intimate connexion between the first-named lesion and emphysema. The most common anatomical seat of emphysema is at the anterior borders of the lungs; while that of bronchial collapse is in their posterior and depending parts; and the way in which the former is produced by the latter is by a disturbance of the mechanism of respiration, that is to say, the collapse of some portions of the lungs permits the over distension of other and previously sound portions. The anatomical postulate, if we may so term it, of emphysema of one portion, is diminution of bulk of another part; and this diminution is most commonly from the pulmonary collapse of bronchitis; but it may be from the cicatrization of cavities, or other causes leading to atrophy of a portion of lung.

(*b*) *Permanent Atrophy of Lung.* Another secondary result of bronchitis is chronic collapse passing into actual atrophy, in which the tissue becomes impermeable to air from actual obliteration of the air-cells. Here the result is the same as after long-continued compression from pleuritic effusion. In such cases of atrophy, the affected parts are reduced to a lax fibrous or are-

[1] Dr. Gairdner observes, that the dogma of the antagonism of tubercle and emphysema, or rather of venosity and tubercles, derives no support from the results of his cases.

olar texture, enclosing the remains of bronchi and vessels, perfectly flaccid, free from all induration or abnormal exudation.

(*c*) *Bronchial dilatations* are ascribed in part to the expansive forces of inspiration acting upon the bronchi of atrophied lung; but it is also argued, that they are "the result of ulcerative excavations of the lung communicating with the bronchi." These excavations then become lined with a false membrane, which is smooth, glistening, and not very vascular, and which is continuous with the lining membrane of the undestroyed bronchial tubes.

(*d*) *Pulmonary Concretions and Cicatrices.* Both concretions and cicatrices have been referred to obsolete and cured tubercle, and no doubt this view is, in a great number of cases, the correct one. But as excavations occur not only from softened tubercle, but also (as it appears) from ulcerative processes following simple bronchitis, broncho-pneumonia, syphilis, gangrene, isolated and multiple abscess, etc., so also such cavities may heal, and give rise to cicatrices, which can only be distinguished from healed tuberculous cavities by collateral evidence. So also concretions, though so often of tuberculous origin, may yet be derived from any other form of pulmonary ulceration or abscess.

Such is a short, and necessarily an imperfect abstract of a very interesting series of papers, the facts of which have to be tested by the observations of others before they can be definitively admitted by practitioners, but which have certainly been collected with great care and industry, and which, as far as we can see, bear on them the impress of truth. (*Edinburgh Monthly Journal*, as abridged in *Medical Times*.)

ON SUPERNUMERARY FINGERS AND TOES. BY ROBT. CRAWFORD, M.D.

"The following facts," Dr. Crawford remarks, "are worthy of being put upon record. They are curious and interesting in a physiological point of view, as illustrating the *paternal* influence on the *physical* conformation of the offspring, and afford an example of the rare occurrence, that a man may have by different women children with the same malformation, as observed by Luber and Meckel, and, what is more rare still, that a deformity of the *father* may be transmitted to his children, as remarked by Burdoch and Osiander,—nay, even to his children's children, disproving the notion frequently entertained, that monstrosities are dependent on the imagination of the mother, frights, etc., etc., and, I may add, are independent of any *original* malformation of the germ, which has been assigned as a cause of these aberrations of nature.

"Mrs. T., after a safe and speedy labour, was delivered of her second child, a strong healthy male, on 19th ultimo. The infant had two supernumerary fingers, one attached by a pellicle to the external aspect of the metacarpo-phalangeal articulation of each little finger. They were well formed, with nails and three phalanges each, but the tendons were in a very rudimentary state. Mr. Craig informs me that his former assistant, Dr. Legat, now in extensive practice at South Shields, attended Mrs. T. in her first labour, and removed from the baby (a female) two supernumerary fingers similarly situated. I have ascertained also from Mr. T., that he had two fingers removed in infancy from the same parts of the hands as his children had, the cicatrices of which he showed me. He has, besides, six toes on each foot. The supernumerary toes project from the dorsum of the middle metatarsal bones. All Mr. T.'s brothers and sisters had more than the natural number of fingers or toes,—some both. His father, who had six toes on each foot, by a second marriage had a son and three daughters. There was nothing peculiar about the latter, but the son has the proximal extremity of both great toes single. They appear to bifurcate about the centre,—or rather, each forms, *from the centre*, two toes surrounded by one continuous skin, terminating at the distal extremity by two nails each. A sister of Mr. T.'s, married, had four children, of whom one (a daughter) has six toes on each foot.

"On the authority of a respected clerical friend, I also state the following facts, which he can personally verify, and which occurred in a parish where he at one time held the *cure:*—

"A female relative (either a sister or aunt) of A. B., had a child with a supernumerary finger or toe on each extremity. A. B. married, he had eight children, two of whom had six fingers or toes on each extremity. A young woman in the neighbourhood accused A. B. of being the father of a child with which she was pregnant; but this he strenuously denied. The woman brought forth twins, and each had six fingers on each hand, and six toes on each foot,—certainly a remarkable coincidence, if the woman's accusation was false; but more probably a strong presumptive proof of the paternity of the offspring. I may add an instructive medico-legal fact, which occurred in the same locality, and which I state on the same authority. A theft was committed, and the authorities, while investigating the matter, detected the impression of a foot on the soil; it presented the appearance of *six toes*, and was traced to the son of A. B. without any difficulty." [*Edinburgh Monthly Journal*, October 1851.]

APPOINTMENTS.

Black, Dr., appointed Warden to the Collegiate Establishment of St. Bartholomew's Hospital, in the room of Mr. Paget, resigned.

Henry, Alexander, M.D., appointed House-Surgeon to the West Kent Infirmary.

Miller, Dr., of Chelmsford, appointed Inspecting Physician of the Lunatic Asylums of the County of Essex, in the room of the late Dr. Badeley.

Parker, Dr., elected Assistant Physician to the London Hospital, in the room of Dr. Pereira, appointed Physician.

OBITUARY.

Hooper, R. L., M.D., of High-street, Newington Butts, aged 55, on 8th November.

Semple, Robert, Esq., many years Medical Officer to the parish of St. Mary, Islington, in Cross-street, Islington, aged 62, on 5th November.

TO CORRESPONDENTS.

Homœopathy. Various communications have been received on this subject; and their authors will be duly communicated with.

OUR NEW VOLUME.

The January and February numbers will contain Communications by:—

Dr. C. J. B. Williams.
Dr. Tyler Smith.
Dr. Sandwith, (Hull.)
Henry Lee, Esq.
Edward L. Falloon, Esq., (Liverpool.)
W. H. Gardner, Esq.
Dr. Mackenzie.
Dr. James Bird.
Dr. Moore, (Ballymoney, Ireland.)
William Harvey, Esq.

AND OTHERS.

INDEX TO VOLUME III.

Abdomen, Dr. C. J. B. Williams on physical examination of, in health and disease, 1, 97, 193; examination by inspection, 2; visible signs of disease in, 3; examination by palpation, 97, 193; Mr. T. H. Wakley on a case of recovery from injury of, 677; Mr. H. C. Field's case of recovery from punctured wound of, 857

Abercrombie, Dr., death and autopsy of, 549

Abscess in neck after scarlatina, Dr. Dépéret-Muret's case of, 373; metastatic, Mr. H. Lee on formation of, 621; perineal, Mr. Milton on, *rev.*, 1014; bronchial, from bronchitis, Dr. Gairdner on, 1144

Acephalous monsters, Dr. Hohl on, 50

Acids, vegetable, M. Delioux on physiological and therapeutic action of, 656

Aconite in papular eruptions, 165

Acranial fœtus, Mr. G. B. Childs' case of, 93

Acton, Mr. W., on Diseases of Urinary and Generative Organs in both Sexes, *rev.*, 644, 709; on blennorrhagia, 644; balanitis, 645; acute inflammation of prostate gland, 646; epididymitis, *ibid.*; inflammation of the bladder, 650; blennorrhagia of vulva, 651; of urethra in female, 652; of vagina, *ibid.*; of ovary, 653; warts, *ibid.*; syphilis, 709; primary syphilis, 710; chancre, *ibid.*; inflammatory chancre, 713; phagedænic chancre, *ibid*; other forms of chancre, 714; secondary syphilis, *ibid.*; syphilitic cutaneous eruptions, *ibid.*; mercurial fumigations, 715; tertiary syphilis, 716; causes of death from syphilis, *ibid.*; syphilis in infants, 717

Adams, Dr. C. G., case of hæmoptysis neonatorum, 665.

Address to the Hunterian Society of London, Dr. Lever's, *rev.*, 456

Air, bad, influence of, in producing phthisis, 402

Air in heart, Dr. Berry's case of, in sudden death after labour, 81

Alison, Dr. Scott, analysis of seventy cases of disease of the heart, 293; on flattening of chest from posture, simulating phthisis, 1070; influence of curvature of surface on sound, 1073

Allchin, Mr. A., on uncertain strength of tincture of opium, 177.

Almanacs, Mr. De Morgan's Book of, *rev.*, 546

Aloin, Messrs. T. and H. Smith on, 269

Cæsarean Section, case of, by Dr. West, 279; by Dr. Oldham, 280; Dr. Radford's successful case of, 947
Cafein, citrate and lactate of, 750
Caizergues, Professor, on bismuth and belladonna in gastralgia, 563, 720
Calcareous concretions in tumour of optic thalamus, 368

Calculi in pelves of kidneys, 664; Mr. Poyser's case of large renal, 787; phosphatic, Dr. Hoskins on decomposition of, in bladder, by salts of lead, 890; case of large biliary, 955
Calomel, and hemlock, in ascites of children, 468. *See* Mercury
Campbell, Right Hon. Lord, Dr. Snow's Letter to, on Chloroform, *rev.*, 353
Camphor, Dr. Snow on inhalation of, 127; Dr. Deutsch on, in cancrum oris, 374
Cancelli of bone, Professor Wyman on arrangement of, 258
Cancer, Mr. Simon on nature of, 345; of uterus, Dr. Oldham's cases of labour complicated with, 204; remarks on occurrence of, in connexion with pregnancy, 207; colloid, of peritoneum and colon, Drs. Ballard and Semple's case of, 801
Cancerous tumours of neck in a child, 554; tumour removed from orbit, 775; disease, secondary, case of, 856; in mediastinum, Dr. Walshe on diagnosis of, 1135
Cancrum oris, Dr. Deutsch on local application of camphor in, 374
Cane, Mr. W. H., case of tracheotomy in epilepsy, 773
Cannabis Indica, a stimulant to uterine contraction during labour, 1048
Cantharidin, Mr. Proctor on chloroform as a solvent of, 748; ointment of, 952
Canton, Mr. Alfred, the Teeth and their Preservation, *rev.*, 654
Caries of spine, Mr. Verral on, 1012
Carpenter, Dr. W. B., Principles of General and Comparative Physiology, *rev.*, 719; Manual of Physiology, *rev.*, 1018
Carpenters, why subject to genu valgum, 732
Cartwright, Dr. S. A., case of application of caustic to Fallopian tubes, 742
Casein in blood, Dr. Panum on, 255
Casts, granular, in renal disease, Dr. G. Johnson on, 112; waxy, 115
Catalogue of Medical and Scientific Works, *rev.*, 654
Catamenia, cases of retention of, 736, 741, 952
Cataplasms, galvanic, of M. Recamier, Dr. Tilt on, 681
Cataract, Mr. B. E. Brodhurst on, *rev.*, 154; hard, displacement of, by lateral traction, 267; sudden recovery of sight after operation for, 278
Catheterism of Fallopian tube, Dr. S. A. Cartwright's case of, 742
Cauliflower excrescence of uterus complicating labour, Dr. Cormack's case of, 212; remarks on surgical interference in, 216; Dr. A. Anderson on structure of, 217
Caustic, in hæmorrhage from leech-bites, 71
Cautery, removal of erectile tumours by, 71
Cazeaux., M., on disease of lungs from congenital syphilis, 927; on syphilitic pemphigus, 929
Cazenave, M., on hydrochlorate of lime in skin diseases, 165; on aconite in papulary eruptions, *ibid.*; on diseases of the skin incompatible with lactation, 179
Cerebral disease, Dr. Devay on premonitory symptoms of, 259; signs furnished by moral and intellectual faculties, 260; by sensorial functions, 263; by motion and sensation, 265
Cerebrum, and cerebellum, Dr. J. D. Brown's case of softening of, 67; Dr. Peacock on weight of, 105; inflammation of, Dr. B. Jones on excretion of phosphates in, 769
Chailly-Honore, M., on amputation of the arm in shoulder presentations, 73
Chalmers, the Rev. Dr., death of, 547; indications of fatty degeneration of heart in, 547
Chancre, Mr. Acton on, 710; treatment of, 711; inflammatory, 713; phagedænic, *ibid.*; indurated, 714
Charcot, M., case of purulent pyelitis, with calculi in renal pelves, 664; case of tumour compressing medulla oblongata, 936
Chemistry, Mr. Galloway's First Step in, *rev.*, 839
Cheroots, mercurial inhalation by, 848
Chest, Dr. R. P. Cotton on form and movements of, in phthisis, 616; Dr. Scott Alison on flattening of, from posture, 1070; Dr. Walshe on diseases of, *rev.*, 1114
Chevallier, M., on diseases of workmen in quinine manufactories, 180
Chevers, Dr. Norman, on Diseases of the Heart and Aortic Aneurism, *rev.*, 918
Chevreuse, Dr., on plantain juice in intermittent fever, 667
Child, acute rheumatism, with pericardial effusion in a, 367; cancerous tumour of neck in a, 554
Children, Births of Misshapen, Diseased and Dead, Dr. Hohl on, *rev.*, 50; calomel and hemlock in ascites of, 468; purulent ophthalmia in, at the Royal Ophthalmic Hospital, 484; syphilis in, Mr. Acton on, 717; Dr. Deutsch on, 924, 930; M. Depaul on syphilitic lung disease in, 926; syphilitic pemphigus in, 927; treatment of syphilis in, 930; Dr. Webster on mortality among, in London, 525, 1060, 1062
Childs, Mr. G. B., case of acranial fœtus, 93
Chloasma hepaticum, white hellebore in, 727
Chlorine, Dr. Snow on inhalation of, 129; inhalation of, in aphonia, 367
Chloroform in lead-colic, 67; compared with sulphuric ether, by Dr. J. D. Gross, 177; Dr. Snow's Letter to Lord Campbell on, *rev.*, 353; Mr. R. Dunn on inhalation of, 670; frictions with, in chorea, 722; a solvent of cantharidin, 748; Dr. Bagot's case of poisoning by, 775; friction with, in tetanus, 842; case of gout in stomach treated by, 953
Chlorosis, iron in, 720; manganese in, *ibid.*; action of metals in, 941
Cholera in the Asylum, Dr. T. G. Wright on, *rev.*, 56; Dr. Knox on mortality from, 57; Dr. Ballard on a case of, terminating in pericarditis, 1068
Chopping, Dr. Roth's definition of, 1015
Chorea, with softening of spinal cord, Dr. Nairne's case of, 91; chloroform frictions in, 722; M. Trousseau on strychnia in, 726; Dr. B. Jones on excretion of sulphates and phosphates in, 769
Christian, Dr., case of extra-uterine pregnancy during twenty years, 1050
Christison, Dr. A., on Indian hemp as an uterine stimulant, 1048
